844. Protocol, S. The Stockholm III Trial on Different Preoperative Radiotherapy Regimens in Rectal Cancer. [cited 2012 February 4]; Preoperative radiotherapy (RT) is recommended to many patients with localised rectal cancer, not previously treated with pelvic RT. However, the optimum fractionation, the timing of surgery and the best use of concomitant chemotherapy remains controversial. Short-course, preoperative RT may induce both acute and late morbidity and has been claimed to cause more morbidity than long-course preoperative RT. There are theoretical reasons to believe that RT given in larger fractions during a shorter period of time might result in more late side effects than giving a conventional, more protracted RT. In addition, the optimum timing of surgery after RT, with respect to postoperative morbidity, mortality and potential downsizing of the tumour is not known.]. I. INTRODUCTION

The aim of this report is to provide an update of the evidence-based recommendations from the 6th ICI regarding the initial assessment of urinary incontinence (Committee 5A) and outcome measurements (Committee 5B) of incontinence for adult men and women.

II. GENERAL INFORMATION

1. TERMINOLOGY

A critical step in the evaluation of urinary incontinence (UI) is the use of up-to-date terminology to describe different types of UI and their associated lower urinary tract symptoms (LUTS). LUTS includes both storage and emptying symptoms in contrast to overactive bladder syndrome (OAB) which describes a subset of storage symptoms (e.g., urgency, frequency, nocturia), with or without the symptom of UI. The use of standardised terminology during the taking of the history of UI ensures an accurate characterisation of the type of UI experienced by each patient.

The ICS 2002 report (1) and the ICS /IUGA Joint Report (2) are recommended for reference, as well as an update of the terminology for nocturia (3). It should be noted however that a bibliometric and questionnaire analysis of the use of standardised terminology documents the low rate of acceptance of new terminology in both the literature and practice, and the slow abandonment of previously accepted common terms. (4)

The Standardisation Steering Committee (SSC) of the International Continence Society (ICS) "establishes terminology and methodology in the ICS's areas of activity, to underpin professional standards of clinical management and research". The value of the SSC is in promoting best standards when clinicians and allied professionals communicate with patients and colleagues, undertake diagnostic tests, proceed to therapeutic interventions and undertake research. Precise use of agreed terminology ensures clear understanding for collaborating centres and readers of publications. Adherence to the diagnostic testing standards gives patients and clinical colleagues confidence that conclusions on which important therapeutic decisions are based are reliable. Development of future insights into mechanisms and treatments of the disease areas relevant to the ICS is enhanced where research studies employ internationally standardised approaches.

The term "urinary incontinence" refers to the complaint of any involuntary loss of urine. The symptom of urinary incontinence can be volunteered by, or elicited from, the individual or may be described by the individual's caregiver. Urinary incontinence can be categorised into several distinct sub-types based on associated characteristics and circumstances surrounding episodes of urine leakage. Although defining the type of incontinence will not establish a definitive underlying diagnosis, it will ultimately guide investigation and treatment. The following are the accepted ICS definitions of these conditions unless referenced (1).

1.1. Types of urinary incontinence

a) Stress (urinary) incontinence: Complaint of involuntary loss of urine on effort or physical exertion e.g., sporting activities), or on sneezing or coughing. (Sporting activities)

b) Urgency (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency.

c) Postural (urinary) incontinence: Complaint of involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position.

d) Mixed (urinary) incontinence: Complaint of involuntary loss of urine associated with urgency and also with effort or physical exertion or on sneezing or coughing.

e) Incontinence associated with chronic retention of urine: Complaint of involuntary loss of urine which occurs in conditions where the bladder does not empty completely as indicated by a significantly high residual urine volume and/or a non-painful bladder which remains palpable after the individual has passed urine. (Note: The ICS no longer recommends the term overflow incontinence. A significant residual urine volume denotes a minimum volume of 300 ml, although this figure has not been well established.)

f) Nocturnal enuresis: Complaint of involuntary loss of urine which occurs during sleep.

g) Continuous (urinary) incontinence: Complaint of continuous involuntary loss of urine.

h) Insensible (urinary) incontinence: Complaint of urinary incontinence where the individual is unaware of how it occurred

i) Coital incontinence (for women only): Complaint of involuntary loss of urine with coitus. This symptom can be further divided into that occurring with penetration and that occurring at orgasm.

j) Functional incontinence: Complaint of involuntary loss of urine that results from an inability to reach the toilet due to cognitive, functional or mobility impairments in the presence of an intact lower urinary tract system.

k) Multifactorial incontinence: Complaint of involuntary loss of urine related to multiple interacting risk factors, including factors both within and outside the lower urinary tract such as comorbidity, medication, age-related physiological changes and environmental factors.

Urinary incontinence can exist in isolation or may be associated with other lower urinary tract symptoms. The ICS classifies lower urinary tract symptoms (LUTS) into bladder storage, voiding and post-micturition, and pelvic organ prolapse symptoms. The following section summarises the definitions of LUTS described by the ICS-SSC.

1.2. Bladder storage symptoms

Bladder storage symptoms are experienced during the bladder filling phase:

a) Increased daytime urinary frequency: Complaint that micturition occurs more frequently during waking hours than previously deemed normal. Traditionally seven episodes of micturition during waking hours was considered as the upper limit of normal, although it may be higher in some populations.

b) Nocturia: Complaint of interruption of sleep one or more times because of the need to void. Each void is preceded and followed by sleep. The number of nocturia episodes and the degree of bother based on number has been questioned and the threshold of 2-3 per night has been suggested(5) (6-10).

c) Urgency: Complaint of a sudden, compelling desire to pass urine which is difficult to defer. (Note: The 'all or none' nature of 'urgency' has been questioned)(8).

d) Overactive bladder syndrome (OAB): Urinary urgency, usually accompanied by increased urinary frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology.

1.3. Bladder sensation

Asking patients about bladder sensory symptoms during bladder filling may be helpful in characterising certain types of incontinence.

a) Increased bladder sensation: Complaint that the desire to void during bladder filling occurs earlier or is more persistent to that previously experienced. This differs from urgency by the fact that micturition can be postponed despite the desire to void.

b) Reduced bladder sensation: Complaint that the definite desire to void occurs later than that previously experienced despite an awareness that the bladder is filling.

c) Absent bladder sensation: Complaint of both the absence of the sensation of bladder filling and a definite desire to void.

1.4. Voiding and postmicturition symptoms

Voiding symptoms are experienced during the voiding phase and post-micturition symptoms are experienced immediately after micturition.

a) Hesitancy: Complaint of a delay in initiating micturition.

b) Slow stream: The individual's perception of reduced urine flow, usually compared to previous performance or in comparison to others.

c) Intermittent stream (intermittency): Complaint of urine flow which stops and starts, on one or more occasions, during micturition.

d) Straining to void: Describes the muscular effort used to initiate, maintain or improve the urinary stream.

e) Spraying (splitting) of urinary stream: Complaint that the urine sprays or splits rather than coming out as a single, discrete stream.

f) Terminal dribble: is the term used when an individual describes a prolonged final part of micturition, when the flow has slowed to a trickle/dribble.

g) Feeling of incomplete bladder emptying: Complaint that the bladder does not feel empty after passing urine.

h) Need to immediately re-void: Complaint that further micturition is necessary soon after passing urine.

i) Postmicturition leakage: Complaint of a further involuntary passage of urine following the completion of micturition.

j) Position-dependent micturition: Complaint of having to take specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forwards or backwards on the toilet seat or voiding in the semi-standing position.

k) Dysuria: Complaint of burning or other discomfort during micturition. Discomfort may be intrinsic to the lower urinary tract or exter- nal (vulvar dysuria in women).

l) (Urinary) retention: Complaint of the inability to pass urine despite persistent effort.

2. ASSESSMENT OF SUB-POPULATIONS REVIEWED BY OTHER COMMITTEES

The targeted assessments and specific outcome measures for conditions of UI in Children (Cmte 9), Neurogenic Patients (Cmte.10), Frail Elderly (Cmte.11), Painful Bladder Syndrome (Cmte.19) and Faecal Incontinence (Cmte.16) are presented separately in the respective reports. The requirements of specific sub-populations negate the ability to recommend a 'universal' initial evaluation. Within the initial assessment of UI, these sub-populations / subgroups are recognised because of the differences within patient groups or the interrelationship between the conditions. Congenital and developmental issues are critical considerations in children. Specific risks for combined storage and emptying abnormalities and upper urinary tract deterioration in the neurogenic population demand a more involved initial and complex evaluation. The effects of ageing on the lower urinary tract, altered toileting functions, and medical co-morbidities in the frail elderly group present unique challenges. These subgroups also include patients with LUTS with and without incontinence and with the presence of pelvic pain or faecal incontinence.

The sub-sections in this report should be utilised in conjunction with other population or condition specific Committee Reports of the Consultation and with the final recommendations of the Consultation which are presented in simplified form in Appendix (1. Definitions). Recommendations for initial evaluation have been developed by the International Scientific Committee and are also published in Appendix (2. Evaluation). In addition, History and Symptom Assessment recommendations are further detailed as the initial steps in the evaluation of the index adult male (3. Initial Management, II. Male), and adult female (3. Initial Management, III. Female). The reader is encouraged to refer to these recommendations and algorithms in combination with this report.

3. EVIDENCE BASED RECOMMENDATIONS

The recommendations presented in this report are evidence-based and utilise the ICUD-EBM grades. A search of the available literature in English obtained from Medline and Pubmed up to June 2016 by the individual committee members employed multiple search terms related to the initial assessment of the patient with urinary incontinence and patient reported outcome assessment.

III. INTIAL ASSESEMENT

1. PURPOSE OF INTIAL ASSESSMENT (EXPERT OPINION OF THE COMMITTEE)

As will be noted, especially in this committee report (5A), the amount and sophistication of the literature that is applicable for the development of evidence-based guidelines is limited. For this reason, the grade of recommendation in the area of "initial assessment" will often rely on 'expert opinion of the panel'. For the purpose of subsection 5A, the 'initial assessment' represents the components of the history, physical examination, laboratory tests, and basic office testing to:

1. Establish a presumptive or condition specific diagnosis, and exclude underlying organ-specific related or unrelated conditions that would require intervention.

2. Assess the level of bother and desire for intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes

3. Prepare for the institution of empirical or disease specific primary therapy based on the risk and benefit of the untreated condition, the nature of the intervention and the alternative therapies – including Conservative (Cmte. 12) or Pharmacological (Cmte. 8) therapies.

4. Prompt the recommendation of additional more complex testing or specialist referral (when indicated).

5. Assess the level of improvement after intervention from information obtained from the patient or caregivers, utilising objective measures or patient reported outcomes (Cmte. 5B).

Once the type of Urinary Incontinence (UI) with associated lower urinary tract symptoms (LUTS) has been established, elaboration of a differential diagnosis can occur, and further investigations may be elected and an eventual treatment plan can be formulated to address or modify the effects of the underlying cause(s). The success of the treatment plan can be measured by patient-reported outcomes (from a simple "yes" or "no" to more complex questionnaires), and/or other objective measures of urinary leakage events (including bladder diaries, pad tests, or urodynamics studies).

The initial assessment must consider the degree of bother, and the costs of further evaluation, balanced against the consequences of a failure to diagnose an underlying condition, the risks and benefits of empirical conservative management or pharmacological therapy, and the need for an accurate diagnosis before more complex intervention or empirical therapy. The burden of these conditions and the availability of resources for individual patients, caregivers, physicians, and health care systems requires that primary intervention strategies be formulated, when available, from evidence based findings and decisions emanating from the initial evaluation.

Of note, LUTS cannot be utilised with confidence to make a definitive diagnosis of a specific lower urinary tract condition or lower urinary tract disease (LUTD), as these symptoms may suggest and indicate pathologies such as urinary tract infection (UTI) or more serious underlying conditions. Basic laboratory tests, such as testing for urinary tract infection (UTI) or blood (haematuria), and appropriate screening for malignancy should be considered before the decision is made to choose therapy for incontinence. Urinary retention with overflow may present as urinary urgency, frequency, and nocturia with urinary loss mimicking OAB.

Concomitant pathology may affect urine production as a co-morbid contributory factor, by affecting fluid balance or renal function (fluid intake and output regulation) and may need to be addressed prior to or in combination with bladder or bladder outlet therapy. A thorough review of medications which alter fluid production or lower balance and urinary tract function should be addressed. The physician should also seek a history of pelvic pathology or surgery and neurological symptoms and signs that may indicate alterations in the control of the lower urinary tract function or be responsible for the cognitive, motivational, or physical factors that determine the ability to perform toileting functions effectively. The physical examination and the appropriate laboratory tests are necessary to refine the differential diagnosis and therapeutic course.

2. INITIAL ASSESSMENT – GENERAL RECOMMEDATIONS

1. Lower Urinary Tract Symptoms (LUTS) cannot be used to make a definitive diagnosis; they may also indicate pathologies other than Lower Urinary Tract Disease (LUTD). Specific to this report, LUTS includes Overactive Bladder (OAB) a syndrome which may be associated with urgency incontinence (OAB-wet) or without incontinence (OAB-dry). (Level 4 - Grade D)

2. Urinary incontinence should be described by specifying relevant factors such as type, frequency, severity, precipitating factors, social impact, effect on hygiene and quality of life, the measures used to contain the leakage and whether or not the individual seeks or desires help. (Level 4 - Grade D)

3. Urinary incontinence should be categorizsed by symptoms into urgency incontinence, stress incontinence or mixed incontinence and conservative (non-invasive) therapies may then be started based on this classification to treat the most troublesome component, or either component of the incontinence (Level - Grade D). More sophisticated testing (e.g., urodynamic studies) is not required prior to the institution of conservative therapy (see indications for urodynamics in the Committee Report on Dynamic Testing Committee 6). (Level 3 - Grade C)

4. Both objective (bladder diary) and subjective (patient reported outcomes – PROs) are recommended for assessment and measurement of the degree of symptoms and bother of UI at baseline, and for the assessment of the impact of therapy. (Level 3 – Grade D).

5. Normal lower urinary tract function requires the ability of the bladder to adequately store urine at low pressure while the bladder outlet remains competent, and the bladder to contract until completely empty while the bladder outlet remains open. In addition to an evaluation of LUT function, a thorough evaluation for co-morbid conditions which affect fluid intake and output should be undertaken. Diseases of the nervous system and pelvic disorders, as well as medications which may affect the LUT should be addressed. (Level 4 - Grade D).

6. Referral to a specialist is recommended for hematuria (visible or microscopic), urinary tract infection (persistent or recurrent), prolapse (symptomatic or below the introitus) , obstruction or re-

tention (symptoms or findings of palpable bladder, hydronephrosis or obstructive renal insufficiency), suspected neurological disease, mass (urethral, bladder or pelvic - benign or malignant), fistula (urinary or bowel), faecal incontinence, a history of prior pelvic surgery or radiation (incontinence, oncologic) (Level 4 - Grade D).

3. INTIAL ASSESSEMENT – GENERAL RESEARCH RECOMMENDATIONS

1. Standardisation of the 'definition of symptoms' and the 'measurements of symptom frequency, severity and bother' are essential for patient care and research. Continued research into the appropriate scales and metrics should be accompanied by a significant attempt to establish best practice guidelines for their use and a consensus on the adoption of universal standards.
2. Recognition and resolution of the differences in common language usage and scientific utilisation of terms should continue. Resolution of the differences in definitions and metrics between recognised societies and agencies is essential for communicating data with respect to patient care, research, and treatment outcomes.
3. Research into the development of accurate measures to objectify subjective symptoms such as "urgency" and other bladder sensory symptoms.
4. Development, standardisation, and universal adoption of symptom assessment tools (questionnaires) to improve the diagnostic accuracy of lower urinary tract symptoms. (Refer to section 5B of this committee's report)
5. Validation of the accuracy of specific components of the history and physical findings to establish an accurate diagnosis and to^{o} initiate non-invasive conservative or pharmacological therapy. In addition, to further identify components that would indicate the need for more invasive testing, complex therapeutic interventions, and indications prior to / or as a result of referral.
6. Creation and institution of evidence based guidelines for the referral of patients to a specialist are needed to improve the efficiency of the healthcare system in treating the large burden of disease. (See Epidemiology, Committee 1). The institution of conservative measures and pharmacology are in the domain of the primary caregiver. Further improvement in the ability to define the index patient, but more importantly the subgroups of patients who will require more complex specialist therapy, will aid in counselling and referral at the primary level. In addition, refining the true risks for significant underlying disease noted while obtaining the history, or during the examination or laboratory findings will improve resource utilization.

IV. GENERAL POPULATIONS

1. INITIAL ASSESSMENT OF URINARY INCONTINENCE

Individuals with UI can be identified through routine screening, or the patient may initiate discussion about incontinence problems. The initial assessment of UI should help the health care provider to understand the type of incontinence, while identifying potentially modifiable contributing factors. Most primary treatment options, such as lifestyle modifications and behavioral treatments, do not vary by type of UI. However, it is important to determine the type of UI since some treatment options do vary according to incontinence. Equally important, establishing the type of UI will lead the health care provider to a list of possible underlying causes, or differential diagnosis of the urinary symptoms. Most causes of UI are non-life threatening, however symptoms of incontinence may also herald life-threatening or more severe disease such as bladder cancer when associated with haematuria; when more specialized testing will be required immediately. Finally, assessing the level or bother and desire for intervention from information obtained from the patient or caregiver is essential for guiding the nature of the treatment plan.

1.1. History

Taking a careful clinical history is fundamental to the clinical process. Some studies have indicated that patient history alone is not completely accurate as the sole determinant of incontinence type (11, 12). However, Martin et al. (13) in a systematic review and meta-analyses on the methods for diagnostic assessment of urinary incontinence, suggested that women with urodynamic stress incontinence (USI) can be correctly identified in primary care from clinical history alone with a sensitivity of 0.92 (95% C.I.: 0.91- 0.93) and specificity of 0.56 (0.53- 0.60); symptoms of urge incontinence were found to be 0.61 (0.57- 0.65) sensitive and 0.87 (0.85-0.89) specific for the diagnosis of detrusor overactivity.

Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI(1, 14).

The general history should include questions relevant to establish the type of UI and to precipitating and aggravating factors of urinary loss, time of onset and duration of symptoms, severity, degree of bother and finally the association with voiding, storage and other urinary symptoms.

The incontinence first should be characterized subjectively. Does the leakage occur: With physical activity? With a sense of urgency? Without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? Secondly, the leakage should be quantified if possible. Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved based on the number of pads used per day or the frequency of clothing changes because of urinary leakage.

Acute symptoms can be defined by documenting patterns of fluid intake and output, acute infection, recent surgery or trauma. Chronic symptoms should prompt queries about a history of congenital abnormalities, neurological disease, relevant surgery or general health issues. History should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease (Red Flag Symptoms).

The voiding pattern should also be defined. What is the frequency of urination during the day and during the night? Are there any voiding symptoms and/or storage symptoms? Previous surgery such as pelvic or back surgery and, in males, prostate or urethral surgery for benign or malignant disease should be investigated.

Information should be obtained concerning medications with known or possible effects on the lower urinary tract. The general history in women should also include assessment of menstrual, obstetric, sexual, gynaecological and bowel function. It is also helpful to determine the impact that the leakage has on the patient's daily life and activities if incontinence limits the individual's activity and if the patient made lifestyle changes because of the threat of leakage. Finally, it is important to emphasize the importance of establishing patient expectation of treatment and an understanding of the balance between the benefits and risks/burden of available treatment options (see Committee Report (5B)).

The reader is referred to the report on Epidemiology (Cmte. 1) for specific risk factors to be considered during the medical history, and to the report on Frail Elderly (Cmte. 11) for a list of co-morbidities and medications that can cause or contribute to UI.

A later section of this Committee Report (5B) presents a complete review and evaluation of questionnaires that are applicable for clinical and research use in evaluating patient symptoms. Structured condition specific questionnaires may be utilised, and may be either clinician or self-administered. Use of questionnaires may facilitate disclosure of embarrassing symptoms, ensure that symptoms are not omitted, and standardise information for audit and research.

In the absence of questionnaire use, Table 1 summarises key questions for the initial assessment of urinary incontinence based on the expert opinion of this committee. Note that the committee strongly encourages the use of standardised questions.

1.2. Bladder Diaries

The micturition time chart records the timing of voids in 24 hours. The term frequency-volume chart is used to describe a chart that records the time of each micturition and the volume voided for at least 24 hours. The bladder diary may include fluid intake, incontinence episodes, pad usage, the degree of incontinence as well as a record of episodes of urgency and sensation and activities performed during or immediately preceding the involuntary loss of urine. Therefore, bladder diaries are most suited for the purpose of comprehensive evaluation of urinary incontinence. However, documentation of the frequency of an individual's lower urinary tract symptoms and the voided volume for at least 24 hours can already be extremely helpful in the initial assessment of urinary incontinence, although 2-3 days of recording generally provide more useful clinical data. Moreover, a diary may be therapeutic as it provides insight into bladder behavior and it can be utilised to monitor the effectiveness of treatment during follow-up.

A frequency-volume chart (FVC) or bladder diary (BD), if properly completed, can confirm all of the following information.

a) Daytime urinary frequency: Number of voids by day (wakeful hours including last void before sleep and first void after waking and rising).

b) Nocturnal frequency/nocturia: Number of times sleep is interrupted by the need to micturate. Each void is preceded and followed by sleep.

c) Twenty-four-hour frequency: Total number of daytime voids and episodes of nocturia during a specified 24-hr period.

d) Twenty-four-hour urine production: Summation of all urine volumes voided in 24 hr.

e) Maximum voided volume: Highest voided volume recorded.

f) Average voided volume: Summation of volumes voided divided by the number of voids.

g) Median functional bladder capacity: Median maximum voided volume in everyday activities.

h) Polyuria: Excessive excretion of urine resulting in profuse and frequent micturitions, defined as

Table 1: Key Questions in the Initial Assessment of Urinary Incontinence

Stress urinary incontinence: Do you sometimes leak urine when you cough or sneeze or when you exert yourself, such as when lifting a heavy object?
Urgency urinary incontinence: Do you sometimes feel an urge to void that is so sudden and strong that you sometimes don't make it to the bathroom on time?
How long have the symptoms been present?
How often do you leak urine and how much do you leak? (Do you need protections and how many during day and night?
Circumstances surrounding urine leakage e.g. sexual activity, change in position, provocation by running
water or 'key in the latch'?
Nocturnal symptoms or enuresis?
Association with other lower urinary tract or pelvic organ prolapse symptoms?
Impact on personal and social life?
Amount and type of fluid intake e.g. coffee, tea, alcohol?
Episodes of urinary tract infection or haematuria?
Previous treatment attempts (successful and unsuccessful)?
Mobility problems?
Cognitive deficits?
Neurological deficits?
Problems with constipation or faecal incontinence?
Number of pregnancies and the type of delivery, with complications?
Previous prostate, pelvic or abdominal surgeries or radiation treatment?
Coexisting diseases (diabetes, heart disease, neurological impairment)?
Types of medications consumed?

greater than 2.8 L of urine during 24 hours for an individual weighing 70 kg.

i) Nocturnal urine volume: Cumulative urine volume from voids after going to bed with the intention of sleeping to include the first void at the time of waking with the intention of rising (excludes last void before sleep).

j) Nocturnal polyuria: Excess (over 20–30% age dependent) proportion of urine excretion (nocturnal voided volume/total 24 hr voided volume x 100%) occuring at night (or when the patient is sleeping)(15)

However, it should be noted that there are some limitations to the use of a frequency-volume chart or bladder diary. There is no evidence that the results of these charts provide a valid prediction of the type of urinary incontinence experienced by each patient (16, 17). Some patients may have difficulty completing the diary in a reliable, meaningful or timely fashion, especially when increasing the complexity or the amount of time (days) required to complete the diary (18). The bladder diary may not yield information about the evolution of incontinence episodes that occurs less frequently than once per day(18, 19).

Several studies have compared patients' preference for, and the accuracy of, electronic and paper voiding diaries in voiding dysfunction(20-24) , but the utility of electronic diaries has not been fully clarified yet.

Due to intraindividual variation, FVC recordings differ on different days. The more days recorded, the more likely it will be that the recordings will capture the whole spectrum of variation. Few data have been reported on the intraindividual variation of FVC parameters(25) (26, 27) . However, these variations have been used in statistical analysis leading to statements on the optimal duration of FVCs. Recommendations for diary duration vary considerably including 24 hours, 3 days or 7 days; this inconsistency is partially explained by differences among study populations, based on diagnosis, age, sex, and geography, and by differences in methods of analysis and in interpretation of the results. In a mini-review on the reliability of FVCs, Yap et al argued that using FVCs of 3 days or

longer might be the most defensible policy, but they found no evidence that compliance rates had been accounted for in the studies reviewed (28). They concluded that in some reports reliability was overestimated. Another review by Bright et al focusing on the validation of FVCs summarised that excessive duration reduces patient compliance, but too short a duration may produce unreliable measurements [(17)

The choice of diary duration may not only be based upon better validity or reliability but also on the possible behavioural therapeutic effect of keeping a diary (29-31). Recently, Bright et al have described the development of the first validated bladder diary for the assessment of LUTS in both male and female adults, using a psychometric validation methodology. The resulting bladder diary is recommended for use over a 3-d period and has been accepted as the ICIQ bladder diary. Urinary incontinence is assessed by the recording of pad use. The ICIQ bladder diary has been validated using a British English-speaking population and as with all such tools, will require cultural adaptation and linguistic validation for other languages using the formal ICIQ protocol (30, 31). The sample validated ICIQ bladder diary is illustrated with the instructions for use in Chapter 24.

In conclusion, voiding diaries generally give reliable data on lower urinary tract function. However, there remains a lack of consensus on diary duration and how well diary data correlate with some symptoms.

1.2.1 Bladder Diary Recommendations

1. Ask patients with urinary incontinence to complete a bladder diary to evaluate co-existing storage and voiding dysfunction. A bladder diary is recommended in order to document and communicate both objective information and to objectify observations by the patient during the diary period. Although never completely diagnostic, diary patterns may characterise normal and abnormal states. (Grade A)

2. A 1-day frequency volume chart (FVC) which includes the first morning void the following day is a reasonable tool to gain insight into voiding habits during normal daily routine. A 3-day FVC or diary is recommended for accurate assessment of LUTS and for confirming a consistent clinical pattern in day-to-day practice. For atypical clinical patterns or clinical research, a 7-day diary may be recommended (most pharmacological studies now employ a 3-day diary as a standard to improve patient compliance). (Grade C)

3. The validated ICIQ bladder diary is recommended for use over a 3-d period. The inclusion of the diary in research studies is recommended and will provide ongoing evidence of validation, as well as the external validity of the diary. (Grade A)

1.2.2 Future Research

a) The ideal duration of a bladder diary based on accuracy, compliance, and the utility of the diary for diagnosis, the selection of therapy, and improving the outcomes of therapy requires further investigation.

b) The utility of paper versus electronic methods of recording voiding patterns requires further research.

c) The ICIQ bladder diary should be culturally and linguistically validated for other languages than British English and be included in research studies for further validation as well as determining external validity.

1.3. Urgency Scale

According to the IUGA/ICS definition urgency is : “Complaint of a sudden, compelling desire to pass urine which is difficult to defer” (2). However, in clinical practice, urgency is often accompanied by other symptoms. Urgency, with or without urgency incontinence, usually with frequency and nocturia, is the cornerstone symptom of overactive bladder syndrome (OAB) (32); while with bladder pain, and frequency urgency are typical symptoms of interstitial cystitis or bladder pain syndrome (33). However sometimes patients with lower urinary tract symptoms may not be able to differentiate between normal urge (desire) to void and urgency (difficult to postpone)(4), furthermore, with history only it may be difficult to define the severity, duration and frequency of urgency(34, 35). Thus, it is important to have appropriate tools that allow accurate diagnosis, to establish tailored therapy and to assess the effectiveness of treatment. Severity questionnaires and scales have been developed specifically to assess urinary urgency, to help the patient to define the symptoms and severity and the physician to establish the therapy and its effects. Table 2 and table 3 show the validated questionnaires and scales respectively, used to assess the urinary urgency.

Table 2: Questionnaires To Assess Urgency (35-38)

Questionnaire	Aim of tool	Items	Population sample	Reliability	Content Validity	Construct Validity	Concurrent Validity	Discriminant Validity	Responsiveness	GR
UPS (Urgency Perception Score) [35]	Grading the urgency to void and assessing the reason why individuals usually void	5	*Men* *Women* OAB + LUTS LUTS (without urgency) Healthy	Yes	Yes	Yes		Yes		B
UQ (Urgency Questionnaire) [36]	Severity of urgency and urge incontinence Impact of urgency and urge incontinence on the quality of life Discomfort of urgency with VAS scale	15 + 10 VAS	*Women* OAB	Yes	yes	Yes	Yes	Yes	Yes	A
USIQ-QoL (Urgency Severity and Life Impact Questionnaire-Quality of life) [37]	Impact of urgency on the quality of life	8	*Women* *Men* OAB	Yes	Yes	Yes .		Yes		B
USIQ-S (Urgency Severity and Life Impact Questionnaire: Severity Symptsoms) [37]	Severity of urgency	5	*Women* *Men* OAB	Yes	Yes	Yes		Yes		B
UU Scale [38]	Monitoring efficacy treatment	10	*Women* *Man* • *OAB*	Yes		Yes			Yes	A

Table 3: Scales to assess the urinary urgency (39-43)

Scale	Aim of tool	Degrees of urgency	Population sample	Reliability Test-re test	Content validity	Construct Validity	Concurrent Validity	Discriminant Validity	Responsiveness	GR
UPS (Urgency Perception scale) [39]	Severity of urgency	3	*Men* *Women* OAB		Yes	Yes	Yes		Yes	B
IUSS (Indevus urgency Severity Scale) [40]	Severity of urgency per void The ability to complete actives	4	*Men* *Women* OAB with urge Incontinence	Yes	Yes	Yes	Yes	Yes	Yes	A
PPIUS (Patients' perception of intensity of urgency scale) [41]	Severity of urgency Urgency incontinence	4	*Men* *Women* Urgency Urge incontinence	Yes	Yes			Yes	Yes	A
USS (Urinary Sensation Scale) [42]	Severity of urgency	5	*Men* OAB+LUTS *Women* OAB		Yes	Yes	Yes	Yes	Yes	A
URS(Urgency Rating Scale) [43]	Severity of urgency	5	*Men*	Na	Na	Na	Na	Na		C

1.4. Urinalysis

"Urinalysis is a fundamental test that should be performed in all urological patients. Although in many instances a dipstick urinalysis provides the necessary information, a complete urinalysis includes both chemical and microscopic analysis." (44). Urine dipstick testing, as opposed to microscopy, is satisfactory for urinalysis in the diagnosis of acute uncomplicated cystitis (45, 46). In relation to urinary incontinence, dipstick urinalysis is not a diagnostic test, but a screening test, utilised to detect haematuria, proteinuria, glycosuria, pyuria and bacteriuria.

Haematuria can indicate important pathology such as urothelial carcinoma in situ, leading to lower urinary tract storage symptoms including incontinence (47). Glycosuria is relevant, as a potential indicator of diabetes mellitus. This can cause symptoms via several mechanisms including polyuria secondary to osmotic diuresis. Diabetic peripheral autonomic neuropathy affecting bladder innervation may be associated with impaired bladder emptying. The clinician should note that a patient does not generally demonstrate glucose into the urine until the blood glicemia is >180 mg/dl. Consequently, a dipstick urinalysis may fail to reveal intermittently high sugars or mild diabetics. If diabetes is suspected, then a random or fasting blood sugar is preferred (48-50).

Pyuria and bacteriuria, detected from urinary dipstick leukocyte esterase and nitrite tests respectively, are important signs of urinary tract infection. The specificity and sensitivity of these latter tests for UTI is increased when used together compared to either individual test (50, 51). Even in the absence of controlled studies, there is general consensus that the benefits of urinalysis clearly outweigh the costs involved, although the use of urinalysis should always be associated with prognostic significance (52). A positive dipstick urinalysis will prompt formal urine microscopy and culture to detect UTI prior to antibiotic treatment and/or the use of additional tests such as endoscopy and urinary tract imaging.

Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI in people with UI (53) and should be included, with urine culture when necessary, in the evaluation of all patients with UI (Le1:GR A based on expert opinion). Urinary incontinence may occur during symptomatic UTI (level 3) (54) and existing UI may worsen during UTI (level 3) (55).

The importance of urinalysis in the basic assessment of patients with urinary incontinence and lower urinary tract symptoms is not dependent on gender, age or aetiology. Indeed, it has been recommended in the evaluation of geriatric patients including nursing home residents who are incontinent (56), in peri- and postmenopausal women (57), and in older women reporting urinary incontinence (58). In the latter context, it has even been observed that clinically significant urine samples can even be obtained from disposable diapers in elderly incontinent women (59). The clinical relevance of asymptomatic bacteriuria (without pyuria) and pyuria (without bacteriuria) in the elderly is controversial as the rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents (level 2; Grade B) (56, 60, 61).

Recently, bacterial communities (microbiota) have been discovered in the female bladder and consequently, the sterile urine paradigm is no longer valid. Emerging evidence suggests that the female urinary microbiota may contribute to symptoms of urinary incontinence in women (62). Several bacterial species are more common in women with urgency urinary incontinence than in asymptomatic controls (63, 64). For these reasons new approaches are being developed: the 16s rRNA sequence analysis and the expande quantitative urine culture protocol (64).

1.4.1 Urinalysis - Recommendation

1. It is considered standard to perform a urinalysis by either using a dipstick test or examining

the spun sediment in incontinent patients. (Level 4- Grade D)

2. If a dipstick test is used, it is recommended that a "multi-property" strip that includes

fields for haematuria, glucose, leukocyte esterase and nitrite tests be chosen. (Level

4 - Grade D) Dipstick is not as accurate as urine culture, being specific for infection but

not sensitive. (Level 2 - Grade C)

3. Additional tests available on urine dipstick strips, such a protein, bilirubin, ketones and

pH, may be helpful in the broader medical management of patients. However, they are

not essential in the context of evaluation of the patient with urinary incontinence or lower

urinary tract symptoms. (Level 4 - Grade D)

4. Do not routinely treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence. (Level 2; Grade B)

1.4.2 Future Research

Emerging evidence challenges the long-held paradigm that the healthy bladder is sterile and evidence indicate that the human urinary tract contains microbial communities; however, the role of these communities in urinary health remains to be elucidated. Interesting findings suggest that previously undetected bacteria in the bladder of women may have a role in UUI that will provide new opportunities for prevention and improvement in the treatment approaches for UUI (65).

On this basis, traditional tools for urinary bacterial assessment (Urinary dipsticks and standard urine cultures) seem to have significant limitations because they are not able to detect slow-growing bacteria. New diagnostic tools are developing: expanded quantitative urine culture and 16S ribosomal RNA gene sequencing and could give allow a greater insight into many lower urinary tract disease including incontinence (66).

1.5. Post voiding residual in the female and male patient

Post-void residual (PVR) volume (also known as residual urine, bladder residual) is the amount of urine that remains in the bladder after representative voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with upper urinary tract dilatation and renal insufficiency. Both bladder outlet obstruction and low bladder contractility contribute to the development of PVR. PVR measurement can be accomplished within a few minutes of voiding either by catheterisation or by calculation of bladder volume using a portable ultrasound scanner.

It is difficult to determine the normal value of post-void residual determination in the initial assessment of urinary incontinence since most studies with data on PVR have not been performed in patients with UI. However, the populations studied have included some women with UI, and incontinent patients with neurogenic bladder disease.

Several studies have compared volumes measured with portable ultrasound scanners versus catheterisation and found portable scanners to be 85-94% accurate (67, 68). A study has imaged the bladder volume after catheterisation and found that the volume of urine remaining in the bladder after catheterisation accounted for most of the difference between the two measurements (67). Bimanual palpation cannot reliably estimate the post-void residual urine volume (69). Since PVR may vary, one measurement of PVR may not be sufficient (70). PVR should probably be measured several times to increase its reliability. In geriatric patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day, with the greatest volume occuring in the morning (71). A non-representative PVR is particularly common if the patient's bladder is not full enough to yield an urge to void. Special consideration is required in male patients with incontinence and bladder outlet obstruction, in incontinent neurogenic patients who may demonstrate combined disorders of storage and emptying (72), and preoperatively in female patients being considered for incontinence surgery.

An increased PVR alone is not necessariliy a problem, but if combined with high pressures it can lead to upper tract problems. If related to UTI's, PVR needs to be treated since UTI's cannot be eradicated in the presence of an infected residual. A significant PVR also decreases the functional bladder capacity and thus contributes to urgency/frequency, urgency incontinence and nocturia. However, a Scandinavian study in nursing home residents found that an elevated PVR was not associated with bacteriuria and incontinence (73), Since recurrent UTI's [due to elevated PVR] can be associated with urinary incontinence it remains necessary to measure PVR in incontinent patients with UTI.

Review of the literature fails to show an evidence-based specific maximum PVR that is considered normal, nor is there a minimal PVR that is considered abnormal. The amount of residual urine that precludes treatment by various therapies has also not been determined. The AHCPR guidelines state that, in general, a PVR less than 50 ml is considered adequate bladder emptying and over 200 ml is considered inadequate emptying (expert opinion of the panel members) (74).

"Normal values" of PVR have been determined in several groups of non-incontinent and incontinent women. Gehrich et al studied 96 women (mean age 60 ± 11 yrs) that were seen in a well-women clinic. These women had no history of incontinence, retention, symptomatic prolapse or neurologic disorders. Most (97%) had a minor (asymptomatic) degree of prolapse, 80% were post-menopausal and 30% had had a hysterectomy. The median PVR was 19 ml (range 0-145 ml; mean 24 ± 29 ml); only 5% had PVR > 100 ml. Only, age > 65 yrs was associated with higher PVR. This study gives some indication on what might be considered normal or relatively normal (75). Tseng et al studied 107 women with urodynamic stress incontinence. They found a mean PVR of 62.5 ml by bladder scan and 38.5 ml by catheterization. Only 15.9% had a PVR greater than 100 ml. The PVR determined by bladder scan offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 ml (76). Haylen et al studying women with lower urinary tract dysfunction found that 81% had a PVR of less than 30 ml (77). Fitzgerald et al studied women with urgency, frequency and urge incontinence: 10% had an elevated PVR of > 100ml. In these women with OAB, the following independent risk factors of increased PVR were found: vaginal prolapse, symptoms of voiding difficulty and abscence of stress-incontinence (78). Lukacz et al found that only 11% of women with pelvic floor disorders had an elevated PVR (79). Wu and Baguley studied 319 consecutive patients (196 women, 123 men) in a subacute general, but predominantly geriatric, rehabilitation unit. 22 had been admitted with catheter and were excluded. Of the 297 "asymptomatic" patients, 21.5% had PVR volumes of 150 mL or more. Patients with elevated PVR (> 150 ml) were significantly more likely to have a urinary tract infection at admission and have urinary incontinence on discharge (80). Milleman et al retrospectively reviewed 201 women (mean age 55; range 20-90) who presented with complaints of urinary frequency, urgency and /or urge incontinence. 19% had an elevated PVR of more than 100 ml (mean 211 ml; range 100-997 ml). On multivariate analysis the following independent predictors

of raised PVR were identified: age > 55 yrs [OR 3.71], prior incontinence surgery [OR 4.32], a history of multiple sclerosis [OR 15.32] and pelvic organ prolapse grade 2 or greater [OR 3.61] (81). In summary, an elevated PVR > 100 ml was found in 5% of women visiting a well-women clinic, in 10-19% of women with OAB, in 11% of women with pelvic floor disorders and in 15.9% of women with urodynamic SUI. Overall, incontinent women have a slightly higher risk of elevated PVR compared to asymptomatic subjects. Does a significant PVR have an impact on the outcome of treatment in patients with incontinence? Nager et al studied the predictive value of urodynamic measures on stress continence outcomes after surgery for stress urinary incontinence. They found that urodynamic measures do not predict outcomes. However, since women with PVR > 150 ml were excluded in this study, one can only conclude that PVR volumes < 150 ml did not have an adverse impact on stress continence outcomes (82).

A PVR measurement is recommended in men with symptoms suggestive of bladder outlet obstruction. It is a well known clinical principle that chronic urinary retention can be associated with overflow incontinence [ischuria paradoxa]. Apart from this there are unfortunately insufficient data on the role of PVR and its significance in male urinary incontinence. Consequently, there are insufficient data to draw conclusions about the association of PVR and urinary incontinence in men as well as the association of PVR and the outcome of incontinence treatment in men.

In the geriatric patient, a PVR should always be measured since it decreases functional bladder capacity and contributes to urgency/frequency, urge incontinence and nocturia.

PVR should probably be measured several times to increase its reliability. In elderly patients, Griffiths et al found a significant variability in PVR measurement depending on the time of the day; the greatest volume occured in the morning (71). Counter-intuitively, a Scandinavian study in nursing home residents was unable to show an association between an elevated PVR and bacteriuria and incontinence (73).

1.5.1 Recommendations

1. Varying degrees of decreased bladder emptying or urinary retention may be a cause of LUTS that are associated with symptoms of decreased urinary storage. The decision to perform a PVR in disease specific sub-groups of incontinent patients should be based on an association of the condition with poor bladder emptying (Grade D), whereas in individual patients this decision may be based on symptoms or physical findings. (Grade C)

2. Female patients who present with storage specific symptoms, with normal sensation and no complaints of decreased bladder emptying, and no anatomical, neurological, organ-specitic, or co-morbid risk factors for retention may be assessed for bladder emptying by history and physical examination alone, depending on the potential morbidity of the failure to diagnose and the nature of the intended therapy. (Grade B). Due to the increased possibility of bladder outlet obstrcution due to prostatic obstruction being increased in the male patient, the threshold for investigating residual urine in the male is significantly lower (Grade D).

3. A PVR should be performed in incontinent patients when decreased bladder emptying is suspected, especially if treatments that decrease bladder contractility or increase outlet resistance are being considered. (Grade D)

4. Non-invasive ultrasound measurement of PVR is as accurate as measurement by catheterization and is therefore the preferred method. (Grade A)

5. A palpable bladder on physical examination is an indication for referral to a specialist (Grade D)

1.5.2 Future Research

1.Development of more specific indications for PVR testing for diagnosis and prior to instituting therapy based on history, physical examination, and disease specific findings.

2.Further development of low cost, minimally invasive, and accurate means of measurement of PVR that do not require catheterisation.

V. SPECIFIC POPULATIONS: EVALUATION OF THE FEMALE PATIENT

1. ESTABLISHING THE TYPE OF URINARY INCONTINENCE IN WOMEN

The aims of the assessment of women with urinary incontinence are the documentation and characterisation of type of incontinence, its timing and its severity, the differential diagnosis, prognosis evaluation and planning of treatment (83). The classification of subjective diagnosis of urinary incontinence into stress, urgency and mixed incontinence is basically clinical. Assessment should include history, symptom assessment, and physical examination. A careful urological history may be helpful to make a first subjective differentiation between the types of incontinence. Infact as shown in Holroyd-Leduc's meta-analysis (16) simple questions to diagnose stress or urgency urinary incontinence have high reliability in women, with the percent agreement between repeated questioning estimated at 90% for stress, urgency and mixed urinary incontinence sub-types (16). Further questioning on the frequency, severity of leakage and degree of bother, is essential for planning treatment and counseling of the women. The leakage should also be quantified if possible by using voiding diaries (84, 85), pad tests (the 1-hour pad test the most used)

(86), and evaluation of the number of pads used per day. Finally, a general history and medication review are helpful to classify the different types of incontinence into uncomplicated and complicated. The definition of complicated or uncomplicated SUI is not widely agreed. According to FIGO's consensus uncomplicated stress urinary incontinence (SUI) is UI without further storage symptoms, absence of voiding symptoms and without history of recurrent urinary tract infections (RUTI), no prior extensive pelvic surgery or prior surgery for stress incontinence and no medical conditions that can affect the lower urinary tract (87). Complicated SUI doesn't fulfil the uncomplicated SUI criteria (87). In a multicentre single nation database (88) SUI has been defined as uncomplicated when the presenting history of SUI has been present for at least 3 months, the post-void residual urine volume is < 150 ml, urinalysis or urine culture is negative and clinical assessment of urethral mobility,with an expressed desire for surgery for SUI, and a positive provocative stress test. Conversely complicated SUI has been defined as incontinence in women with previous surgery for incontinence, history of pelvic irradiation, pelvic surgery within the previous 3 months, and anterior or apical pelvic-organ prolapse of 1 cm or more distal to the hymen (88). Nevertheless several studies (11, 88) have shown that patient history alone is not completely accurate in determining the type of incontinence. Symptom assessment by validated questionnaires can provide a very helpful complement to the patient history, to assess the impact of urinary incontinence on quality of life, and the symptoms (89-93). In the literature there are no studies that prove the usefulness of physical examination to typify the urinary incontinence. However, it is recommended to identify risk factors as well as significant associated or underlying pathology, such as significant prolapse, obstruction, neurological disease and malignancy(16).

2. GENERAL MEDICAL HISTORY

The main goal of the general medical history in women with urinary incontinence is trying to identify all comorbidities that could initiate or worsen UI as well as those which could negatively impact treatment success. The main factors associated with urinary incontinence are: obesity(94) (95, 96), diabetes and other metabolic conditions (96), neuropsychiatric disorders (97-100) , heavy occupational work, smoking, previous pelvic surgery and constipation (100, 101)

Neurologic diseases, pelvic neoplasms (malignant or benign) and radiotherapy can also lead to incontinence. Therefore, a careful surgical history should be taken and specific attention should be given to pain and other neurological symptoms, especially over the sacral nerve dermatomes, which could suggest neurologic disease or an intrapelvic nerve entrapment.

Pelvic pain can also be associated with apical support defects, endometriosis or pelvic congestion syndromes. The latter two can be associated with neurogenic urgency, depending on localization of lesions and varicosities, and require specific approaches.

Anorectal dysfunction, such as anal incontinence and obstructed defecation must also be carefully assessed and treated simultaneously, as these symptoms are strongly associated with urinary incontinence and may share a common aetiology and be associated with a pelvic support defect.

A careful surgical history should be taken, especially for pelvic surgery and other continence procedures, as the former can disrupt the endopelvic fascia (102) or result in intrapelvic nerve entrapment, thus generating secondary UUI (103) (104, 105). For recurrent SUI, there seems to be a trend for better results with retropubic and/or adjustable slings; however, there is still not enough data to recommend or refute any of the different management strategies for recurrent or persistent stress incontinence after failed suburethral tape surgery (105).

3. SYMPTOM ASSESSMENT

As classification of Urinary incontinence is clinical, a careful symptom assessment is mandatory and it is particularly important to plan the appropriate treatment. Furthermore, it is important to quantify the degree of leakage before and after therapy to evaluate the impact of the disease on quality of life, and to identify patients with complicated incontinence that need to be referred for specialised management (87). To achieve these objectives there are several tools including history and clinical assessment together with validated questionnaires, voiding diaries and pad tests. Many validated questionnaires have been developed to assist in the evaluation of urinary symptoms and to help in diagnosing the type of urinary incontinence (89-93). They may be used in combination with history and clinical examination. The International Consultation on Incontinence (ICI) has developed an ICI questionnaire (ICIQ) to assess pelvic floor function in both clinical practice and research settings (106, 107). It includes many modules about both female and male urinary symptoms or pelvic dysfunctions in particular urinary incontinence (ICIQ-UI). Franco at al (108) and Karantanis et al(109) showed that the short form (ICIQ-SF) correlates well with the 1-hour and 24-hour pad test for evaluation of the severity of SUI. The severity of SUI seems to be correlated to Intrinsic sphincter deficiency, although the diagnosis is possible only by urodynamic study (Urodynamic valsalva leak point pressure (VLPP) < 60 cm water believed to be diagnostic) (110).

The Modified Gaudenz-Incontinence questionnaire increases the likelihood of accurately diagnosing both stress and urge incontinence, however this questionnaire is validated only in the Japanese language (16) , while the Bladder Instability Discrimination Index (91) and Versi's questionnaire (111), although useful to diagnose urgency and stress incontinence, are

complex and sometimes not easily used in the practical clinical setting. The patient-completed Questionnaire for Urinary Incontinence Diagnosis(112) contains 6 questions, of which 3 are intended to predict stress incontinence and 3 are intended to predict urgency incontinence. It appears to increase the likelihood of correctly diagnosing urgency incontinence (positive LR, 3.7; 95% CI, 1.6-9.0; negative LR, 0.27; 95% CI, 0.17-0.42), but is not as helpful in the diagnosis of stress incontinence (positive LR, 2.8; 95% CI, 1.6-4.9; negative LR, 0.21; 95% CI, 0.12-0.37)(16). The Urogenital Distress Inventory (113), that is a widely used symptom tool, is a questionnaire helpful to assess LUTS bother, including incontinence, in women. The Questionnaire for Urinary Incontinence Diagnosis is a reliable 6-item questionnaire able to diagnose stress urinary incontinence and urgency urinary incontinence in a referral urogynecology patient population with accuracy (93). Overactive bladder symptom scores are also very useful for women with storage symptoms including urgency incontinence (32) (34-42) (114) (115).

4. PHYSICAL EXAMINATION (FEMALE)

The main objective of physical examination is to detect signs, defined as any abnormality indicative of disease or a health problem, detectable on examination of the patient; an objective indication of disease; or a health problem. No studies were found to support evidence that clinical examination improves care for diagnosing the type of urinary incontinence (UI) in women. Nonetheless, there is a wide consensus recommending clinical examination as an important part of assessment women with UI, including: abdominal, neurological, gynaecological and pelvic examination, with the purpose of detecting associated or underlying pathology that may explain lower urinary tract symptoms (LUTS). Height and weight should be recorded so that the body mass index can be calculated (Kg/M2) as obesity is an important risk factor for UI (112, 115, 116).

a) Abdominal examination. Observation of the abdomen may yield evidence of scars from previous surgery or abdominal striae. Increased abdominal striae may be found in association with other markers of abnormal collagen metabolism, and are more likely in patients with prolapse and stress incontinence (117, 118).

Bladder fullness or retention may be identified by abdominal palpation or by suprapubic percussion. In one study designed to look at the clinical utility of basic assessment in elderly women, palpable enlargement indicated a post-void residual volume of at least 300ml (119). Other abdominal mases or abdominal distension (e.g. ascites) can also be detected by abdominal examination. Tenderness or a mass in the renal area must be excluded by examination.

b) Neurological examination. Neurological signs related to S2-4 can suggest a possible neurogenic lower urinary tract or pelvic floor dysfunction. Saddle anesthesia will occur with lesions affecting S2-S4. Assessment of gait, abduction and dorsiflexion of the toes (S3) and sensory innervation to the labia minora (L1-L2), sole and lateral aspect of the foot (S1), posterior aspects of the thigh (S2), and cutaneous sacral reflexes bulbocavernosus and anal reflexes) are additional features of the neurological exam that may be assessed. A rectal examination will provide a subjective assessment of resting and voluntary anal tone (S2-S4). For patients with possible neurogenic lower urinary tract dysfunction, a more extensive neurological examination is indicated. In the elderly, full cognitive and mobility assessments are also recommended. An evaluation of hand dexterity should be performed when self-catheterisation is being considered as a treatment option for incontinence associated with chronic urinary retention.

c) Gynaecological examination (vulva and vagina). There are few scientific data documenting the parameters of a normal pelvic examination in women of various ages and with various obstetrical histories. The components of the examination have not been universally agreed upon. Gynaecological examination should include: inspection of the vulva, perineum and vagina, as well as vaginal palpation, with the evaluation of pelvic floor muscle tone, muscle mass and defects. The location of any vaginal pain should be noted and any tenderness over the course of the pudendal nerve. Bimanual pelvic examination is also part of the gynaecological examination, with the assessment of the size, location, and mobility of the uterus and the adnexal structures. Palpation of any pelvic mass or unusual tenderness is possible by vaginal examination together with suprapubic palpation.

Vulval inspection allows a description of the skin and the presence of any abnormal anatomical features (atrophic changes, scars, erythema of the vulva, lichen sclerosis, cysts, other tumors). With inspection of the external genitalia a urethral caruncle may be noted (a small, soft, smooth friable red outgrowth along the edge of the urethra) or urethral mucosa prolapse (smaller eversion of the urethral urothelium, generally involving the posterior lip).

Another important aspect of the examination is the observation of the perineal movement when the patient is asked to cough or Valsalva. This is a way to evaluate the pelvic floor muscles function. We can observe a perineal elevation as the inward (cephalad) movement of the vulva, perineum, and anus and a perineal descent as an outward (caudal) movement of the vulva, perineum, and anus. During cough or Valsalva maneuver the perineum should show a ventral movement due of the contraction of the pelvic floor muscles; a downward movement might indicate a weak pelvic floor.

With vaginal examination we obtain information of the vaginal length and mobility, presence of scarring

and/or pain, and level of oestrogenisation. Vulvar and vaginal atrophy (VVA) is a common condition and is a consequence of reduced oestrogenisation of urogenital tract that results in a loss of vaginal elasticity, dryness, decreased lubrication, with associated irritation, dyspareunia, and urinary symptoms (120). Vaginal atrophy can be treated with vaginal estrogen application and this should be considered as an adjunctive treatment in the management of common pelvic floor disorders in postmenopausal women (121, 122) . A urethral diverticulum presenting as a palpable suburethral mass, can also be detected on vaginal examination. The most common finding is a tender anterior vaginal wall mass and if the sacculation communicates with the urethra, it may be possible to express a purulent exudate from the urethra. Occasionally, a stone may develop within the diverticulum. Many patients with urethral diverticula are asymptomatic and need no treatment although symptomatic patients report swelling of the urethra, recurrent cystitis, dyspareunia, urinary incontinence, urinary dribbling after passing urine and voiding difficulties (123-125).

d) Rectal examination. Anal sphincter tone and strength can be classified as good or poor, in the absence of any quantitative assessment. Ano-rectal abnormalities can be found by inspection and digital examination: hemorrhoids, fissure, intussusception; rectovaginal or anocutaneous fistula or tumor. Anal sphincter tear may be recognized as a clear “gap” in the anal sphincter. The presence or absence of fecal impaction may also be assessed.

e) Specialised tests for diagnosis UI in Women

Three special manoeuvres can be performed during the initial assessment of women with urinary incontinence: the stress test, the Q-tip test, and the pad test.

Stress Test. The stress test involves observation for urine loss when women, with a full bladder, are coughing forcefully or during a Valsalva maneouvre. If the patient leaks with the onset of the cough and terminates with its cessation, the test is positive and confirms stress incontinence. It is an easy test to perform in a single visit and the results are immediately available. The stress test performed with coughing appears to be reliable. Reliability data are not available for tests performed using the Valsalva maneouvre. This procedure can be performed while the patient is in the lithotomy position, if no leakage is observed, the test should be repeated in standing position [2]. A negative supine cough test does not exclude incontinence. Rimstad et al found that in the supine position only 49% of the women leaked during the stress test (126). Earlier studies have also found that the supine cough test has low sensitivity (127). A positive stress test is helpful in diagnosing the type of urinary incontinence. When stress incontinence is suspected by the symptoms, the cough stress test is the most reliable clinical assessment for confirming the diagnosis (128). When compared with multichannel urodynamic studies, the cough stress test demonstrates good sensitivity and specificity for stress incontinence (129-131). A detrusor contraction may occasionally cause leakage during a stress test and thus the possibility of a detrusor overactivity. Kulseng-Hanssen et al have demonstrated that only 5 of 100 stress and mixed incontinent women had a detrusor contraction simultaneously with stress leakage, and in none was detrusor over-activity the sole cause of leakage (132). Lagro-Janssen et al noted that the presence of urgency incontinence in the absence of stress incontinence excluded the possibility of SUI and had a high specificity for the diagnosis of detrusor overactivity (DO) (133). Holroyd-Leduc et al. reviewed existing evidence on the diagnostic accuracy of the stress test for stress urinary incontinence (16). Results from the meta-analysis revealed that a positive stress test increases the likelihood of a diagnosis of stress urinary incontinence (summary LR, 3.1; 95% CI, 1.7-5.5), while a negative test result decreases the likelihood (summary LR, 0.36; 95% CI, 0.21-0.60).

The main limitations of this test is the variability in the intensity of cough and bladder volume. However, in women complaining of stress urinary incontinence, cough stress test is important as an objective measure to confirm the diagnosis, particularly when surgical treatment is planned.

Pad test. A pad test it is a non-invasive diagnostic tool, involving the continuous wearing of a continence pad for a set period of time. The objective of pad testing is to quantify the volume of urine lost by weighing a perineal pad before and after some type of leakage provocation. It is as an optional test for the evaluation of urinary incontinence, to distinguish continent, from incontinent women, but is not diagnostic of the type of urinary incontinence (134, 135). Holroyd-Leduc et al. reported that a positive pad test increases the likelihood of an incontinence problem (LR, 3.3; 95% CI, 2.0-5.4), while a negative pad test makes an incontinence problem much less likely (LR, 0.11; 95% CI, 0.05-0.27) (16). Price and Noblet have demonstrated that in women with symptoms of predominant stress urinary incontinence, the cough stress test is more reliable than the pad test (131). Pad tests can be divided into short term tests, usually performed under standardized office conditions, and long-term tests, usually performed at home for 24–48 hours. Pad tests are generally performed with a full bladder or with a fixed known volume of saline instilled into the bladder before beginning the series of exercises. Only the “1 hour pad test” has been standardized by the International Continence Society (ICS-pad test) (136). This short test is appropriate in routine evaluation of patients during initial evaluation, however it can be affected by many factors, if either the patient or physician have doubts about the accuracy of the initial test, evaluation should be extended by an additional hour or repeated. The 24-hr test is more reproducible than a 1-hr test, but longer testing requires more preparation and a greater commitment on the part of the patient. A pad weight gain >1 g is considered positive

for a 1-hour test, and a pad weight gain >4 g is positive for a 24-hour test. These values may need to be modified in situations of increased perspiration (137). There is wide variation in the pad weight gain in incontinent women participating in clinical trials. Although some studies have found high test-retest correlations in pad tests (136, 138), some other studies have reported low inter-subject and intra-subject reliability (139, 140). The correlation coefficient between total leakage during two long-term tests appears to exceed that of a standard 1-hour test (141, 142)

A pad test is a good instrument for evaluating severity of urinary incontinence, however, it is not a perfect "gold standard" for UI severity. A pad test should always be interpreted in conjunction with standard self-assessment questionnaires including the bother index. In the analysis of 1-hr pad test, an increase of 1–10 g is classified as representing mild incontinence, 11–50 g moderate and >50 g severe incontinence. Good correlation has been reported by Abdel-Fattah et al. between the self-assessment questionnaires and the 1-hr pad test (141). The King's Health Questionnaire showed a 96% sensitivity and 93% specificity of a 1-hr pad test in identifying incontinent patients(141). The good correlation between self-assessment questionnaires and 1-hr pad test, but not the 24-hr pad test supports the value in standardization. In addition there is also good correlation between the 24-hr pad test and the International Consultation on Incontinence Questionnaire—Short Form (ICIQ-SF) (109). The values for 24-hr pad test are classified as follows: Mild (4–20 g/24 hr), moderate (21–74 g/24 hr), and severe (>75 g/24 hr) incontinence (143). However these values have to be considered with caution and they may change depending on the sample characteristics (eg, proportion of women with more severe incontinence, etc). In another study comparing pad-weighing test with the Incontinence Severity Index (ISI), the mean pad-weights (grams per 24 hours, 95% confidence intervals), were : 7 for slight, 39 (26-51) for moderate, 102 (75-128) for severe, and 200 (131-268) for very severe UI. Spearman's correlation coefficient for pad weighing results and severity index was 0.58 ($p < 0.01$), and bother increased significantly with increasing severity (144).

The main limitation of the pad test as a diagnostic tool for UI is the value for the cutoff of a positive test and the inability to distinguish between types of incontinence. This limitation is especially important when this test is used as an outcome measure, when surgical treatment of stress urinary incontinence is evaluated, as these women can suffer "de novo" urgency urinary incontinence.

Q-tip test. Stress urinary incontinence (SUI) may be classified based on urethral mobility. Urethral hypermobility is associated with greater surgical success after suburethral sling placement. Assessment of urethral mobility is an essential part of pelvic examination in women with symptoms of SUI, especially when surgery is planned. The Q-tip test has traditionally been used to assess the mobility of the urethro-vesical junction. The test involves placement of a lubricated cotton swab or Q-tip in the urethra to the level of the bladder neck while the woman is in the lithotomy position. The degree of rotation of the free end of the swab is then measured while the woman performs a Valsalva maneouvre. The free end should remain horizontal if no anatomical defect is present. If the free end moves above the horizontal, urethral hypermobility is suspected, this can occur in patients with stress urinary incontinence. A straining angle of 30º or greater relative to the horizontal during Valsalva or cough has been considered clinically relevant and defined as hypermobility (145, 146). In a meta-analysis by Holroyd-Leduc et al. that examined the accuracy of the Q-tip test for diagnosing stress urinary incontinence, only two relevant studies met the inclusion criteria(16). Results of the analysis suggested that a positive Q-tip test does not accurately predict the diagnosis of stress urinary incontinence in women.

Although the Q-tip test is a useful tool, it may be uncomfortable for many women due to the insertion of a rigid cotton tipped swab into the urethra. The identification of visual examination tool to determine urethral hypermobility would help to eliminate this uncomfortable test. A study has compared the diagnostic accuracy of the Q-tip test with visual urethral mobility examination (VUME) and concluded that VUME is a diagnostic alternative to Q-tip test for the initial assessment of urethral hypermobility when performed by an experienced operator and is preferred by women(147) . A recent publication comparing a vaginal swab test with the urethral Q-tip test has demonstrated that the vaginal swab test, with a cotton-tipped swab placed in the vagina 3 cm proximal to the external meatus in the midline at rest, is equivalent to the standard Q-tip test in measuring urethral mobility with less discomfort for patients (148).

Another noninvasive method to identify women with urethral hypermobility is translabial ultrasound (149, 150). This more specialised testing with pelvic floor ultrasound and other imaging techniques appears to be gradually replacing the Q-tip test for a more advanced assessment of bladder neck hypermobility, however they are limited to their cost, availability and special training requiered.

5. PELVIC ASSESSMENT: PELVIC FLOOR STRENGTH AND PELVIC ORGAN PROLAPSE

5.1. Assessment of Pelvic Floor Muscle Strength

Pelvic floor muscles (PFM) play an important role in continence and support of the pelvic organs. Voluntary pelvic floor muscle contraction and relaxation should be evaluated during the initial assessment. Pelvic floor muscle function can be clinically as-

sessed by several different methods, including inspection, visual palpation, ultrasound, electromyography (EMG), dynamometry and manometry (151-154).

Due to the location of the PFM inside the pelvis, the evaluation of the PFM function is difficult only by observation. Vaginal palpation is an accepted method to evaluate muscle tone and strength and is perhaps the most accessible and valid measure of PFM function (155, 156). PFM contractility measured by digital vaginal palpation can be scored according to the Modified Oxford Scale (MOS)(157). According to the joint guidelines published by IUGA/ICS in 2010, pelvic floor muscle strength is qualitatively defined by the tone at rest and the strength of a voluntary or reflex contraction as strong, normal, weak or absent, or by a validated grading symptom (2). Any or all of the following factors can be assessed including muscle strength (static and dynamic), voluntary muscle relaxation (absent, partial, complete), muscular endurance (ability to sustain maximal or near maximal force), repeatability (the number of times a contraction to maximal or near maximal force can be performed), duration, coordination, and displacement. If possible, it is desirable to document findings for each side of the pelvic floor separately to allow for any unilateral defects and asymmetry. The ICS report into the standardization of terminology of pelvic floor muscle function and dysfunction (158) classifies the pelvic floor muscles according with the ability to contract in:

a) Normal pelvic floor muscles: Pelvic floor muscles which can voluntarily and involuntarily contract and relax.

b) Overactive pelvic floor muscles: Pelvic floor muscles which do not relax, or may even contract when relaxation is functionally needed, for example, during micturition or defaecation.

c) Underactive pelvic floor muscles: Pelvic floor muscles which cannot voluntarily contract when this is appropriate (155) .

d) Non-functioning pelvic floor muscles: Pelvic floor muscles where there is no action palpable.

The morphology and integrity of the pelvic floor muscles, including the puborectalis muscle, may be also assessed by palpating its insertion on the inferior aspect of the os pubis. If the muscle is absent 2–3 cm lateral to the urethra, i.e., if the bony surface of the os pubis can be palpated as devoid of muscle, an “avulsion injury” of the puborectalis muscle is likely (159). This finding is significantly associated with a reduction in MOS, as disconnection of a muscle from its insertion results in functional impairment. Studies in symptomatic women have showed an association between avulsion and reduced contractile strength (160, 161). All these studies demonstrated that MOS grading is strongly associated with subjective and objective measures of pelvic floor dysfunction, both clinically and sonographically, however it appears that MOS obtained by simple digital palpation might be a more valid measure of PFM contractile function than ultrasound measures of tissue dsplacement (154, 162).

5.2. Assessment of Pelvic Organ Prolapse

Assessment of pelvic organ prolapse described in this section is in accordance with the joint guidelines produced by IUGA/ICS in 2016 (163, 164). Pelvic organ prolapse (POP) as a sign is defined as the descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix) or the apex of the vagina (vaginal vault or cuff scar after hysterectomy). Urinary incontinence and pelvic organ prolapse are separate clinical entities that often coexist. It is important to assess pelvic organ prolapse in a woman with incontinence, because repair of one pelvic support defect without repair of concurrent symptomatic pelvic support defects can predispose to accentuation of unrepaired efects and new symptoms. Significant pelvic organ proplase can obstruct voiding and defaecation. The term stress incontinence on prolapse reduction (occult or latent stress incontinence) describes the development of stress urinary incontinence after the reduction of co-existent prolapse by surgical repair or pessary insertion (163, 164).

The presence of any sign of POP should be correlated with relevant POP symptoms, commonly this correlation would occur when the prolapsed organ reaches the level of the hymen or beyond (165, 166). All examinations for pelvic organ prolapse should be performed with an empty bladder (and if possible an empty rectum). An increasing bladder volume has been shown to restrict the degree of descent of the prolapse (167). The choice of the woman's position during examination, e.g. left lateral (Sims), supine, standing or lithotomy is that which can best demonstrate POP in that patient and which the woman can confirm as the maximal extent she has perceived e.g. by use of a mirror or digital palpation (168). The degree of prolapse may be worse after a lengthy time in the upright position.

Pelvic organ prolapse staging. Each aspect of POP, uterine (cervical) prolapse, anterior vaginal wall (compartment), posterior vaginal wall (compartment), vaginal vault (cuff scar) prolapse can and should be subject to a clinical staging. The hymen always remains the fixed point of reference for prolapse description. According with the IUGA/ICS guidelines for POP in 2016 (163, 164) , the following stages are considered:

Stage 0: No prolapse is demonstrated.

Stage I: Most distal portion of the prolapse is more than1 cm above the level of the hymen.

Stage II: Most distal portion of the prolapse is situated between 1 cm above the hymen and 1cm. below the hymen.

Stage III: The most distal portion of the prolapse is more than 1 cm below the plane of the hymen but everted at least 2cm less than the total length.

Stage IV: Complete eversion or eversion at least within 2 cm of the total length of the lower genital tract is demonstrate

Uterine/ cervical prolapse: Observation of descent of the uterus or uterine cervix.

Anterior vaginal wall (compartment) prolapse: Observation of descent of the anterior vaginal wall (compartment). Most commonly this might represent a bladder prolapse (cystocele). Higher stage anterior vaginal wall prolapse will generally involve descent of uterus or vaginal vault (if uterus is absent). Occasionally, there might be an anterior enterocele (hernia of peritoneum and possibly abdominal contents), most commonly after prior hysterertomy or reconstructive surgery.

Posterior vaginal wall (compartment) prolapse: Observation of descent of the posterior vaginal wall. Commonly, this would represent rectal protrusion into the vagina (rectocele). Higher stage posterior vaginal wall prolapse after prior hysterectomy will generally involve some vaginal vault (cuff scar) descent and possible enterocele formation. Enterocele formation can also occur in the presence of an intact uterus.

Vaginal vault (cuff scar) prolapse: Observation of descent of the vaginal vault (cuff scar after hysterectomy

Pelvic organ prolapse quantification (POP-Q). The need for an objective, site-specific method of quantifying and staging POP led to the design and validation of the POP-Q system. The original description of the POP-Q was by Bump et al in 1996 and is shown in figures 1, 2 and 3 (169) . This standardised system, which represents a reliable and internationally accepted tool for describing the anatomic position of the pelvic organs, has been validated in the dorsal lithotomy, standing, upright and lateral position(170-172).

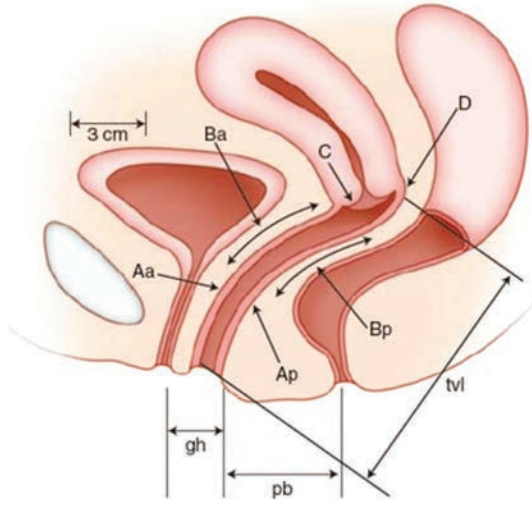

Figure 1: The six sites (Aa, Ba, C, D, Bp and Bp), the genital hiatus (gh), perineal body (pb) and total vaginal length (tvl) used cm above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). Alternatively, a three by three grid can be used to organize concisely the measurements as noted in Figure 2.

Anterior wall Aa	Anterior wall Ba	Cervix or Cuff C
Genital hiatus gH	Perineal Body pB	Total Vaginal Length TVL
Posterior wall Ap	Posterior wall Bp	Posterior Fornix D

Figure 2: Grid presentation of POP-Q measurements

The POP-Q records defects relative to the hymeneal remnants in centimetre gradients. These measurements are further staged according to the most distal defect. The POP-Q system for POP considers the anatomic position of six defined points (two on the anterior vaginal wall, two in the superior vagina, and two on the posterior vaginal wall) measurement are in centimetres (cm) above or proximal to the hymen (negative number) or cm below or distal to the hymen (positive number), with the plane of the hymen being defined as zero (O). For example, a cervix that protruded 3 cm distal to the hymen would be + 3 cm. All

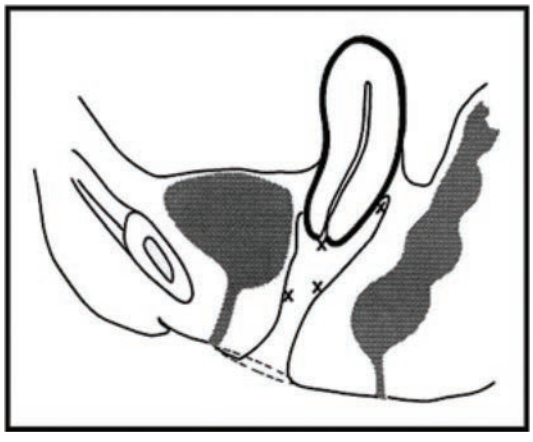

Figure 3: Simplified POP-Q

points are measured on maximal straining (except total vaginal length). The POP-Q as a system for quantitative prolapse description defines also other landmarks and measurements: The genital hiatus (GH) is measured from the middle of the external urethral meatus to the posterior margin of the hymen. The total vaginal length (TVL) is the length of the vagina (cm) from posterior fornix to hymen when Point C or D is reduced to its full normal position. The perineal body (PB) is measured from the posterior margin of the hymen to the mid-anal opening.

Anterior vaginal wall prolapse is defined as descent of the anterior vagina so that the urethra-vesical junction (a point 3cm proximal to the external urinary meatus) or any anterior point proximal to this is less than 3cm above the plane of the hymen. On vaginal examination, there is a loss of the transverse crease between the lower and middle thirds of the anterior vaginal wall and descent of the anterior vaginal wall. Anterolateral protrusion into the vaginal canal may represent unilateral or bilateral detachment of the pubocervical fascia along the anterolateral vaginal sulcus from its attachment to the arcus tendineus fascia pelvis (white line). Central protrusions of the anterior vaginal wall may represent defects in the pubocervical fascia below the trigone and base of the bladder. Advanced prolapse of the upper anterior vaginal wall may obstruct a well-supported bladder neck. The two anterior vaginal wall points are as follows:

Point Aa located in the midline of the anterior vaginal wall three (3) cm proximal to the external urethral meatus. By definition, the range of position of Point Aa relative to the hymen is −3 to +3 cm.

Point Ba that represents the most distal (i.e., most dependent) position of any part of the upper anterior vaginal wall from the vaginal cuff or anterior vaginal fornix to Point Aa. By definition, Point Ba is at −3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff (Point C) in women with total uterine prolapse or post-hysterectomy vaginal eversion.

Prolapse of the apical segment of the vagina is defined as any descent of the vaginal cuff scar (after hysterectomy) or cervix, below a point that is 2cm less than the total vaginal length above the plane of the hymen. In some women, the intravaginal portion of the cervix may become elongated and cause the cervix to extend into the lower vaginal canal, simulating prolapse; however, the uterine fundus may have good support. In other women, the uterus may prolapse fully outside the hymen as uterine procidentia. Following hysterectomy, the vaginal cuff may be well supported or may prolapse fully outside the hymen, along with other vaginal segments. The two superior vaginal points are as follows:

Point C that represents either the most distal (i.e., most dependent) edge of the cervix or the leading edge of the vaginal cuff (hysterectomy scar) after total hysterectomy.

Point D that represents the location of the posterior fornix in a woman who still has a cervix. It is included as a point of measurement to differentiate suspensory failure of the uterosacral-cardinal ligament “complex” from cervical elongation. When the location of Point C is significantly more positive than the location of Point D, this is indicative of cervical elongation which may be symmetrical or eccentric. Point D is omitted in the absence of the cervix.

Posterior vaginal wall prolapse is defined as any descent of the posterior vaginal wall so that a midline point on the posterior vaginal wall 3cm above the level of the hymen or any posterior point proximal to this, less than 3cm above the plane of the hymen. Posterior protrusions into the vaginal canal are most commonly caused by defects in the recto-vaginal fascia allowing protrusions of the small bowel (enterocoele) and/or rectum (rectocele). Normally, the anterior vaginal wall lies upon the posterior vaginal wall. Therefore, protrusions of the posterior vaginal wall can affect the function of the urethra and bladder that lie upon the anterior vaginal wall. For example, distal loss of support in the posterior segment may result in a bulge that compresses the urethra and affects voiding. The two posterior vaginal wall points are as follows:

Point Ap is located in the midline of the posterior vaginal wall three (3) cm proximal to the hymen. By definition, the range of position of Point Ap relative to the hymen is − 3 to +3 cm.

Point Bp represents the most distal (i.e., most dependent) position of any part of the upper posterior vaginal wall from the vaginal cuff or posterior vaginal fornix to Point Ap. By definition, Point Bp is at −3 cm in the absence of prolapse and would have a positive value equal to the position of the cuff in women with total post-hysterectomy vaginal eversion.

The POP-Q system has not been widely adopted in clinical practice particularly by non-urogynaecologists; owing somewhat to difficulty in learning the assessment (173, 174). A simplified version of the POP-

Q was published by Swift in 2002, whereby the ordinal staging system of the original scale was retained (175) . This is based on the POP-Q with similar ordinal staging but with only four points measured instead of nine. There is no Stage 0; it is combined with Stage 1. It is undertaken in the dorsal lithotomy position with patient forcefully bearing down, performing Valsalva or coughing. Four points used: Point Ba in the anterior vaginal segment (estimated around 3 cm proximal to hymenal remnants). Point Bp in the posterior vaginal segment (estimated around 3 cm proximal to hymenal remnants). Point C (cervix). The apex / posterior fornix is Point D in non-hysterectomized women and point C in hysterectomized. (Fig.3). The inter-observer correlation of the simplified POP-Q was investigated in a secondary analysis of data from a large multicenter study. Weighted kappa statistics for the four POP-Q sites ranged from 0.53 (indicating poor agreement) to 1.0 (denoting excellent agreement) (176, 177).

Despite the difficulties highlighted with the adoption of the POP-Q, reproducibility and reliability of the assessment system have been demonstrated (178, 179). Hall et al demonstrated that the examination could be completed within four minutes by new learners and two minutes by clinicians experienced with the assessment (70) . With experienced practitioners, POP-Q staging performed using the measurement technique and estimation based on clinical examination are not significantly different (180). Parnell et al have described a POP-Q model in order to teach the POP-Q examination(181).

The relationship between anatomical defects measured by the POP-Q and lower urinary tract symptoms or other pelvic floor symptoms in women with pelvic floor disorders has been investigated and the symptom feeling of a bulge in the vagina is the only symptom that correlated with POP-Q in all vaginal compartments (182-185) . A recent published study demonstrates that the sensitivity and specificity of this symptom were 60% and 83% when point Ba was 1 cm below the hymen. Whereas they were 55% and 83% when point C was 3 cm above the hymen (186).

The correlation between posterior compartment prolapse measured by POP-Q and obstructed defecation symptoms has been also investigated; the best-designed studies utilizing validated measures show a significant association between presence of posterior compartment prolapse and specific obstructed defecation symptoms, most significantly splinting, straining, and incomplete emptying (187, 188) . A retrospective study by Collins et al showed that a point Bp value of >-5 on the POP-Q, was found to be strongly correlated with defaecatory dysfunction with symptoms of stool trapping and incomplete evacuation according with the CRADI-8 score(189).

The POP-Q has been used for the linguistic validation of condition specific health related quality of life questionnaires such as the Prolapse Quality of life (P-QOL) (190, 191), Pelvic Floor Distress Inventory (PFDI)(192-194), Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ12) (195), Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised(PISQ-IR) (196-202), and validation of the Patient Global Impression of Improvement (PGI-I) for urogenital prolapse(202).

An advantage of the widespread adoption of the POP-Q system is the capability to compare results and surgical outcomes of different studies. The POP-Q has been used to define improvement in POP after surgical interventions in a number of studies; including vaginal mesh or abdominal mesh(203-236), laparoscopic techniques(237-240), colpocleisis(241-244), sacrospinous fixation(244-246), and collagen coated mesh repairs(247-249).

The quantification of POP using the POP-Q was compared with dynamic MRI; the results showed that correlations of the anterior compartment were good to moderate, compared with central and posterior compartment that were poor to moderate. Correlations were independent of the POP-Q staging measurements (250-253). The agreement of MRI-based POP staging with the POP-Q is excellent, but the added clinical value is questionable due to poor association with clinical findings and pelvic floor symptoms (251). The relationship between clinical assessment of female pelvic organ prolapse using the POP-Q and dynamic 2D transperineal ultrasound (TPUS) has been also investigated. It was observed that the accuracy of pelvic floor US staging was limited and that clinical assessment remains the gold standard(252). An observational study using POP-Q and pelvic ultrasound for the assessment of the type of cystocele, analysed the agreement between physical POP-Q and the Green radiological classification of cystocele. Kappa co-efficients ranged between 0.56-0.54 and 0.32-0.79 for clinical and ultrasound diagnosis respectively. The clinical utility of these findings has not been established(253, 254). A recent study compared clinical examination and imaging findings, especially regarding cut-offs for the distinction between normal pelvic organ support and prolapse. The conclusion was that the proposed cut-offs for 'significant prolapse' on ultrasound and POP-Q (Ba ≥ -0.5 and cystocele ≥ 10 mm below the symphysis pubis, C ≥ -5 and uterine position of 15 mm above the symphysis pubis, are plausible and mutually consistent (254, 255).

General recommendations in the female patient

A global evaluation for women is essential for an effective treatment and prevention of recurrence of UI, especially in patients with other comorbidities. Identifying and treating those symptoms are directly related of treatment success and resolution of symptoms, as well as their recurrence.

Pain and urgency must be carefully assessed, as they may indicate that incontinence can be secondary to a neurologic or other functional conditions.

Urethral mobility can be assessed using the Q-Tip test and predict success/failure of TOT.

A ring pessary test, VLPP and MUCP have been advocated to elucidate pelvic support-related incontinence/symptoms and predict the outcome of a surgical procedure, but their predictive values still need to be assessed.

VI. SPECIFIC POPULATION: EVALUATION OF THE MALE PATIENT

1. CHARACTERISTICS OF MALE LUTS

In the male population, Lower Urinary Tract symptoms (LUTS) may present with dysfunction of the storage and emptying phase as well as with post micturition signs or symptoms. These symptoms can be non-specific in presentation and are multifactorial in origin. LUTS are a progressive and age related but not sex or organ-specific. They cause significant bother and impair quality of life (256, 257). Traditionally LUTS were thought to be secondary to bladder outlet obstruction due to prostatic enlargement; however, recent scientific evidence failed to show this relationship(257). Often, LUTS are unrelated to changes in prostatic size. Current research is aimed at understanding the impact of the bladder itself in LUTS. Bladder dysfunctions, such as Detrusor Underactivity, Detrusor Overactivity and other functional abnormalities can contribute significantly to LUTS(258).

In vitro as well as in vivo animal studies show a correlation between oxidative stress and ischemia with changes in bladder contractility in animals(259, 260).

LUTS are strongly associated with ageing and represent a major health burden for the patient and the society. Several epidemiological reports have demonstrated that storage symptoms (including urinary urgency and urinary urgency incontinence) defined as overactive bladder syndrome also increases with age in men. LUTS are often under-diagnosed and undertreated and still unfortunately often accepted as part of ageing. In regards to urinary incontinence, epidemiological studies have shown that obesity is an independent risk factor for incontinence. Several studies indicated that each 5-unit increase in body mass index (BMI) above normal weight is associated with a 40% to 70% increased odds of urinary incontinence in a 5 to 10 yearstime period [296]. There is a gender disparity as the correlation between obesity and urinary incontinence is higher in women, with 60 to 70% of incidence of urinary incontinence among severely obese women. Although the incidence appears lower in men, is still quite relevant, as 24% of severely obese men have urinary incontinence(261). Obesity is a potentially modifiable condition. A recent meta-analysis confirmed that weight loss is associated with a reduction on incidence and severity of urinary incontinence among women and men. Specifically, in male population, obesity appears to be more frequently associated with urgency incontinence(261).

Chronic prostatic pain syndromes (e.g. non-bacterial chronic prostatitis) and other pelvic floor dysfunctions can also present with a component of symptoms compatible with a component of symptoms compatible with storage symptoms. In younger men, primary bladder neck dysfunction is a common cause of LUTS, with or without pelvic pain. Functional abnormalities of striated sphincter relaxation may also occur in young men. The complexity of the presenting symptoms and the various differential diagnoses mandate a thorough basic assessment of the lower urinary tract in men to plan optimal therapeutic intervention.

Recent epidemiologic studies and meta-analyses confirm a high prevalence of LUTS in the community. There is an increased prevalence of LUTS with ageing(262). The incidence appears to be of 3.5% in men in the fourth decade of life, while in men over age of 85 the incidence is higher than 30%. These epidemiologic data are confirmed by the finding that in the time period from 1992 to 2001 there was an increase of medical treatment for male LUTS from less than 2% to more than 10%. In the same time frame, there was also an increase in the time between the first diagnosis of LUTS and the time to surgery. The Multinational Survey of the Aging Male (MSAM-7) surveyed over 12 000 men age 50 to 80 in mayor countries of Western Europe and USA [297]. Across all countries, prevalence increased from 22% in men aged 50–59 years to 45% in men aged 70–80 years . 31% of men reported moderate-to-severe LUTS (34% in the USA and 29% in Europe). Interestingly, despite the fact that 19% of men with LUTS present with complaints, only 10% received and appropriate medical treatment (263).

Based on the Integrated Health Care Information Solutions (IHCIS) database, LUTS are among the most frequent reasons for medical consultation among the male population over 50. The fourth most common diagnosis in this population is BPH, after coronary artery disease, hyperlipidemia, hypertension and diabetes mellitus(264).

LUTS have a significant impact on quality of life but also on potentially life-treating conditions such as falls in elderly population. As reported by Parsons et al. moderate and severe LUTS independently increase the 1-year risk of falls, particularly recurrent falls, in community-dwelling older men(265). In their study of 5,872 participants in the Osteoporotic Fractures in Men study were assessed for LUTS, using the AUA symptom score. Patients with moderate LUTS were found to have 11% higher risk of at least one fall, while the risk of fall increased to 33% in subjects with severe LUTS(265) . Falls in the elderly population

might have serious consequences and screening elderly patients for LUTS by primary care providers should be assessed routinely.

2. MALE INCONTINENCE

Improvement in early detection of prostate cancer has led to an increase of men treated for this condition. The rate of post-prostatectomy incontinence (PPI) is difficult to determine because of the varying definitions of incontinence, but approximately one in five men require the use of pads in the long term after radical prostatectomy (RP)(266). Incontinence has a significant negative impact on quality of life. This potential complication is also patients' greatest fear, especially in the youngest subset of patients (65 years or younger), requiring RP(267). Robot-assisted laparoscopic prostatectomy (RALP) was introduced with the aim of improving surgical outcomes, but controlled or randomized studies on the long-term effects are few and present knowledge of effectiveness is based mainly on case series or registry data(268).

The Swedish LAP PRO trial brings some very useful insights into answering the question of true incidence of PPI and whether there are any differences across techniques. In summary, this trial focused on the primary end point of urinary incontinence 12 months after RALP, as reported by the patients (to reduce the potential bias of Surgeon-Patient relationship)(269). Notably, this study recruited only patients for high volume surgeons, those with more than 100 procedures done, to avoid the bias of the single surgeons learning curve. The study recruited 4000 patients and the final analysis included 2625 patients. 778 patients underwent an open retropubic radical prostatectomy (RRP) and 1847 underwent RALP. The study showed that patients classified as having urinary incontinence ranged from 20% to 56% after RRP and from 21% to 57% after RALP. The percentage of incontinence was even higher if a definition of dryness was combined with no use of pads and zero leaks(269).

Catalona et al. showed that incontinence after prostate surgery was primarily dependent on the age of patients(270). The older the patient, the more likely he is to be incontinent and to never regain urinary control. For 40-49 year olds only 3% (12/358) had long term incontinence but that increased to 8% (48/632) in 50-69 year olds 8% (48/632) and 13% (38/282) in men over age 70; for an overall prevalence of 7.7%(270).

Special consideration is needed for irradiated patients as the success rate and incidence of post incontinence surgery differ significantly from non-irradiated patients. The revision rate of Artificial Urinary Sphincter (AUS) surgery, a procedure done for PPI, was significantly higher in irradiated versus non irradiated men (mean 37.3 versus 19.8%; $p < 0.007$) after a mean follow-up of 38.4 months(271). Revision is typically performed for infection, erosion or urethral atrophy. Persistent urinary incontinence was also more than twice as likely in irradiated versus non-irradiated men (29.5 versus 12.1%; $P = 0.003$) with an odds ratio of 2.08(271). Radiation induced changes involving the bladder neck and urethral tissue, such as fibrosis, are considered to be the primary etiology for the development of incontinence. Surprisingly, the timing of radiation therapy does not seem to have any influence on the incidence of urinary incontinence. Similar rates of incontinence are reported in early and late radiation therapy after radical prostatectomy. Sowerby and colleagues reported the incidence of urinary incontinence to be 24.5% in men who underwent radiation less than 6 months from surgery and 23.3% in men with radiation greater than 6 months after prostatectomy(271).

Urgency incontinence is a failure of bladder storage usually due to the underlying pathology of detrusor overactivity (DO). Urgency incontinence commonly presents as part of the overactive bladder (OAB) syndrome. OAB is described as urinary urgency, with or without urgency incontinence, usually with frequeny and nocturia, in the absence of infection or other obvious pathology [1]. In men, OAB symptoms often coexist with emptying phase LUTS. Men with emptying phase LUTS such as poor flow and hesitancy are often assumed to have benign prostatic obstruction, though research has shown they may not.

3. SYMPTOM ASSESSMENT

Symptom assessment in men with incontinence should identify and exclude patients with complicated incontinence, who need to be referred for specialised management. Complicated incontinence comprises patients with recurrent incontinence after failed previous surgery, with total urinary incontinence, and/or with associated symptoms such as pain, haematuria, recurrent urinary tract infection, voiding symptoms, and/or a history of previous pelvic radiotherapy or radical pelvic surgery(272).

Because the occurrence of LUTS in men does not necessarily indicate concomitant prostate enlargement and/or obstruction, specific modalities should be used to ascertain the potential for the aetiologic role of these entities. A variety of symptom scores have been described to assess male patients with LUTS. It is important that symptom scores have a wide applicability across a number of different cultures and languages. Ideally, symptom scores should also help to determine the underlying etiology of LUTS (for example, BOO, DO, impaired detrusor contractility); however, this is made difficult by the fact that different conditions can produce similar or even identical symptoms. Each symptom score has advantages and disadvantages, but it is clear that the worldwide use of such scores has helped in evaluating symptoms, treating patients, and communicating findings globally. Symptom scores have been used in male LUTS for a variety of the purpose. 1) to assess

symptom severity, 2) to examine the relationships between clinical measure/ test results and scores from symptom and quality of life (QOL) questionnaires, 3) to predict to treatment, 4) to assess the outcome of treatment.

The following symptom scores for male LUTS have been evaluated.

Table 4 Symptom Questionnaires for Male-LUTS

The IPSS: symptoms and QOL impact of LUTS
The International Consultation on Incontinence Modular Questionnaire-Male-LUTS (ICIQ-MLUTS): symptoms of LUTS and urinary incontinence
The Danish Prostatic Symptom Score (DAN-PSS): symptoms of LUTS and urinary incontinence
The OAB Symptom Score (OABSS)
The core LUTS Score (CLSS): symptoms of LUTS
The Urgency and Nocturia Scoring TOOL (UWIN): symptoms of LUTS

Three questionnaires with a high level of psychometric validity and reliability are the IPSS, the ICS's ICS-male questionnaire (now known as the ICIQ-MLUTS), and DAN-PSS. Although each was designed with the same purpose, only six symptoms are common to all three, including incomplete emptying, urgency, decreased stream, frequency and nocturia.

In men, the American Urological Association symptom score for BPH (AUA-7) is most commonly used in North America for assessment of subjective symptoms. However, equally reproducible data can be obtained from the International Prostate Symptom Score (IPSS)(273), the ICSmale questionnaire (now renamed the ICIQMLUTS, long and short forms, as part of the ICIQ modular questionnaire: www.iciq.net).

The IPSS has been the most widely used (in many countries and languages), but one of the major criticism of the IPSS is the fact that it is not disease or condition specific. In addition, it neglects the symptom of urgency incontinence, a symptom that produces significant bother. Urgency incontinence is an important symptom, particular in regard to therapeutic outcome in BPO patients. The prevalence of this symptom was also reported as common by the ICS-"BPH" study group and was higher in men with BOO than in those without (274).

ICIQMLUTS (ICSmale-SF) is slightly longer (14 questions), but takes into account the symptom of urgency incontinence, and in fact may be divided into voiding (ICS-male-VS) and incontinence (ICS-male-IS) subscores (275). Thus, it is particularly a questionnaire for assessment of the occurrence and bothersomeness of a wide range of LUTS in man. However, to date, it has not been as widely used as the IPSS, but may be more widespread use as part of the ICIQ Modular Questionnaire.

As the concept of OAB has become widespread, a simple symptom questionnaire to quantitatively assess OAB symptoms, the OABSS, was developed and psychometrically validated. Overactive bladder symptom scores are also very useful for male patients with storage symptoms including urgency incontinence(276, 277). Other new symptom questionnaires to assess male-LUTS include UWIN and the CLSS.

Ten LUTS (increased daytime frequency, nocturia, urgency, urgency incontinence, stress incontinence, slow urinary stream, straining, a feeling of incomplete emptying, bladder pain, and urethral pain) were selected as core symptoms from 25 LUTS defined by the ICS committee, and symptom questionnaire to assess the core symptoms we developed as the CLSS (277). Symptoms were scored according to their frequency and severity. The CLSS questionnaire was confirmed to show good test-retest reliability. The CLSS was compared with IPSS in men with LUTS, and it was suggested that the CLSS is more comprehensive than IPSS for symptom assessment of men various diseases and conditions (278). The CLSS provides overall assessment of relevant symptoms without omission, and may be useful for new patients, patients with multiple diseases, and patients without a definite diagnosis, as well as before and after intervention that may cause other symptoms.

Among LUTS, urgency, nocturia, and hesitancy are most bothersome, whereas weak stream, urgency, and frequency are the most prevalent in pooled populations being evaluated for BPH(279). Postmicturition dribbling is often provoked by an obstructing disease such as BPH or urethral stricture but can also be a symptom of a urethral diverticulum. As yet there is no validated symptom questionnaire that assessed post-micturition symptoms (post-micturition dribble and post-micturition incontinence).

To determine the cause of post-prostatectomy incontinence, many studies have stressed the lack of reliability of symptoms and emphasized the important role of urodynamic testing(280, 281). Nevertheless, valuable information can be gained from a careful history with regard to incontinence, especially when related to sphincter dysfunction. The symptom of stress incontinence is highly predictive of the presence of sphincter dysfunction. Chao and Mayo found that 67 of 71 men with post-prostatectomy incontinence secondary to sphincteric dysfunction complained of the symptom of stress incontinence(282). Similarly, Ficazzola and Nitti found 95% positive predictive value and a 100 % negative predictive value for symptom of stress incontinence(283). Urgency incontinence as a predictor of bladder dysfunction doesn't seem to be as valuable, and the presence of bladder dysfunction cannot be determined accurately without urodynamic testing(282, 283).

An important aspect of the assessment of male incontinence should be a description of the type and severity of incontinence and precipitating events, Severity

may be determined by the number of episodes per day, the need for protection (e.g., pads, penile clamp, external catheter), and the impact of incontinence on activities of daily living. Bladder diaries and pad tests can quantify severity.

A bladder diary (or frequency volume chart) kept for 3 to 5 days may be useful in almost all male patients, especially in those with OAB. The time and voided volume are recorded for each micturition during several 24-hour periods. Bladder diary completion by the patient provides useful evidence about the normal urinary habits of the patient, including giving some estimate of bladder capacity and diurnal and nocturnal frequency, urgency and stress incontinence. It also helps to identify patients with nocturnal polyuria or excessive fluid intake which are common in the aging male. The data obtained from frequency-volume chart provide a strong correlation to cystometric capacities and are reasonably immune to the effect of detrusor overactivity in men with LUTS(284).

The 24 hour pad test is an excellent test to quantitate the amount of urine leakage in men. Since most patients use different size and type of pads, it is difficult to compare number of pad/day per patient. Furthermore, some patients are very disturbed by any leakage at all and change the pad very frequently, before they are saturated. The other distinction to be made is between a safety pad and true urinary incontinence. In general, the each 1g weight equals 1 ml urine loss. It is proposed to use a cut-off value of 250 g of urine to categorize minor from more troublesome or severe leakage(285). Recently, Machold et al. suggested that the technical feasibility of the 20-min pad test to evaluate post-prostatectomy incontinence was excellent. The results correlated significantly with both the self-assessment via questionnaire ($r = 0.63$; $p < 0.001$) and the 1-hour pad test (ICS; $r = 0.66$; $p < 0.001$). Moreover, it was highly reliable ($r = 0.74$; $p < 0.0005$) with excellent patient acceptance (286).

4. PHYSICAL EXAMINATION

The assessments focus on general physical examination, digital rectal examination (DRE) and neurological testing of the perineum and lower extremities.

In a general physical examination, specific attention should be placed on the evaluation of surgical scars, the presence or absence of a distended bladder and excoriation of the genitals secondary to urinary incontinence. Abdominal palpation should be performed to evaluate bladder distension, especially in elderly incontinent men, who may have overflow leakage due to obstruction. In patients suspected of urinary retention, post-void residual volume should be measured. The examination should also include external genitalia, location of the urethral meatus, retractability of the foreskin and evidence of congenital malformation. The evidence of urethral discharge after abdominal straining (a Valsalva manoeuvre) or coughing in either the supine or upright position should be evaluated so that the presence of stress incontinence can be ascertained.

A focused neurological examination is also highly recommended. In a patient suspected of neurogenic bladder, evaluation of perineal sensation and lower extremity neuromuscular function, and anal sphincter tone, which is often decreased in neurogenic patients is important (287). A focused neurogenic examination should also assess the patient's general mental status and ambulatory status.

DRE should include palpation of the prostate to assess size, symmetry and consistency of the gland and its relation to the pelvic sidewall and the rectum. Enlarged, indurated and painful prostate may imply BPH, prostate cancer and prostatitis, respectively. The locally advanced prostatic cancer can also produce OAB-like symptoms including incontinence. DRE may exclude prostatic cancer, although its specificity and sensitivity is low(288). The DRE is 53% sensitive and 85% specific for identifying underlying prostate cancer when abnormalities (i.e. induration or nodule) are present(289). Furthermore, abnormal rectal tone can raise suspicion of an occult neurogenic disorder that may be contributing a patient`s symptoms. DRE tends to underestimate the true prostatic size: if the prostate feels large by DRE, it usually also is found to be enlarged by ultrasound or other measurement technique(290, 291). Prostate volume has been associated with the risk of BPH progression (292) and response to treatment (293). It has been reported that men with BPH with idiopathic detrusor overactivity showed a significantly higher incidence (54%) of intravesical protrusion of the prostate(294). This finding suggests that intravesical protrusion may in some way increase afferent impulses from the prostate and alter the stability status of the bladder. Occasionally tumors of the anal canal can be diagnosed while performing DRE of the prostate.

4.1. Urinalysis and Urine Cytology

All patients undergoing an evaluation for LUTS due to BPH should have a urinalysis performed to evaluate for UTIs or other uropathology. The most significant findings would include evidence for pyuria, bacteriuria, and/or hematuria. Bladder cancer, carcinoma in situ of the bladder, urinary tract infections, urethral strictures, and bladder stones can cause OAB-like symptoms including incontinence in aged men. Although haematuria or pyuria is not universally present in those conditions, urinalysis is important to rule out these conditions. Urinalysis is not a single test; complete urinalysis includes physical, chemical, and microscopic examinations. Dipstick urinalysis is certainly convenient but false-positive and false negative results may occur. It is considered an inexpensive diagnostic test able to identify patients with urinary tract infection as indicated by the presence of leucocyte esterases and nitrites. A substantial proportion of older patients with chronic OAB-like symptoms have significant bacteriuria, sometimes accompanied by

pyuria. In men, recent urinary tract infections were associated with OAB without urgency incontinence (prevalence ration=2.9; 95% CI: 1.6-5.0) (295). However, infection may exist in the absence of pyuria and, in the elderly population, pyuria may develop in the absence of urinary tract infection.

Microscopic haematuria can be easily identified by dipsticking because of the presence of haemoglobin. The detection of haematuria is important because the condition is associated with a 4-5% risk of diagnosing urological disorder or malignancy within 3 years.

A systemic review and economic evaluation of diagnostic tests and algorithms used to investigate hematuria concluded that the evidence based on which to determine the ideal means of investigating hematuria was insufficient(296). However, because of the high prevalence of urinary tract infection and the increase of LUTS in the presence of urinary tract infection, various guidelines on the management of patients with LUTS suggestive of BPO, and urinary incontinence, endorse the use of urinalysis in primary care management (297, 298).

Urine cytology is also recommended in male patients with haematuria and a predominance of storage symptoms, especially with a history of smoking or other factors, to aid in the diagnosis of bladder carcinoma in situ and bladder cancer

4.2. Measurement of the Serum Creatinine

Epidemiological studies in community dwelling men have shown the absence of any association between BPO/BPE and chronic kidney disease(297, 299) suggesting that screening for renal function is not justified in male patients. Diabetes and arterial hypertension appear to be the most important causes of elevated serum creatinine in men with BPH and renal failure(297). Data from the MTOPS study showed that the risk of developing de novo renal failure in men with LUTS is low (less than 1 %) suggesting that is not necessary to monitor renal function in patients with LUTS / BPO(292). However, a study examining the association between(299) LUTS and glomerular filtration rate (GFR) in men concluded that in older men without obvious enlargement of the prostate, as LUTS became more severe, GFR fell (300).

4.3. Measurement of the Serum Prostatespecific Antigen (PSA)

In most patients, a normal DRE may be sufficient to exclude locally advanced cancer as a cause of LUTS or OAB. There is no consensus as to the measurement of prostate specific antigen (PSA) in patients with LUTS. The rationale for measuring PSA is twofold: to screen for prostate cancer [337] and to measure a parameter with prognostic value for the progression of BPH and the response to treatment [328,329]. Because prostatic cancer is one of the potential causes of LUTS or OAB in men, PSA (together with DRE) is a relatively sensitive way to exclude prostatic cancer as a diagnosis(301, 302). PSA measurement is recommended in men with LUTS and a life expectancy of over 10 years in whom the diagnosis of prostate cancer would change the management of patient's symptoms. Given the uncertainties surrounding prostate cancer detection physicians must use clinical judgment in determining which patients should or should not undergo transrectal ultrasonography and prostate biopsy in response to a particular PSA (303).

However, it is important to understand that about 25% of men with BPH have a serum PSA greater than 4 ng/ml. Because of the overlap between serum PSA values in men with BPH and those with clinically localised prostate cancer, other parameters (PSA velocity, free/total PSA ratio, complexed PSA and PSA density) will assist diagnostic specificity (304, 305). It has been suggested that a relationship between initial PSA level and subsequent prostate cancer detection with a stepwise increase in cancer detection rate (from <1% to 58%) in patients with <1.0 ng/ml, 1.1-2.5, 2.6-4.0, 4-1-10.0 and >10 ng/ml PSA value in over 26.000 patients enrolled in a screening program(306, 307). In addition, Thompson reported data on prostate cancer prevalence from the prostate cancer prevention trial (307) confirming a stepwise increase in the risk of having a prostate cancer in patients with serum PSA from 0.5 to 4.0 ng/ml but showing the limitation of the current threshold of 4.0 ng/ml. Change of PSA threshold from 4.0 to 2.0 ng/ml has been proposed but currently no consensus exists (308).

In addition, serum PSA is a reasonable predictor of prostate volume in men with LUTS and can be used in this capacity in clinical decision making(303). It has been reported that the role of IPSS score in the assessment of BOO is questionable, and that the grade of obstruction is more related to prostate volume, PVR, and Qmax(309). It has been demonstrated that moderate-to-severe LUTS in men can result in urinary retention. The incidence of retention in men with untreated LUTS in community-based trials is 6.8 per 1000 during longitudinal follow-up of 4 years(310) . If only patients with moderate-to-severe symptoms are considered, the rate of retention increases to 25 per 1000(311). In a meta-analysis of predictors of retention in pooled groups of placebo patients from clinical trials of men with LUTS undergoing active interventions (4300 patients), Roehrborn et al. found PSA and prostate volume to be strong independent predictors of urinary retention and the need for surgery in men with LUTS followed up longitudinally in clinical trials (291, 312).

Laniado et al have also tested the hypothesis that PSA level could be used to predict the presence or absence of BOO, evaluated by pressure flow studies (313). In patients with LUTS, those with a PSA more than 4 ng/ml are significantly more likely to have some degree of BOO. Conversely patients with PSA less than 2 ng/ml have a 33% risk of BOO.

Recommendations

A variety of symptom scores have been described to assess patients with Male-LUTS. The IPSS, ICIQ-MLUTS, and DAN-PPS have been the most tested and were found to reproducible, valid, and sensitive for initial assessment. (Level 2). However, the IPSS neglects of symptom of incontinence.

Urinalysis is recommended in patients with male-LUTS. There are currently insufficient evidences to recommend routine measurement of serum creatinine and post-void residual urine in male patients with incontinence

In addition to DRE, PSA measurement is recommended in selected male patients with OAB.

Future Research

1. Improve the understanding of the underlying pathophysiology and contributory clinical factors involved in the development and treatment of detrusor overactivity in the male patient, especially in differentiating the condition from female patients.

2. Development of simple, non-invasive, cost-effective methods to determine the contribution of bladder storage and bladder emptying abnormalities in male patients.

I. INTRODUCTION

The last update of the International Consultation on Incontinence report broadened the scope of this review to include all patient-reported outcomes, not just health-related quality of life. This chapter updates the previous literature reviews of Patient Reported Outcome Assessments (PROs), for lower urinary tract symptoms (LUTS) and bowel incontinence outcome measures, in addition to providing recommendations for questionnaire selection for use in clinical practice and research. In addition, this summary will review the purpose and content of the ICI questionnaire (ICIQ) modules. The expansion of this review to include all types of patient reported outcomes (PRO) is an important step in recognising the conceptual differences of various PROs each with different assessment goals. A PRO is defined as "any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else"([1][1]). PROs measure different aspects of disease and therapeutic impact such as: symptom frequency or symptom bother, health-related quality of life (HRQL), treatment satisfaction, or work productivity measures (**Figure 1**). An essential component of selecting a PRO for use is to ensure that the selected PRO is consistent with the objective of the study or clinical purpose. For example, if the goal is to assess treatment satisfaction, then a treatment satisfaction measure should be incorporated into the study design or as a clinical outcome. The matching of appropriate PRO selection with desired outcomes is critical to success when assessing PRO's and will be reviewed further in this chapter.

Ultimately, the last decade has been one of tremendous growth in the area of PROs with influences from scientific and regulatory communities. As such, the ICI will endeavour to continually update the recommendations it offers on the basis of emerging data and published evidence based on the recommendations of the prior reviews.

1. SELECTING PRO MEASURES FOR CLINICAL TRIALS AND CLINICAL PRACTICE

How does a researcher choose which instruments are most appropriate for a particular research study and/or clinical assessment? The following section provides general guidelines for use in conducting PRO assessments in clinical trials or other research investigations related to urinary or faecal incontinence.

As there are many available PROs, it is of utmost importance to select the PRO measure that is relevant and applicable to one's desired outcome. If an intervention is designed to reduce symptom bother, then a relevant PRO would be a symptom bother measure. Multiple PROs can be included in clinical practice or in a research study; however the designation of the PRO as a primary, co-primary, secondary, tertiary or exploratory endpoint must be noted. In addition, issues of staff and participant burden, time constraints, and resources should be considered in the selection of a PRO measure. Once it has been decided which outcomes are to be assessed it is important to choose a questionnaire that has been scientifically developed and validated. Principles of validation and questionnaires that have been validated are presented in this chapter.

2. SELECTING PRO MEASURES FOR RESEARCH STUDIES

2.1. Study Design

There are several protocol concerns that must be taken into account when using PRO measures in research studies, including the length of the study, the frequency of contact with the study participants, the timing of clinical assessments, the complexity of the study design, the number of participants enrolled, and participant and staff burden. The goal of the PRO assessment is to "fit" the PRO measures to the protocol without compromising either the study objective or design. For example, if the study design is complex with frequent participant contacts and multiple clinical measures, it may be necessary to keep the PRO measures at a minimum or to reduce the number of times the PRO is assessed (e.g. baseline and end of study rather than during all participant contacts) to minimise participant and staff burden. At the same time, however, PROs must be viewed as an important variable in the overall trial design and should not be devalued in the data collection process. Consequently, PRO measures cannot be altered or reduced to accommodate study design as such alterations may yield less reliable measures or may seriously diminish the integrity of the overall study design and yield useless information. Having well developed research

goals and questions regarding PROs will help to guide clinicians in the selection of measures for a study. The aim is to develop a conceptually adequate, yet practical PRO battery given the study population, the specific intervention, and the study design.

The frequency with which a PRO will need to be assessed in a research study will depend upon the nature of the condition or intervention being investigated and the expected effects (both positive and negative) of the treatment. At a minimum, as with all measurements collected in a research study, a baseline and end of study assessment should be completed. In addition, PRO assessments should be timed to match expected changes in functioning due to either the intervention, the condition or the disease itself. Timing follow-up assessments to coincide with typical patient follow-up visits, if appropriate, may also reduce the costs involved in the follow-up PRO assessments.

2.2. Study Population

It is critical to specify key population demographics that could influence the choice of instruments, the relevant dimensions of the PRO to be assessed, and the mode of administration. Thus, age, gender, educational level, language spoken, and cultural diversity should be carefully considered prior to selecting PRO measures. For example, a cohort of patients over the age of 70 may have more visual problems than middle-aged persons, making self-administered questionnaires potentially inadvisable. Ethnically diverse groups also require measures that have been validated across different cultures and/or languages.

In clinical trials, it is also important to consider how the disease or condition will progress and affect the outcomes of patients in the control group as it is to understand the effects of the study treatment. For example, in patients with incontinence assigned to a placebo-control arm of a study, one might expect a symptom to worsen and thus have an effect on daily functioning. The point is to select PRO measures that are sufficiently sensitive to detect changes in both the treatment and the control group patients. Use of the same measures for both groups will ensure an unbiased and comparable assessment.

2.3. Intervention

There are three major factors related to the intervention that are relevant to PRO assessment, and therefore require careful consideration: 1) the positive and adverse effects of treatment; 2) the time course of the effects; and 3) the possible synergism of the treatment with existing medications and conditions. It is crucial to understand how a proposed treatment can affect patient outcomes in both positive and negative ways. For example, some drug therapies may relieve LUTS but produce side effects like dry mouth or sexual dysfunction.

In addition, the time course of an intervention's effects on PROs is also critical both in terms of the selection of measures and the timing of when PRO measures are administered to study participants. For example, in a trial comparing coronary artery bypass graft (CABG) surgery to angioplasty, an assessment of PRO one week post-intervention might lead to an interpretation that the surgical arm had worse outcomes than angioplasty for PRO since the individuals in this arm of the trial would still be suffering the effects of the surgical procedure (for instance, sore muscles and surgical site discomfort) which could overwhelm any benefits associated with CABG. However, at six months post-intervention, the benefits of CABG surgery such as, relief from angina might be more profound than the benefits received from angioplasty. Thus the timing of when PROs are assessed could influence how one interprets the benefits (or negative effects) of the interventions.

Finally, it is important to have a clear understanding of the current medications the patient population is likely to be taking prior to randomisation to the study treatment, and how these medications might interact with the trial intervention, (either a pharmacological or behavioural intervention), to influence patient outcomes.

3. TYPES OF PRO MEASURES

There are two types of PRO measures: generic and condition-specific. Generic measures are designed to assess outcomes in a broad range of populations (e.g., both healthy as well as ill individuals). These instruments are generally multidimensional, and assess at least the physical, social and emotional dimensions of life. An example of this type of instrument is the Medical Outcomes Study SF-36 Health Status Profile [2][2]. A second type of measure is condition-specific (e.g., instruments designed to assess the impact of specific diseases, conditions, age groups, or ethnic groups). Condition-specific measures can be similar to generic instruments in that they assess multiple outcome dimensions, but condition-specific measures also include items more specific to the particular condition or population being studied. Examples of condition specific instruments in urology and urogynaecology include the Incontinence Impact Questionnaire [3][3], the King's Health Questionnaire [4][4], and the OAB-q [5][5].

In general, it is now common to include condition specific outcome measures in clinical trials due to their enhanced sensitivity to change and the need to minimise participant burden. Importantly, the type of instruments selected for inclusion in a research study will depend on the goals of the intervention and the specific research questions to be addressed. In practice, clinical trials that include PROs usually incorporate a combination of PRO measures most relevant to the study population and intervention, if applicable, being mindful of resource constraints and staff and participant burden.

3.1. Quality-adjusted Life Year (QALY)

Increasingly HRQL outcome measures are being used in the development of quality-adjusted life year (QALY) measures. A QALY is a universal health outcome measure applicable to all individuals and all diseases, which combines gains or losses in both life quantity (mortality) and life quality (morbidity) and enables comparisons across diseases and programs. QALYs are widely used for cost-utility analysis [6][6]. In the past decades, economic evaluation has been increasingly important for the decision maker to decide which treatment or intervention is more cost effective, in order to allocate limited healthcare resources soundly. Economic evaluation aims to compare interventions in terms of their costs and benefits, including their patient outcome impact. Health benefits can be quantified as QALYs which have become a standard measure and are now recommended in most of health economics guidelines as the method of choice [7][7]. The economic chapter contains additional information regarding QALYs, as do the following references: [8[8], 9[9]].

4. LITERATURE SEARCH STRATEGY

For the current version of this chapter the previous literature search was updated. A number of databases were accessed, electronically, with specific search criteria, such as validation work from the period January 2006 through August, 2016. Age and gender limits were not specified. Databases used included Pub-Med/MEDLINE, and websites accessed included oab.com, proqolid.com, ncbi.nlm. nih.gov and mapi-institute.com.

The following key words were used separately and/or in combination: “urinary incontinence”, “urinary symptoms”, “urgency”, “overactive bladder”, “stress incontinence,” “incontinence,” “questionnaire,” “epidemiology,” “prostate,” “prolapse,” “faecal,” “bowel,” “anal,” “quality of life,” “sexual,” “geriatric,” “paediatric,” “satisfaction,” “symptom bother,” “goal attainment”, “screener,” and “generic.” Questionnaires evaluated in this chapter were updated with any new information if new validation work was found. New questionnaires not in the previously updated resource tool were added to appropriate sections if they were validated and relevant with regard to the search terms specified above. Grades were evaluated for correctness, based on previous and new validation work, and modified if and when necessary to demonstrate any changes with respect to instrument validation.

II. THE MEASUREMENT OF PATIENT- REPORTED OUTCOMES (PROS) OF INCONTINENCE, OTHER LOWER URINARY TRACT SYMPTOMS, AND BOWEL PROBLEMS

The symptom impact of urinary incontinence and other lower urinary tract symptoms (LUTS) as well as bowel problems and the treatment benefit of any modality in this field can be assessed in several ways. While taking a detailed clinical history is the most traditional method, patient-completed tools have gained more importance and proved their reliability in the symptom and outcome assessment such as voiding diaries and validated questionnaires.

Patient self-completed questionnaires or patient reported outcomes (PROs) build the basis of the patient-centered healthcare system and represent the most important clinical review of symptom impact and treatment benefit from a patient perspective [10[10], 11[11]]. PROs or the synonymously used new term patient reported outcome measures' (PROMs) provide a method for the standardised collection of data, or an objective assessment of subjective phenomena, from patients relating to incontinence, other LUTS, and bowel problems. Clinicians' assessments of patients' outcomes have often been shown to underestimate the degree of bother perceived by patients, and to focus on issues of lesser importance to patients [12[12]].

1. BASIC DEFINITIONS AND TERMINOLOGY

It is important to understand the advances in terminology of outcome measures that are categorized in 3 groups: clinical, humanistic and economical [13[13]]. The humanistic outcome measures may focus on role performance and emotional status, whereas economical outcomes on expenses and saving. The clinical outcomes measure cure or survival and they can be further sub-classified as clinician reported, caregiver reported, physiological (e.g. urodynamic improvement) or patient reported. If the patient is observed for the outcomes by a clinician, researcher or caregiver then the outcomes are termed observer reported outcomes (OROs) [14[14]]. Proxy reported outcome is a measurement based on the report by someone other than the patient reporting as if he or she is the patient and are different from a PRO or ORO [15[15]].

According to US-FDA, a PRO is any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else [15]. The European Medicines Agency’s (EMA’s) Reflection Paper on the Regulatory Guidance for the Use of Health Related Quality Of Life (HRQL) Measures in the Evaluation of Medicinal Products defines a PRO similarly as “any outcome directly evaluated by the patient and

based on patient's perception of a disease and its treatment[s)" [16[16]].

Although PROs are commonly used as an umbrella term to also include health related quality of life (HRQOL) some authors consider PROs to differ from HRQOL measurements for the following reasons. Firstly, HRQOL is multidimensional whereas a symptom is a one-dimensional property. Secondly, PROs are directly related to disease and treatment effect compared to HRQOL where there is an indirect relation to them. Thirdly, in the case of PRO concepts symptoms are often considered for behavioral objective measures but seldom for HRQOL. Thus, PRO concepts are simple whereas the concepts are complex in HRQOL [11].

The US-FDA has described the basic definitions related to PRO that are shown in **Table 1** [15]. PRO instruments can also be classified as generic, disease specific, dimension specific, region/site specific, individualized, utility measures, and summary items having their own advantages and disadvantages [11,17[17]].

Since the last ICI, electronic PROs (ePRO) have gained more importance since clinical trial managers and regulators prefer electronic collection of PRO data directly from the patient for PRO-based end points [18[18]]. It has been suggested that ePRO leads to improved data quality, more complete data, less subject and administrative burden, as well as better implementation of skip patterns [19[19],20[20]]. Furthermore, it has been shown that electronic data collection yields more reliable and accurate data, allowing a stronger test of the study objectives and a better picture of the patient's experience [20].

2. PRO QUESTIONNAIRE DEVELOPMENT AND VALIDATION

PRO questionnaires can be used to record the presence and severity of urinary and bowel symptoms, as well as the impact of symptoms on everyday activities and health-related quality of life (HRQL) and satisfaction with treatment, etc. To ensure that the results obtained with PROs are clinically useful, data must be gathered using valid and reliable instruments. Prasanna et al have reported the characteristics of an ideal PRO instrument that are shown in **Table 2** [11]. Questionnaire design and development is not a simple process. Developing such instruments requires a multistep, structured process that incorporates cognitive psychology, psychometric theory, and patient and clinician input. The process begins by determining the intent and purpose of the PRO and culminates in studies that demonstrate the measure's validity, reliability, and responsiveness. The specific steps required for developing a PRO questionnaire are outlined in the following section and are shown in **Figure 2** and each step is further detailed in **Table 3** [15].

The development of a PRO is a rigorous, scientific process to provide confidence that the PRO is measuring what it is intended to measure, that it does this reliably, and is appropriate for use in the patient or population group under investigation. The final instrument must have demonstrated validity and reliability in the intended target population. PROs need to be

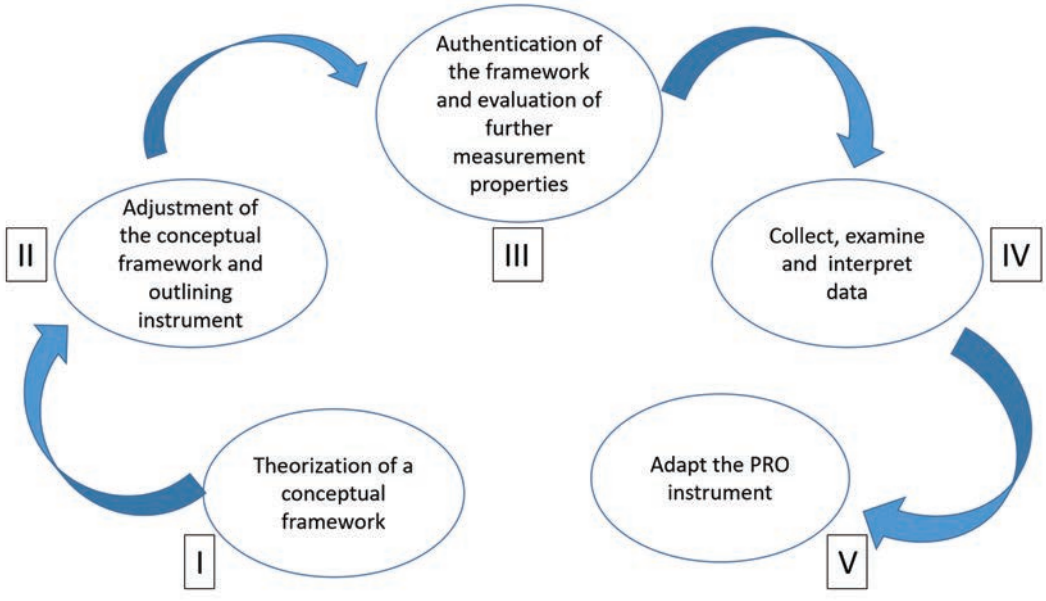

Figure 2: Five-step development of PRO instrument (adapted from ref 6)

developed with patient and clinician input and have the psychometric, or measurement, properties of the PRO evaluated to determine that it is a valid outcome measure. To be a useful measurement tool, a PRO instrument must also be easy to administer, reliable, and valid. Only PROs that have undergone this process and have published validation data are discussed in this chapter.

2.1. Determining Questionnaire Intent and Purpose

The first task in developing a PRO measure is to determine why the instrument is needed. Given the current number of disease-specific questionnaires available in the field of incontinence and related pelvic disorders, a new PRO measure must fill a need that has not already been met by an existing instrument. Once the need for the measure is recognized, its purpose and clinical usefulness need to be considered because the purpose dictates the validation design process. For example, a symptom and a treatment satisfaction measure would be developed and validated differently because the outcome is different.

The development stage would focus on the outcome of interest (e.g., symptoms patients experience and the significance of each symptom, or what issues patients consider when determining how satisfied they are with treatment) with the items derived from the patient perspective and relating to the outcome of interest. Validation efforts would include designing a study focused on the outcome of interest with the appropriate patient inclusion/exclusion criteria to enhance generalizability while maintaining internal consistency and providing opportunities to test—at a minimum—reliability and validity.

2.2. Developing the Items

Designing a clinically useful PRO measure involves more than just developing a series of questions. In addition to clinician input and literature review, questionnaire items must be generated from a patient perspective and include patient views. This is obtained through focus groups or one-on-one interviews to provide qualitative data on issues pertinent to patients and to identify the words patients use to describe their symptoms or disease impact. Focus groups and one-on-one interviews should be carefully planned to address the goals of the questionnaire being developed. For example, if a measure is intended to assess symptom bother, interview questions should pertain to the patient's symptom experience. Importantly, rather than using clinical terminology which patients may not comprehend, the words used during the focus groups or interviews should be common to patients. The results of the qualitative patient interviews lead to item generation. After items are generated, the newly drafted questionnaire should be reviewed by other patients and experts to ensure its readability and content validity.

An alternative approach to questionnaire development is to adapt an existing measure to meet the needs of the desired questionnaire. Patients need to be involved in the questionnaire adaptation to ensure that the revised measure is pertinent to the population of interest. The adapted questionnaire must be validated on its own in the target population as the validity of the original questionnaire does not apply to an adapted measure.

For newly developed and adapted questionnaires, think out loud interviews or cognitive interviews should be used to ascertain the correctness and validity of the revised questionnaire. In a think out loud interview, patients are asked to review a question and describe what they are thinking as they cognitively process the question; the patients think out loud about what the question means to them and how they think through their response to the question. For a cognitive interview approach, patients review and respond to the questionnaire items, and then they are interviewed about what each item meant to them as they completed the questionnaire. Both approaches provide information about what patients consider when responding to each question.

2.3. Determining the Mode of Administration of a Questionnaire

When generating the PRO items, the mode of administration must be considered. Will the measure be completed by the patient (i.e., self-administered) or administered by an interviewer (i.e., interviewer-administered)? How the questionnaire will be completed needs to be determined before the validation stage because mode of administration can affect patient responses. For highly personal or intimate questions, a self-administered questionnaire is recommended to avoid response bias. Questionnaires that are self-administered are preferable to interviewer-administered questionnaires because the data collection burden is reduced and patients are more likely to provide unbiased information on self-administered questionnaires. Importantly, if a questionnaire has been validated for a particular mode of administration (self-administered pen and paper), this does not make the questionnaire valid for all modes of administration (e.g. electronic administration via web or hand held device). Should the mode of administration change from the original validation, processes must be undertaken to ensure no change in meaning or content have occurred with the format change. Guidelines for this type of adaptation are clearly outlined by Coons et al (2009) [21[21]].

2.4. Questionnaires' Psychometric Properties

All PRO measures must demonstrate reliability, validity, and responsiveness, which are described in detail below. This can be accomplished in several ways:

Perform a stand-alone cross-sectional study to validate the questionnaire in the patient population for which it was designed;

Administer the untested questionnaire in a clinical study and use the baseline data to perform psychometric validation (the end-of-study data can also be used to evaluate responsiveness); or

Perform a stand-alone longitudinal study with an intervention to determine the instrument's psychometric performance and responsiveness in a non-clinical trial setting.

The following psychometric properties must be tested for and demonstrated in a validated questionnaire.

Reliability refers to the ability of a measure to produce similar results when assessments are repeated (i.e., is the measure reproducible?). Reliability is critical to ensure that change detected by the measure is due to the treatment or intervention and not due to measurement error [22[22]]. One measure of reliability is the questionnaire's internal consistency, which indicates how well individual items within the same domain [or subscale) correlate. Cronbach's alpha coefficient is used to assess internal consistency reliability, with higher alphas indicating greater correlation. Typically, Cronbach's alpha should be greater than 0.70 to indicate good internal consistency reliability [22, 23[23]]. If the item-to-total alpha is less than 0.20, the question should be removed or rewritten.

Test-retest reliability, or **reproducibility,** indicates how well results can be reproduced with repeated testing. To assess test-retest reliability, the same patient completes the questionnaire more than once, at baseline and again after a period of time during which the impact of symptoms is unlikely to change (e.g., a few days or weeks) [22, 23]. The Spearman's correlation coefficient and intraclass correlation coefficient are used to demonstrate reproducibility. For group data, a Spearman's correlation coefficient or an intraclass correlation coefficient of at least 0.70 demonstrate good test-retest reliability [22, 23].

Inter-rater reliability indicates how well scores correlate when a measure is administered by different interviewers or when multiple observers rate the same phenomenon [22]. Demonstration of inter-rater reliability is not necessary for self-administered questionnaires but is necessary for instruments based on observer ratings or using multiple interviewers. A correlation of 0.80 or higher between raters indicates good inter-rater reliability [22].

Validity refers to the ability of an instrument to measure what it was intended to measure [22, 23]. A measure should be validated for each specific condition or outcome for which it will be used. For example a measure designed to assess stress incontinence would not be valid for OAB unless it were specifically validated in patients with OAB symptoms.

Content validity, convergent validity, discriminant validity and **criterion validity** typically are required to validate a questionnaire [22, 23].

Content validity is a qualitative assessment of whether the questionnaire captures the range of the content it is intended to measure [22, 23]. For example, does a measure of symptom severity capture all the symptoms that patients with a particular condition have, and if so, is the measure capturing the items in a manner meaningful to patients in language patients can understand? To obtain content validity, patients review the measure and provide feedback as to whether the questions are clear, unambiguous, and comprehensive.

Convergent validity is a quantitative assessment of whether the questionnaire measures the theoretical construct it was intended to measure [22, 23]. Convergent validity indicates whether a questionnaire has stronger relationships with similar concepts or variables. Stronger relationships should be seen with the most closely related constructs and weaker relationships seen with less-related constructs [22, 23].

Discriminant validity indicates whether the questionnaire can differentiate between known patient groups (e.g., those with mild, moderate, or severe disease) [22, 23]. Generally, measures that are highly discriminative are also highly responsive.

Criterion validity reflects the correlation between the new questionnaire and an accepted reference, or gold standard [22, 24[24]]. One difficulty in establishing criterion validity is that a gold-standard measure might not be available [22, 24]. When criterion validity can be established with an existing measure, the correlation should be 0.40 to 0.70; correlations approaching 1.0 indicate that the new questionnaire may be too similar to the gold-standard measure and therefore redundant [22, 24].

Responsiveness indicates whether the measure can detect change (for better or worse) in a patient's condition [25[25]]. An aspect of responsiveness is determining not only whether the measure detects change but whether the change is meaningful to the patient. This can be done by determining the minimal important difference (MID) of the measure. The MID is the smallest change in a PRO questionnaire score that would be considered meaningful or important to a patient [26[26]]. A treatment that is statistically significantly better than another may not necessarily have made a meaningful difference to the patient; the MID indicates whether the treatment made such a difference from a patient perspective.

Unfortunately, there is no scientific test for MID as it is an iterative process that involves two methodologies to determine the MID of a questionnaire: an anchor-based approach and a distribution-based approach [27[27], 28[28]]. With the anchor-based approach, the MID is determined by comparing the measure to other measures (or "anchors") that have clinical relevance [27]. With the distribution-based approach, the

MID can be determined by the statistical distributions of the data [27], using analyses such as effect size, one-half standard deviation, and standard error of measurement [27, 28, 29[29]].

Another methodology to evaluate treatment benefit is to examine the cumulative distribution function (CDF) of responses between treatment groups. The CDF provides plots to examine the treatment effect and mean improvements by treatment group to see if the mean improvement varies by patient subsets [15, 29].

2.5. Linguistic and Cultural Validation

Increasingly, PRO questionnaires are required to be used in a number of different populations and settings, however, questionnaires and their psychometric properties are not necessarily transferable [30[30], 31[31]]. A measure that is valid and reliable for a particular language and culture may not prove to be so after translation. Linguistic and cultural adaptation of a questionnaire can occur during the development phase before validation, or it can be done after the questionnaire is validated in the language in which it was initially developed, with the latter being the more common approach. Ensuring the linguistic and cultural validity of a questionnaire is especially important for measures used in multinational clinical trials [30, 31].

The principal steps in adapting a measure for different languages and cultures are as follows:

two forward translations of the original instrument into the new language;

quality-control procedures that may include a backward translation (translating the instrument back into the original language) [31];

adjudication of all translated versions;

discussion by an expert panel to ensure clarity of the translated questionnaire; and

testing the translated instrument in monolingual or bilingual patients to ensure that it measures the same concepts as the original instrument [31, 32[32]].

However, if a backward translation of the measure does not produce a semantically equivalent instrument, then the instrument may need to be developed in the target language, rather than just translated [31].

After cultural and linguistic validation, PROs should also be psychometrically validated within the target language. Thus, reliability, validity, and responsiveness need to be assessed with each language translation to confirm the same measurement properties are present in the translated language(s) to ensure psychometric equivalence. If psychometric equivalence is not present (e.g., not achieving similar or better results in new language translation), the cultural and linguistic translations need to be reevaluated and perhaps a new instrument may need to be developed.

The ICIQ questionnaires and many of the other questionnaires discussed in this chapter have multiple linguistically validated versions making them useful for International implementation. It is also important to note that the step after linguistic validation, demonstrating psychometric equivalence, should also be demonstrated to ensure that the PRO performs equivalently in different languages and cultures (e.g., Coyne et al. 2008 [33[33]]).

2.6. Regulatory Oversight

As clinicians and scientists have begun to appreciate and accept PROs as appropriate outcome measures, regulatory authorities have issued guidance documents on current best practices in the development and implementation of PRO in clinical trial settings [15, 34[34], 35[35]]. For PROs to be acceptable outcome measures for regulatory authorities, documentation of measurement properties must be present as well as evidence of inclusion of the patient perspective and understanding of the PRO and a cohesive conceptual framework that stipulates how the PRO is related to the intervention. While PROs within this document may have a "recommended" status, they may not meet all of the required regulatory guidelines and may require additional validation work either from a qualitative or quantitative perspective. It is strongly suggested that regulatory authorities be contacted early in the process of selecting a PRO for clinical trials to ensure regulatory acceptance of the PRO.

2.7. Questionnaire Development - Conclusion

PROs are the most suitable method for assessing the patient's perspective of their lower urinary tract, vaginal and bowel symptoms [27[36]]. Questionnaires may be long and detailed for use in research, but need to be short and easy to use to be relevant for clinical practice. In addition to being valid and reliable, they need to be easy to complete, and, if they are being used to measure outcome, sensitive to change. Developing a new questionnaire and testing it thoroughly takes a great deal of time and is only necessary if there is not an existing instrument available.

There are many questionnaires currently available for use and these have been reviewed and described with recommendations from the Committee for their use in the last four ICI reports.

The major purpose of the ICI has been to provide a definitive international review and consultative opinion regarding the recommended measures to assess patient reported outcomes within the area of urinary incontinence and LUTS. To this end since the First Consultation, the ICI has worked to develop a modular format for the various patient reported outcomes allowing clinicians and researchers to select internationally recommended questionnaires for the assessment of their patients in both clinical practice and clinical trials. In this sixth ICI review, the ICIQ modular

questionnaires (supported by the International Consultation) are presented in detail and their use evaluated. Whilst some of the modular questionnaires are still currently under full evaluation their content and format are presented within this chapter.

III. RECOMMENDED PRO QUESTIONNAIRES

GRADES OF RECOMMENDATION FOR QUESTIONNAIRES 2016

As with previous Consultations, the Committee continues to use three grades of recommendation. However, we have added a + sign to indicate when published content validity is available for an instrument:

Questionnaires were 'highly recommended' and given a **Grade A** if the Committee found "Published data indicating that the questionnaire is valid, reliable and responsive to change following standard psychometric testing. Evidence must be published on all three aspects and questionnaires must be relevant for use with persons with incontinence. **Grade A + indicates there is additional evidence of *published* content validity."**

Questionnaires were "recommended" and given a **Grade B** if the Committee found "Published data indicating that the questionnaire is valid and reliable following standard psychometric testing. Evidence must be published on two of the three main aspects (usually validity and reliability). **Grade B + indicates there is additional evidence of *published* content validity."**

Questionnaires were considered to have "potential" and given **Grade C** if the Committee found "Published data (including abstracts) indicating that the questionnaire is valid or reliable or responsive to change following standard psychometric testing. **Grade C + indicates there is additional evidence of *published* content validity."**

The Committee decided that evidence published in abstracts or posters could be used to indicate a developing questionnaire's potential, but was not sufficiently peer-reviewed to provide the basis for a stronger recommendation.

As decided in the Fourth Consultation the recommendation will be to preferably utilize questionnaires from the ICIQ modules described in detail below. Many, but not all, of these questionnaires are Grade A or A+ questionnaires by previously stipulated criteria. Within the description of the ICIQ modules below the grade assigned to each module is indicated.

Should none of the modular questionnaires be deemed appropriate for specific research or clinical purposes, ICI's recommendation is to use a Grade A+ or A questionnaire as previously recommended. When no suitable instrument exists a Grade B or C questionnaire, performing additional validation as indicated prior to use if feasible, should be used.

For UI and UI/LUTS, the Committee examined the quality of the psychometric evidence. Only where published data were scientifically sound was the label 'with rigor' allowed. Where the Committee had concerns about the quality of evidence, this is noted in the descriptions of the questionnaires below. The Committee considered that the number of high quality questionnaires means that there are now sufficient questionnaires for most purposes and it is not necessary to encourage the development of new questionnaires, except for particular patient groups (see below).

Table 1: Important definitions of PRO according to US-FDA Industry Guidance (Ref 15)

PRO instrument	(i.e., a questionnaire plus the information and documentation that support its use) is a means to capture PRO data used to measure treatment benefit or risk in medical product clinical trials.
PRO concept	It is nothing but the thing or event being measured. It can be called as the specific goal of the instrument. e.g. symptom or group of symptoms
PRO domain	A subconcept represented by a score of an instrument that measures a larger concept comprised of multiple domains. e.g. depression
PRO item	An individual question, statement, or task (and its standardized response options) that is evaluated by the patient to address a particular concept. e.g. Are you feeling depressed?
Conceptual framework	The conceptual framework explicitly defines the concepts measured by the instrument in a diagram that presents a description of the relationships between items, domain (sub-concepts) and concepts measured and the scores produced by a PRO instrument.
Endpoint	The measurement that will be statistically compared among treatment groups to assess the effect of treatment and that corresponds with the clinical trial's objectives, design, and data analysis.
End point model	A diagram of the hierarchy of relationships among all endpoints, both PRO and non-PRO, that corresponds to the clinical trial's objectives, design, and data analysis plan.
Conceptual equivalence	It is the equivalence in relevance and meaning of the concepts being measured in different languages and /or cultures.
Health Related Quality of Life	In simple words HRQOL can be defined as personal health status of the individual. Actually, it is a multidomain concept which represents the patient's general perception of the effect of illness and treatment on various aspects of life such as physical, psychological, and social. Some other aspects also can be predicted to affect HRQOL like- economical, disease symptoms, adverse drug reactions, patient-education, disease-treatment given to the patient.

Table 2: Ideal properties of PRO instrument (adapted from ref 20)

To be specific to the concept being measured.
To be based on *end-point model*.
To have conceptual equivalence.
To be based on the conceptual framework.
To contain optimum number of items.
To have easy and specific measurement properties i.e. use of the scales which is easiest for the intended population to understand.
To have proper evidences for the conceptual framework.
To maintain the confidentiality of the patient.
To be reproducible.

Table 3: A detailed description of PRO development phases (Adapted from ICI 2013 and ref 6)

Theorization of a conceptual framework	Outline hypothesized concepts and potential claims Determine intended population Determine intended application/characteristics (type of scores, mode and frequency of ad ministration) Perform literature expert review Develop hypothesized conceptual framework Place PROs within preliminary endpoint model Document preliminary instrument development
Adjustment of the conceptual framework and outlining instrument	Obtain patient input Generate new Items Select recall period, response options and format Select mode/method of administration/data collection Conduct patient cognitive interviewing Pilot test draft instrument Document content validity
Authentication of the framework and evaluation of further measurement properties	Confirm conceptual framework with scoring rule Assess score reliability, construct validity, and ability to detect change Finalize instrument content, formats, scoring, procedures and training materials Document measurement development
Collect, examine and interpret data	Prepare protocol and statistical analysis plan {final endpoint model and responder model) Collect and analyze data Evaluate treatment response using cumulative distribution and responder definition Document interpretation of treatment benefit in relation to claim
Adapt the PRO instrument	Change wording of items, populations, response options, recall period, or mode/method of administration/data collection Translate and culturally adopt to other languages Evaluate modifications as appropriate Document all changes

IV. INTERNATIONAL CONSULTATION ON INCONTINENCE MODULAR QUESTIONNAIRE (ICIQ): WHAT IS THE ICIQ?

The ICIQ modular questionnaire was developed to meet the need for a universally applicable standard guide for the selection of questionnaires for use in clinical practice and clinical research for lower pelvic dysfunction [37[37], 38[38]].It was recognised that there were many good validated questionnaires each developed for a specific purpose and each subtly different. Although developers of the questionnaires were familiar with their content and use, the increasing number of questionnaires made appropriate selection difficult and limited the ability to compare similar clinical and research data due to different data collection methods.

The decision to develop standard questionnaire modules was taken by the Committee after the first ICI meeting in 1998, and resulted in the development of the ICIQ core questionnaires discussed in this section.

An international advisory board was established to continue the development of the modular ICI questionnaire outside the limits imposed by triennial convening of the ICI Committee. The advisory board consisted of clinicians and researchers with experience in the design and use of questionnaires representing the major societies involved in the assessment and research of lower genital tract, lower urinary tract and bowel function. The ICIQ modular questionnaire was then established. Researchers who have developed questionnaires that they would like to be reviewed by the advisory board for inclusion should send the questionnaires and relevant publications to www.iciq.net. The project is a series of living documents that will be continually updated.

1. AIMS AND OBJECTIVES

The ICIQ's objective is to provide international consensus on the use of patient completed questionnaires for the assessment of lower pelvic symptoms and their impact on patient's lives. Three aims underpin the ICIQ in order to achieve clarity over questionnaire use:

To recommend high quality self-completion questionnaires according to evidence of validation as stipulated by the five prior ICI Committees;

To promote wider use of questionnaires to standardise assessment of lower urinary tract and pelvic dysfunction and its impact on patients' lives, in order to;

Facilitate communication in different patient settings and different patient groups both in clinical practice and wider clinical research.

The ICIQ recognised that many high quality published questionnaires already existed and, with permission from the authors, those instruments were adopted into the modular project. It was not possible to adopt all available questionnaires and where more than one option existed, the most appropriate questionnaire for the purpose was included. Where high quality questionnaires were not available, the need to develop a new questionnaire was acknowledged. Questionnaires are developed according to rigorous methodology which complies with industry-standard guidance for PRO development [1]. Collaborative efforts to develop new questionnaires are welcome and encouraged.

The ICIQ's international nature requires that linguistically validated translations are available. More than 50 language versions of various modules have been validated to date and conducted according to established protocol.[39][39]

Sixteen ICIQ modules/questionnaires are currently available for use, with further modules in development (discussed in detail below). Clinicians or researchers are able to select module(s) to meet the particular requirements of their study or clinical practice. In order to simplify this selection process, modules have been categorised as shown in **Figure 3**. It must be stressed that although multiple questionnaires can and probably should be used they must be used in the format in which they were originally designed and the questionnaires cannot be merged together as this may affect their measurement capability.

In recent years, increasing advances have been made in the area of electronic documentation, particularly with regard to patient care. It is recognised that questionnaires requiring written completion by hand may lack versatility and therefore prevent uptake of the ICIQ, hampering attempts to promote standardisation of evaluation. Evaluations of electronic ICIQ modules have been completed, indicating equivalence of their measurement properties and acceptability to the target audiences.[40][40] Cognitive interviewing was conducted with participants representative of potential respondents, namely men and women with lower urinary tract symptoms of varied cause and of varying age. Further participants completed electronic and paper versions of the questionnaires, in a randomised order, to provide comparison data and the opportunity to compare completion over the telephone was also included. Electronic versions demonstrated excellent equivalence with their paper counterparts, supporting use of these formats as long as they are prepared in the specific ICIQ format. Telephone completion was found to produce slightly poorer correlations although acceptable equivalence was still observed. This is as expected as these questionnaires are intended for self-completion but this

Figure 3: The ICIQ Modular Structure

CONDITION	RECOMMENDED MODULES	OPTIONAL MODULES	RECOMMENDED ADD-ON MODULES		
	A) Core modules		**QoL**	**Sexual Matters**	**Post-Treatment**
Urinary Symptoms	Males: ICIQ-MLUTS Females: ICIQ-FLUTS	Males: ICIQ-MLUTS LF Females: ICIQ-FLUTS LF	ICIQ-LUTSqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	ICIQ-S* (satisfaction)
	ICIQ-Bladder diary				
Vaginal Symptoms	ICIQ-VS		ICIQ-VSqol*		
Bowel Symptoms	ICIQ-B	ICIQ-IBD			
Urinary Incontinence	ICIQ-UI SF	ICIQ-UI LF*	ICIQ-LUTSqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
CONDITION	**B) Specific Patient Groups**		**QoL**	**Sexual Matters**

OverActive Bladder	ICIQ-OAB		ICIQ-OABqol	Males: ICIQ-MLUTSsex Females: ICIQ-FLUTSsex	
Underactive Bladder	ICIQ-UAB/UAB PRO*				
Neurogenic	ICIQ-Neuro Bowel		ICIQ-Neuro bowel*		
Long term catheter	ICIQ-LTCqol				
Children	ICIQ-CLUTS*		ICIQ-CLUTSqol*		
Absorbent pads			ICIQ-Padprom*		
Cognitively impaired elderly	ICIQ-Qoldem*				
Inflammatory bowel disease incontinence	ICIQ-IBD				

**In development*

study has provided reassurance that their use over the telephone is acceptable if self-completion is not practicable.

In this chapter, questionnaires forming part of the ICIQ modular format are referred to as those preferred for usage. Although many of the modules are Grade A or A+ questionnaires, others are still under various phases of development and are graded appropriately. Questionnaires that are in early stages of development and have yet to reach Grade C are described as “in development”. Where an ICIQ module is not available it is recommended that a Grade A+, A,B or C questionnaire is used.

2. ICIQ MODULES

2.1. Core Modules

Questionnaires to assess the core symptoms and impact on health related quality of life (HRQL) of lower pelvic dysfunction are contained in this section, in addition to impact on sexual matters. Core modules (**Table 4**) provide evaluation of:

- Lower urinary tract symptoms
- Urinary incontinence
- Vaginal symptoms
- Bowel symptoms

Each symptom module is intended for the comprehensive yet succinct measurement of symptoms and associated 'bother'. The bother item attached to symptom items, where applicable, enables the individual to indicate areas that cause the greatest negative impact on HRQL as perceived by them. This can be a more sensitive indicator of treatment goals than frequency of symptoms alone. The HRQL questionnaires cover specific issues that are a consequence of symptoms, such as life limitations and emotional impact. Sexual matters modules specifically evaluate the impact of lower urinary tract symptoms on this aspect from the male and female perspective.

A further core module has been added that moves away from the retrospective questionnaire format in the form of a bladder diary. This is a fully validated prospective tool for the measurement of bladder events as they occur.

2.2. Specific Patient Group Modules

Questionnaires to assess specific conditions or symptom complexes such as nocturia, overactive bladder and underactive bladder, in addition to management strategies such as long term catheter and pad usage are contained in this section along with HRQL modules for these specific symptom complexes where available. This category also includes specific patient groups, for example, children. These instruments contain only question items characteristic of the symptom complex or have been developed specifically for use in a diverse group, which defines their context of use making the items/ questionnaire only utilisable in that population.

- Nocturia
- Overactive bladder
- Underactive bladder
- Neurogenic
- Inflammatory bowel disease
- Lower urinary tract symptoms in children
- Individuals using long term catheters
- Individuals using absorbent pads

2.3. Optional Modules

This category lies within the core symptoms and includes lengthier questionnaires for more in- depth evaluation of lower pelvic dysfunction. Whilst these questionnaires are suitable for use in clinical practice, they have not been shortened for clinical efficiency and are therefore more widely used in research studies where exploration of broader associated symptoms may be desired.

- Lower urinary tract symptoms
- Urinary incontinence

2.4. Post-treatment Module

The ICIQ module for post-treatment satisfaction is in the early stages of development. Assessment of a patient's satisfaction with treatment (behavioural, surgical or medication) provides information on treatment impact on their condition and life and includes their perception of effectiveness, tolerability and convenience. It is not yet clear if satisfaction following treatment can be characterised by a set of common question items that are applicable to all lower pelvic health conditions. As with HRQL, there are generic and disease specific questionnaires that assess satisfaction. Ongoing studies will provide further evidence on which to make suggestions regarding post treatment evaluation but it is likely that this will encompass both generic and condition specific measures. Ultimately, the development of post treatment modules will also rely on advice from regulatory authorities (e.g. FDA, EMA) to ensure that measures capture a recognised multidimensionality of satisfaction.

3. GUIDANCE FOR USE OF THE ICIQ

The ICIQ recommends the use of a symptom and HRQL module that match the intended purpose of a study in order to provide a comprehensive evaluation of these two perspectives. The extent of burden placed on the respondent and the study or clinical outcomes must be considered however and ultimately guide questionnaire selection. The characteristics of each module are summarised below, although more extensive information can be found on the project website, www.iciq.net. Modules currently under development are summarised in **Table 5**.

Table 4. ICIQ Module Description

Name	Scope of assessment	Domains	Items	Grade
ICIQ-MLUTS [41][41] (ICS*male*SF)	Male lower urinary tract symptoms and associated bother.	Voiding Incontinence Individual items evaluating frequency and nocturia	13	A
ICIQ-FLUTS [42][42] (BFLUTS SF)	Female lower urinary tract symptoms and associated bother.	Filling Voiding Incontinence	12	A
ICIQ-Bladder [43[43], 44[44]] Diary	Prospective bladder events	Voided volumes Leaks Bladder sensations Fluid input Pad use	24 hour monitoring	A+
ICIQ-VS [45][45]	Vaginal symptoms including prolapsed and associated bother.	Vaginal symptoms Sexual matters Quality of life	14	A
ICIQ-B [46[46], 47[47]]	Bowel symptoms including anal incontinence and associated bother	Bowel pattern Bowel control Quality of life	21	A+
ICIQ-UI Short Form [48[48]]	Urinary incontinence.	Urinary incontinence frequency, overall interference Perceived cause of incontinence	4	A
ICIQ-LUTSqol[4, 48] (King'sHealth Questionnaire))	HRQL issues associated with urinary symptoms and associated bother.	Life restrictions Emotional aspects Preventive measures	22	A+
ICIQ-MLUTSsex[49[49]] (ICS*male*)	Male sexual matters associated with urinary symptoms and associated bother.	Erection and ejaculation issues Overall interference	4	A
ICIQ-FLUTSsex[50[50]] (BFLUTS)	Female sexual matters associated with urinary symptoms and related bother.	Pain and leakage with sexual intercourse Overall interference	4	A
ICIQ-FLUTS Long Form (BFLUTS*)*	Detailed assessment of female lower urinary tract symptoms and associated bother.	Varied lower urinary tract symptoms	18	A
ICIQ-MLUTS Long Form (ICS*male)*	Detailed assessment of male lower urinary tract symptoms and associated bother.	Varied lower urinary tract symptoms	23	A
ICIQ-N	Comprehensive assessment of symptoms of nocturia and associated bother.	Frequency Nocturia.	2	A
ICIQ-OAB	Comprehensive assessment of symptoms of overactive bladder and associated bother.	Frequency Nocturia Urgency Urgency incontinence	4	A

Table 4. ICIQ Module Description (continued)

Name	Scope of assessment	Domains	Items	Grade
ICIQ-OABqol (OAB-q) [5]	Detailed assessment of health- related quality of life issues associated with overactive bladder.	Coping Concern/Worry Sleep Social Interaction	25	A
ICIQ-Nqol (NQOL)[51[51],52[52]]	Detailed assessment of HRQL issues associated with nocturia.	Issues associated with sleep disturbance Life restrictions Preventive measures	13	A+
ICIQ-LTCqol [53][53]	Detailed assessment fo HRQL associated with long term catheter use	Catheter function and concern Lifestyle impact	*19*	*B*

Table 5. ICIQ Description of modules in Development.

Name	Purpose	Current status
ICIQ-CLUTS [5454]	Assessment of urinary symptoms in children.	Validity testing published awaiting reliability and responsiveness evaluation.
ICIQ-Padprom	Assessment of use and HRQL associated with the use of absorbent pads	Validity and reliability established. Requires responsiveness evaluation.
ICIQ-UAB	Assessment of underactive bladder symptoms and their impact on HRQL.	Extensive qualitative development completed. Preliminary quantitative development undertaken. Requires responsiveness evaluation.
ICIQ-Neurogenic	Two modules in development: Assessment of urinary symptoms and impact on HRQL associated with specific management devices and related bother. Assessment of bowel symptoms and impact on HRQL associated with neurogenic disease.	Initial qualitative development completed. Requires quantitative evaluation. Validity, reliability and responsiveness explored, awaiting publication.
ICIQ-VSqol	Detailed assessment of HRQL issues associated with vaginalsymptoms and related bother.	Initial qualitative development completed. Quantitative evaluation underway.
ICIQ-Satisfaction	Generic assessment of post- treatment satisfaction for lower pelvic dysfunction including surgical and conservative intervention.	Initial qualitative development completed. Quantitative evaluation underway.

4. ICIQ QUESTIONNAIRE IMPLEMENTATION

The ICIQ modular questionnaire has attracted considerable attention from both clinicians and researchers worldwide since its structure was finalised in 2004. More than 2000 requests for use of the various modules have been documented and over 350 published studies were identified up to June 2016. The most widely applied module is the ICIQ-UI Short Form, particularly to evaluate female urinary incontinence. Reports on further validation and transla- tions of the ICIQ and related educational projects are growing in number. This is essential in order to achieve standardised evaluation of pelvic floor dysfunction, which is a primary aim of the initiative.

The ICIQ has also been applied to clinical and general practice settings, and has been adopted in national guidelines for the management of urinary incontinence in:

- women (NICE clinical guideline 171)
- primary care (SIGN 79)(www.sign.ac.uk/pdf/sign79.pdf)
- included in a primary care resource pack by the British Society of Urogynaecology

5. CONCLUSION

The ICIQ modular questionnaire project (www.iciq.net) provides a growing series of standardised questionnaires for the patient reported assessment of lower pelvic dysfunction symptoms and their impact on patients lives. The ICIQ provides clarity over the selection of questionnaires by recommending only those with evidence of high quality and robust psychometric validation including validity, reliability and sensitivity to change. Testing psychometric equivalence of the ICIQ electronic formats also provides reassurance of their rigorous measurement capabilities in specific alternative formats. This assurance provides the user with confidence in the results obtained, which is important in clinical practice and research where treatment decisions or trial outcomes depend on this evidence. Increasing awareness of the ICIQ aims to promote increased use of standardised questionnaires and further evaluation of existing modules in order to advance the evidence base supporting use of these tools. These efforts aim to increase communication between clinicians and researchers and enable more wide- spread comparisons between different treatments and patient groups worldwide. Collaboration with the ICIQ is encouraged among clinicians and researchers in order to further develop new and existing ICIQ modules and translations.

V. PATIENT-REPORTED OUTCOME (PRO) QUESTIONNAIRES TO ASSESS THE IMPACT OF URINARY INCONTINENCE, OAB AND LOWER

1. URINARY TRACT SYMPTOMS

There are a variety of PRO measures available for use in clinical practice and research that assess a range of concepts (e.g. HRQL, patient satisfaction, symptom bother, etc). Encouragingly, PROs awarded the highest ICI grade are being used widely in studies, with short forms that are easily accessible being preferred.[55][55] This section provides an overview and assessment of these measures. Importantly, clinical practitioners and researchers need to clearly determine their clinical and research objectives before selecting a PRO as it is these objectives and the target patient population that will help determine which validated PRO is appropriate to use. **Tables 6 to 10** provide a brief overview of all current PRO measures for urinary incontinence and LUTS, their purpose, psychometric properties, translation availability, and recommended ICI grade.

Please note, as instrument development and validation is an ongoing process, the tables below contain publications through June 2016. As additional work may have been performed on a instrument, it is always prudent to conduct a further literature search and/or contact the instrument developer prior to selecting an outcome measure for your clinical practice or study. Further study-specific testing should also be considered to ensure a tool's appropriateness for the intended purpose. When using a questionnaire in a patient group other than the group in which it was initially developed, cognitive interviews with the new patient population should be held to review the applicability of the questionnaire to the new patient group. Several of the main questionnaires to be discussed below have now had modified versions published in the literature. The Committee's view is that although it may be appropriate to modify established questionnaires for use with some populations, it is advisable to keep such modifications to a minimum, and to use the original versions whenever possible. Any modifications of established questionnaires may result in changes (sometimes substantial) in the psychometric performance of the instrument, and thus all modified instruments should be subjected to the same psychometric testing as that employed in developing a completely new instrument. Specifically, modified instruments should report information regarding the instrument's construct validity, reliability, and test- retest reliability, at a minimum, and sensitivity to change, in intervention studies.

2. HEALTH-RELATED QUALITY OF LIFE MEASURES

Health-related quality of life (HRQL) measures help to assess the impact of disease and treatment on those aspects of quality of life related to health. UI is a symptomatic condition that has been shown to affect many aspects of a patient's life - physical, emotional, and social relations and cause concern and burden. As such, it is important to assess HRQL in clinical research and practice. **Table 6** provides a quick overview of the variety of HRQL measures available and their validity and characteristics to determine which mea- sure is suitable for your objectives.

3. PATIENT SATISFACTION AND GOAL ATTAINMENT SCALING

Patient satisfaction and Goal Attainment Scaling are two important but separate types of PROs that allow for individualised assessment of disease impact and treatment. Patient satisfaction is the subjective, individual evaluation of treatment effectiveness and/or the service provided by the healthcare system. Goal attainment scaling (GAS) is a method developed to ascertain individual patient treatment goals and using those to facilitate patient-provider interaction and tailor the treatment plan based on those individual's goals [56][56].

Measures of patient satisfaction can include evaluation of accessibility/convenience, availability of resources, continuity of care, efficacy, finances, humaneness, information gathering and giving processes, pleasantness of surroundings and perceived quality/competence of health care personnel [57][57]. At its most basic level, satisfaction is a comprehensive evaluation of several dimensions of health care based on patient expectations and provider and treatment performance. As an outcomes measure, patient satisfaction allows health care providers to assess the appropriateness of treatment ac- cording to patient expectations. In chronic diseases, where patients must live with treatment, patient satisfaction may be the distinguishing outcome among treatments with comparable efficacy [58][58].

Table 7 at the end of the chapter presents a summary of satisfaction instruments identified in UI, OAB and other LUTS.

GAS has been used to measure clinically important change in several therapeutic areas. Although it was originally developed to assess health outcomes in mental health settings, it has recently been expanded to include evaluations in urogynaecology [59[59], 60[60], 61[61], 62[62], 63[63]]. GAS has been linked to several possible benefits compared with traditional outcome measures, such as improved clarity concerning treatment objectives for both the healthcare provider and the patient, active involvement of the patient in problem-solving efforts, establishment of realistic patient and healthcare provider expectations of treatment, and increased motivation of patients toward improving their health condition [56]. The end result of GAS is to clarify patients' expectations for their treatment, document goal achievement, and eventually increase patient satisfaction and improve therapeutic outcomes.

One GAS instrument for lower urinary tract symptoms has been well developed, the Self Assessment Goal Attainment (SAGA) questionnaire. Numerous linguistically validated translations are available at: http://www.pfizerpatientreportedoutcomes.com [64][64].

4. SCREENING TOOLS

In order to improve the detection of incontinence, OAB and other LUTS, several screening tools have been developed (**Table 8**). These tools help patients self-describe symptoms and facilitate diagnosis of LUTS by the clinician. Only the B-SAQ has been designed to screen for general lower urinary tract symptoms (LUTS) rather than solely symptoms of one condition. The majority of patients with LUTS have mixed urinary symptoms, and therefore a questionnaire which can detect more than one symptom complex may be more functional as a screening tool in clinical practice than a highly specific questionnaire. The Leicester Impact Scale (LIS), OAB-V8, OAB-SS and QUID are all Grade A, short, simple to understand and complete, and easy to interpret. However the LIS is interviewer, not patient administered. Importantly, with screeners, responsiveness is not assessed, however the sensitivity and specificity of each tool is critical.

5. ASSESSING SYMPTOM BOTHER AND OVERALL BOTHER

Measures that can be used to assess how bothered patients are by urinary symptoms are included in **Table 9**. The Patient Perception of Bladder Condition (PPBC) [65][65] and the Urogenital Distress Inventory are the only Grade A recommend instruments. However, there are several Grade B and C measures which assess bother for incontinence and LUTS.

6. ASSESSING THE IMPACT OF URGENCY

Several instruments have been developed specifically to assess urinary urgency, which is defined by the International Continence Society as "the complaint of a sudden compelling desire to pass urine

which is difficult to defer"[66][66]. Urgency is the driving symptom of OAB [67][67], thus assessing the effect of treatment on this symptom and its impact on HRQL is important. With any measure designed to evaluate urgency, patients must be able to distinguish between the normal desire to urinate (urge) and the difficult-to-postpone need to urinate (urgency) [68[68], 69[69]]. Wording thus becomes critical in the development of urgency assessment measures. Chapple and Wein [70][70] make a case for describing urgency as a "compelling desire to void in which patients fear leakage of urine" as a means of distinguishing this abnormal sensation from the normal need to void. However, some patients may have a sensation of urgency without fear of leakage, further complicating attempts to define urgency. Importantly, with some of these scales, patients have the option of indicating that they experienced UUI (an event) rather than the strongest feeling of urgency (a sensation) itself. Several instruments have been developed to assess urinary urgency these are summarised in **Table 10**.

VI. QUESTIONNAIRES FOR SPECIFIC PATIENT GROUPS

Most studies and questionnaires have been developed for use with members of the general population or urology/gynaecology patients with incontinence or POP. However, some specific patient groups may experience particular problems with incontinence (for example, children, frail elderly or those who are severely disabled), which may require independent investigation and potentially the development of more specific measures or the addition of a new subset of items on already developed instruments. The Committee advises that researchers should use existing highly recommended or recommended questionnaires if possible as this aids comparison and to reduce the increasing proliferation of questionnaires. Many of the questionnaires developed below for particular conditions (e.g. prostate cancer) pre-dated the development of highly recommended questionnaires, and highly recommended questionnaires should be used preferentially.

1. OLDER PEOPLE

Urinary incontinence symptoms play an influential role on the overall HRQL in older people (>65) and causes a significant decrease in HRQL, as severe as that of many chronic disease states. Since the elderly commonly have a number of associated co-morbid conditions, it may be difficult to measure the impact of urinary incontinence with generic HRQL measures. The use of incontinence specific tools to measure patient-reported outcomes in the elderly, therefore, is of considerable importance. Validated incontinence-specific PRO questionnaires, such as IIQ, I-QOL or KHQ, are used for clinical trials or research on urinary incontinence including elderly people, but their validity has not been specifically assessed in this age group. Okamura assessed symptoms and HRQL in older people (men and women)with lower urinary tract symptoms including incontinence, using the KHQ and IPSS. They demonstrated that symptoms and HRQL in the elderly with LUTS could be assessed by IPSS and KHQ and that urinary incontinence appeared to be more associated with a decreased HRQL in elderly women [71][71].

On the other hand, there are a variety of factors affecting older people, including physical, social, mental, economic or environmental conditions, which are different from those of the young. In frail elderly people with dementia or physical impairment, it may be difficult to assess the impact of urinary incontinence alone. Questionnaires specifically developed for the elderly may be of great importance in this respect. However, there is little relating to the development or validation of particular questionnaires for older people with urinary incontinence. Two questionnaires dealing with older people were found and are described below. No questionnaires dealing with patient outcomes specifically for frail older incontinent people were found.

1.1. The Urge Impact Scale (URIS) [Grade B]

The Urge Impact Scale (URIS) was designed and tested specifically for older persons with urgency incontinence. The URIS was developed and validated by DuBeau et al. [72][72] and included 32 items, reduced to 24 items (URIS-24). The URIS-24 was psychometrically assessed for validity and reliability in community-dwelling older (>65y) men and women with urgency incontinence. Cronbach's alpha was 0.84 for the URIS-32 and 0.94 for the URIS-24. In assessment of test-retest reliability, interclass co- efficient (ICC) was 0.88. The URIS-24 had modest but nearly significant correlation with the number of urgency incontinence episodes (rho=-0.39, p=0.05). Factor analysis revealed 3 component structures corresponding to physiological burden, perception of personal control and self-concept. There was no analysis for responsiveness. They showed that the URIS-24 is an internally consistent, highly reproducible tool for the assessment of the QOL impact of urgency incontinence on older persons.

1.2. Caregivers

The Overactive Bladder Family Impact (OAB-FIM) scale was developed to assess the impact of OAB on family members of patients with OAB. This 19-item tool consists of 6 subscales [73][73]. Four subscales (Irritation, Activities, Travel, Concern) could be used for all family members; however 2 additional subscales (Sleep, Sex) should only be administered to spouses/ significant others. The OAB-FIM was highly discriminating between OAB and control family members, with all OAB family members indicating significant impact (all p<0.0001). Internal consistency reliability (Cronbach's alpha >0.71) and 2-week test-retest reliability (intra-class correlation coefficients >0.73) were high for all subscales. Concurrent validity of the OAB-FIM was demonstrated through statistically significant

($p < 0.001$) Spearman correlations with the OAB-q (coefficients ranging from 0.35 to 0.58) and the PPBC (0.31 to 0.56). No differences were noted on the OAB-FIM by patient incontinence status (none, urge vs. mixed). OAB-FIM scores also discriminated by family member perceptions of OAB severity, particularly among the Irritation, Activities and Travel subscales. Correlational analyses among the OAB-FIM and relationship quality measures suggest that greater OAB symptom impact on the family member was associated with increased problems in the patient–family member relationship. The responsiveness of the OAB-FIM is yet to be assessed. This measure can be found at www. pfizerpatientreportedoutcomes.com.

2. CHILDREN

Some questionnaires have been developed specifically to assess issues for children and can include parent and child versions of the questionnaire. Enuresis is a particular focus in addition to specific disorders such as Spina Bifida (ISI-P). See Chapter 9 (Children) and section on ICIQ modular questionnaire.

3. SPINAL CORD INJURED / NEUROLOGICAL IMPAIRMENT

Individuals who have a spinal cord injury or are neurologically damaged can experience particular difficulties with incontinence and the use of various devices. It would be useful to investigate whether Grade A questionnaires, developed for people without neurological damage, can be used in this group, or whether additional modules or instruments are required. New instruments available in this area are detailed below.

3.1. QUALAS-A: Quality of Life Assessment in Spina Bifida for Adults

The QUALAS-A was developed to evaluate quality of life associated with bladder and bowel disorders in adults with Spina Bifida [74][74]. Items were generated through interviews and a focus group and refined to develop the 53 item pilot instrument. International recruitment achieved a sample of 532 participants to evaluate validity and reliability to assist item reduction. The resulting 15 item questionnaire provides a comprehensive assessment organized within three domains: Health and relationships, Esteem and sexuality, and bladder and bowel.

3.2. IUI: Incontinence Utility Index

The IUI is a condition-specific preference-based measure for urinary symptoms related to neurogenic detrusor overactivity that provides population based utility scores to value health states [75][75]. The instrument was developed from the I-QoL and neurogenic module by applying Rasch modeling. 442 participants were interviewed to estimate social preferences and explanatory models identified that demonstrated adequate predictive validity.

3.3. Qualiveen: Quality of Life Related to Urinary Problems in Spinal Cord Injury [Grade A]

The Qualiveen was developed to evaluate the specific impact of urinary dysfunction on the quality of life of spinal cord injury patients in France [76][76]. The initial items were developed following patient interviews, and were then assessed for validity and reliability in 281 spinal cord injury patients with urinary difficulties. The Qualiveen contains 30 items and has demonstrated good reliability and validity [76]. Further validation of the Qualiveen has occurred in multiple sclerosis patients [77][77] and it has been translated and validated into English [78][78], German [79][79], and Portuguese [80][80]. The Qualiveen has demonstrated responsiveness in multiple sclerosis patients and has a suggested MID of 0.5 [81][81].

4. PROSTATE / BLADDER CANCER

Many PRO questionnaires are available for assessment in this area: Post-radical prostatectomy questionnaire [82[82], 83[83]], Cancer Rehabilitation Evaluation System - Short Form (CARES-SF) [84][84], Prostate Cancer Treatment Outcome Questionnaire (PCTO-Q) [85][85], Prostate Cancer Specific Quality of Life Instrument (PROSQOLI) [86][86], Modified Southwest Oncology Group (SWOG) [87][87], Functional Assessment of Cancer Therapy - (FACT-G), Bladder form (FACT-B) and Prostate form (FACT-P) [88][88],Functional Assessment of Cancer Therapy Vanderviet Cystectomy Index (FACT-VCI) [89][89], EORTC metastatic prostate cancer [85], Changes in Urinary Function [90][90], Prostate-targeted Health Related Quality of Life [91][91]. While it is beyond the scope of this chapter to review and recommend PROs in this area, the principles and guidelines discussed herein apply to selecting a PRO related to prostate and bladder cancer.

5. LOWER URINARY TRACT SYMPTOMS/BENIGN PROSTATE DISEASE

Many questionnaires have been developed to assess LUTS and benign prostate disease; however, most do not contain a full evaluation of UI. Perhaps the most widely known urology PRO is the AUA Symptom Index [92][92], I-PSS (International Prostate Symptom Score) [92, 93[93]]. The IPSS has been utilitised internationally to assess symptoms of prostate disease with documented reliability, validity and responsiveness. More recently a Visual Prostate Symptom Score [94][94] has been developed and an app version of the IPSS has been evaluated, providing alternative approaches to the assessment of symptoms associated with prostate disease [95][95]. Additional PRO

measures for BPH are as follows: Patient-completed modification of the Boyarsky[96][96], BPH Impact Index [97[97][98][98] and BPH Health-related QoL survey [99][99]

Table 6: Health-related Quality of Life measures for Lower Urinary Tract Symptoms

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
BFLUTS (Bristol Female Lower Urinary Tract Symptoms Questionnaire). Currently the ICIQ-FLUTS (ICIQ-Female Lower Urinary Tract Symptoms); Grade A [42]	34-question tool used to assess female LUTS, particularly urinary incontinence, measure impact on quality of life and evaluate treatment outcome	Women, inconti- nence	√	√	√		√		None	www.iciq.net
Contilife® (Quality of Life Assessment Questionnaire Concerning Urinary Inconti- nence); Grade B [100]100	28-intem tool used to assess the impact of urinary incontinence on HRQL. Originally developed in French and designed for women with UI (urge, stress and mixed UI)	Women, SUI	√	√ (ICC = 0.96)			√		√	www.proqolid.org
DAN-PSS-1(Danish Prostatic Symptom Score); Grade A [101]101	15-item tool used to evaluate males with LUTS suggestive of uncomplicated BPH	Men, BPH	√	√	√		√			www.proqolid.org
EPIQ (Epidemiology of Prolapse and Incontinence Questionnaire); Grade B [102]102	49-item tool developed and validated in English and Spanish to assess the presence or absence of AI, OAB, SUI, and pelvic organ prolapse in female population	women, PFD	√	√	√	√	√	√		contact developer
ICIQ-UI Short Form (International Consultation on Incontinence Questionnaire - Urinary Inconti- nence Short Form (ICIQ-UI Short Form); Grade A[38]	4-item tool used to assess the symptoms and impact of urinary incontinence in clinical practice and research	men and women, Urinary symptoms	√	√	√		√	√	√ (8 weeks)	www.proqolid.org
ICSmale (ICIQ-	23-item tool used to	men with	√	√	√		√		√	www.proqolid.

Table 6: Health-related Quality of Life measures for Lower Urinary Tract Symptoms (continued)

MLUTS) (International Continence Society - Male); Grade A [49]	provide a thorough evaluation of the occur- rence and bothersomeness of lower urinary tract symptoms and their impact on the lives of men with benign prostatic disease	LUTS and possible BPH								org
ICSQoL (International Continence Society-Benign Prostatic Hyper- plasia study quality-of-life); Grade A [103][103]	8-item tool used to assess impact of lower urinary tract symptoms on the lives of men with LUTS	men with LUTS and possible BPH	√	√	√		√			www.proqolid.org
IIQ (Incontinence Impact Question- naire); Grade A [104][104]	30-item tool developed to describe the severity of incontinence in a popula- tion. It was validated in a group of women aged 45 and over attending two continence clinics for SUI primarily. Used to assess the impact of urinary incontinence on HRQL.	Women, UI		√	√		√		√ (12Weeks)	contact developer
IIQ-7 (Incontinence Impact Question- naire - short form); Grade A [105][105]	7-item tool used to assess the impact of urinary incontinence on HRQL	*validation study on men after radical prostatec- tomy who had UI	√ (Cronbach's Alpha = 0.93)	√ (Spearman's Rho = 0.99; ICC = 0.75)	√	√	√	√		contact developer
IOQ (Incontinence Outcome Ques- tionnaire); Grade B [106][106]	27 question tool developed for assessing quality of life after surgery for stress urinary incontinence	Women SUI	√ (Cronbach's Alpha = 0.83)		√	√			√	contact developer

Table 6: Health-related Quality of Life measures for Lower Urinary Tract Symptoms (continued)

PRO Name/ICIQ Grade	Purpose/Description of Tool	Population Sample	Reliability		Validity				Responsiveness (Treatment Duration)	Instrument Access & Translation(s)
			Internal Consistency	Test-retest	Content (Item Generation)	Criterion	Concurrent	Discriminant		
I-QOL (ICIQ-Uqol) (Urinary Incontinence-Specific Quality of Life Instrument); Grade A [107[107], 108[108]]	22-item tool used to assess quality of life of women with UI	women, UI	√	√	√			√	√	www.proqolid.org
ISI (Incontinence Severity Index); Grade C [109][109]	2-item severity measure recommended by the World Health Organization for studying the epidemiology of incontinence and other LUTS; Developed in an epidemiologic study of 28,000 women in Norway.	Women, SUI				√	√			contact developer
ISQ (Incontinence Stress Index: ISQ-P [Patient]; ISQ-SOPS [Staff Observation of Patient Stress]; ISQ-SR [Staff Reaction to UI]); Grade C [110][110]	40-item tool (20-items in short form) used to assess psychological stress associated with urinary incontinence	Women	√	√						www.proqolid.org
ISS (Incontinence Symptom Severity Index); Grade A [111][111]	8-item instrument used for the self-assessment of severity of female urinary storage and voiding symptoms, rather than symptom bother or effects of on quality of life	Females		√ (ICC = 0.62 - 0.91)			√		√ (Duration not specified)	contact developer
KHQ (ICIQ-LUTSqol) (King's Health Question- naire); Grade A+ [4, 48]	21-item tool used to assess the symptoms impact of LUTS including urinary incontinence on HRQL. Developed in a clinical perspective to evaluate incontinence in women.	UI, OAB, men and women	√ (all domains except severity measure (Cronbach's Alpha = 0.60) demon- strated excellent IC)	√	√	√	√	√	√ (12Weeks)	www.proqolid.org

VII. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQOL IMPACT OF PELVIC ORGAN PROLAPSE

Women complaining of lower urinary tract symptoms often also complain of concomitant symptoms associated with urogenital prolapse and there are now a number of validated questionnaires available to use in the subjective assessment of women with prolapse symptoms. These questionnaires should be used in conjunction with the clinical assessment and standardised measurement of urogenital prolapse which is reported elsewhere in this section. In addition, given the number of conservative and surgical management options available for women with symptomatic prolapse standardisation of subjective outcome measurement is increasingly important.

This section will review the standardised symptom assessment tools for pelvic organ prolapse and, whilst the questionnaires described do not allow the clinical staging or planning of prolapse treatment they should be used alongside more objective tools to measure the subjective outcome of treatment. Evidence form previously reported studies [182][182] has shown the importance or patient reported outcome measures and subjective assessment may provide a more meaningful assessment tool when compared to more traditional objective measurements. The use of these subjective outcomes has been shown to be robust and correlated with objective assessments during long term follow up [183][183].

Although the number of HRQoL questionnaires available to assess impact of urogenital prolapse is not as great as those associated with lower urinary tract dysfunction there are now a number of recommended and validated questionnaires available. However, it is important to consider that where specific problems associated with urogenital prolapse need to be considered, such as lower urinary tract symptoms or sexual function, then it may be preferable to consider the use of one of the questionnaires designed specifically for that purpose. In addition, as prolapse is often multidimensional, selecting questionnaires in the modular format of the ICIQ may be more useful in clinical practice.

Women who have symptomatic urogenital prolapse may also complain of sexual dysfunction and the Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ) is now available in short form (PISQ-12) and has been validated in Turkish [184][184], French [185][185], Chinese [186][186], Swedish [187][187], Portuguese [188][188], Iranian [189][189] and Dutch [190][190].

More recently an IUGA revised version (PISQ-IR) for both sexually active and inactive women has been reported and has now been been validated in French[191][191],Japanese[192][192], Arabic[193][193], Mandarin Chinese[194][194], Hungarian[195][195] and German[196][196].

This update of the last triennial report has again examined the quality of the psychometric evidence and only where published data were scientifically sound were the questionnaires included in the overall report.

For this current report the previous literature search was updated using the Pubmed/Medline databases from January 2013 – August 2016 in addition to the website mapi-institute.com. The following key words were used either separately or in combination; 'questionnaire', 'prolapse' and 'quality of life'. The grading of questionnaires was also reviewed and updated if new information had become available.

Whilst the search found no new HRQoL instruments for the assessment of urogenital prolapse a number of new linguistic validations have been reported including Spanish [197][197], French[198][198] Persian[199][199] and Polish[200][200] versions of the Prolapse Quality of Life questionnaire (P-QoL). In addition the Pelvic Floor Impact Questionnaire (PFIQ-7) and Pelvic Floor Distress Inventory (PFDI-20) have recently been validated in Brazilian Portuguese[201][201] Swedish [187] and Danish [202][202].

Although HRQoL questionnaires remain the most commonly used form of patient related outcome measure that are used in patients with pelvic floor dysfunction other measures of outcome have also been developed and reported. The Patient Global Impression of Improvement (PGI-I) was initially developed for lower urinary tract symptoms [145] and has more recently been validated for use in patients with urogenital prolapse [144]. The use of a simple one answer patient reported outcome measure has also been used in studies using composite endpoints with the validated HRQoL questionnaires [203][203].

When reviewing the available HRQoL questionnaires the committee examined the quality of the psychometric evidence and only where the published data were robust were the instruments considered for recommendation **[Box 1]**.

Box 1: Recommended questionnaires for the evaluation of symptoms and HRQoL impact of Pelvic Organ Prolapse

Grade A (recommended)

Pelvic Floor Distress Inventory (PFDI) [120]

Pelvic Floor Impact Questionnaire (PFIQ) [120]

Prolapse Quality of Life Questionnaire (P-QoL)[204]

Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire (PISQ)[205],(PISQ 12)[206]

Pelvic Organ Prolapse Urinary Incontinence Sexual Questionnaire –IUGA Revised (PISQ-IR)[207]

ICIQ vaginal symptoms questionnaire (ICIQ-VS)[208]

Grade B

The Austrian Pelvic Floor Questionnaire (AFPQ)[209]

Pelvic Floor Symptom Bother Questionnaire (PFBQ)[210]

Electronic Personal Assessment Questionnaire-Pelvic Floor (ePAQ-PF)[211]

Grade C (with potential)

Pelvic Floor Dysfunction Questionnaire[212]

Danish Prolapse Questionnaire[213]

VIII. QUESTIONNAIRES TO ASSESS SYMPTOMS AND HRQL IMPACT OF FAECAL INCONTINENCE

There are now a number of patient reported outcome measures which have been developed for the assessment of patients with Anal Incontinence (AI) and Faecal Incontinence (FI). Due to the considerable overlap between faecal incontinence and other forms of pelvic floor dysfunction questionnaires used for urinary and prolapse symptoms may also contain domains for anal and faecal incontinence. Likewise, items relating to faecal incontinence may also be included in questionnaires used to evaluate colorectal disease. In addition, due to the wide variation in normal bowel function within, and between individuals, some of these questionnaires may lack sensitivity and specificity for more specific bowel disorders such as Irritable Bowel Syndrome (IBS), Irritable Bowel Disease (IBD) evacuation disorder and constipation.

Since anal incontinence, faecal incontinence and bowel evacuation are closely related to pelvic floor function it may be inappropriate to consider bowel function simply in terms of continence and constipation. Constipation and evacuation disorders may result from a number of different pathologies such as outlet obstruction and slow transit in addition to other mechanical, pharmacological, metabolic and neurogenic causes [214][214].

Anal incontinence is known to occur in both men and women with the prevalence depending on age and the symptoms are known to be important in terms of the underlying pathophysiology. Faecal urgency and faecal urgency incontinence are thought to be associated with the loss of voluntary control due to impaired external sphincter function whereas passive faecal incontinence is thought to be associated with impairment of the smooth muscle of the internal anal sphincter [215][215].

This update of the last triennial report has again examined the quality of the psychometric evidence and only where published data were scientifically sound were the questionnaires included in the overall report.

For this current report the previous literature search was updated using the Pubmed/Medline databases from January 2013 – August 2016 in addition to the website mapi-institute.com. The following key words were used either separately or in combination; 'questionnaire', 'faecal', 'anal', 'bowel' and 'quality of life'. The grading of questionnaires was also reviewed and updated if new information had become available.

The updated search found no new HRQoL instruments for the assessment of anal or faecal incontinence and, in addition there were no further validation studies reported on those questionnaires which were ungraded. Consequently the recommendations of this triennial report remain unchanged.

The grades of recommendation are as outlined in previous sections. **Box 2** summarises the questionnaires reviewed and grades of recommendation.

Box 2: Recommended questionnaires for the evaluation of symptoms and HRQoL impact of faecal incontinence

Grade A+

ICIQ-B [46,47]

Grade A

Faecal Incontinence Quality of Life Scale [171]

Birmingham Bowel and Urinary Symptom Questionnaire [167,168]

Questionnaire for assessment of Faecal Incontinence and Constipation [164]

Grade B

Colorectal Functional Outcome Questionnaire [176]

Manchester Health Questionnaire [172]

Bowel Control Self Assessment Questionnaire [173]

Pelvic Floor Bother Questionnaire [216][216]

Elderly Bowel Symptom Questionnaire [177]

Faecal Incontinence and Constipation Assessment [169]

Grade C

Faecal Incontinence Questionnaire [166]

Ungraded

Postpartum Flatal and Faecal Incontinence Quality of Life Scale [174]

Bowel Function Questionnaire [217][217]

Surgical Outcome Tool for Faecal Incontinence [175]

Tables 11, 12 and 13 provide details of the specific psychometric properties and development of each questionnaire

IX. QUESTIONNAIRES TO ASSESS SEXUAL FUNCTION/SEXUAL HEALTH AND URINARY SYMPTOMS

Sexual dysfunction affects many people and may be caused by psychological, emotional or physiological factors, often with multifactorial and interrelated etiologies. Sexual function may be regarded as a dimension or aspect of overall HRQL, for which a number of dimension-specific measures have been developed and validated. There is a wide choice of available instruments, the selection of which will depend on the clinical or research setting where the instrument is to be employed. Established and widely used measures that have been shown to be valid, reliable and responsive are clearly desirable, however the feasibility and appropriateness of using a particular instrument in a particular setting must also be considered. A large number of different instruments exist in this field, which aim to evaluate specific aspects of sexual function and sexual health.

While the importance of investigating male sexuality as part of a normal male urological assessment is established, this has not been established for female evaluation. Many physicians underestimate the prevalence of female sexual dysfunctions and do not routinely perform an assessment of sexual wellness as a part of their practice [218][218], despite evidence that many women with LUTS have sexual problems [219][219]

In a comprehensive assessment of women with pelvic dysfunction sexual function should be investigated. However it is may be a difficult issue to discuss during a consultation because of discomfort or embarrassment. Female discomfort may stem from personal embarrassment, a sense that sexual dysfunction is not a medical problem and this may be compounded by a lack of time during health care visits [220][220].

In addition many physicians report a lack of training in how to appropriately address sexual function with patients [221][221]. Clinicians who treat sexual problems often prefer to use unstructured rather than structured interviews or questionnaires in clinical practice as an unstructured approach allows the tailoring of questions to suit the couple or the individual being assessed. Unstructured interviews enable the clinician to support patients who feel vulnerable and encourage discussion. In this setting, vocabulary can be modified, as can the level of assertiveness and the depth of questioning to suit the needs of the individual. This flexibility is not readily achievable with questionnaires which individuals may also find difficult to complete due their impersonal nature or because of physical or mental impairment, cultural or language differences. However, some patients find the discussion of intimate issues with clinicians very difficult and questionnaires may allow these issues to be measured in private, at ease and more effectively before subsequently exploring questionnaire responses in the clinical interview itself. Therefore there is a wide choice of available instruments, which could help the physician during history taking and the selection of an instrument will depend on the clinical or research setting where the instrument is to be employed.

Table 14 and Table 15 outline sexual health measures with a Grade A, B, C rating based on the criteria provided above, and the linguistic validations of each questionnaire are also documented.

This table includes the questionnaires useful to assess female and male sexual function in patients with any pelvic dysfunction and urinary symptoms. Questionnaires obtaining an A+ rating demonstrate reliability and validity and also that content was derived with patient input and responsiveness to treatment has been shown.

A Rated group: the Female Sexual Function Index (FSFI) [178,222[222],223[223]], the Female Sexual Distress Scale (FSDS) [224][224] , the International Consultation on Incontinence Questionnaire-Vaginal Symptoms (ICIQ-VS) [45] and the Derogatis Sexual Functioning Inventory (DISFI) [225][225]. These questionnaires assess female sexual function and measure the quality of a patients current sexual functioning. The Menopausal Sexual Interest Questionnaire (MSIQ) [226][226] is also included in this group but only two domains. For male patients the International Index of Erectile Function (IIEF) [227][227] is recommended to assess men with erectile dysfunction. Most of the identified measures are self-reported, easy and quick to administer and many have various language versions available. The majority have also been previously used in incontinence populations

***B Rated group*:** the Daily Log of Sexual Activities (DLSA) [228][228], the Female sexual distress scale-revised (FSDSr) [229][229], the Index of Sexual Functioning for women (BISF-W) [230][230], the Change in Sexual Functioning Questionnaire (CSFQ) [231[231],232[232]],and the Sexual Interest and Desire Inventory Female (SIDI-F) [233][233]. They assess the sexual dysfunctions in women with sexual desire disorder and functional sexual arousal disorder. The Pelvic Organ Prolapse Urinary Incontinence Sexual Question (PISQ-12) [179] assesses sexual function after surgery in women with Pelvic Floor Dysfunction and has been validated in women with urinary incontinence and pelvic organ prolapse. The Sexual Quality of Life–Female (SQoL-F) [181] is useful to assess the impact of female sexual dysfunction on quality of life, while the Sexual Satisfaction Scale for Women (SSS-W) [234][234] measures the women's sexual satisfaction and distress in patients with pelvic floor dysfunction. The Sexual Function Questionnaire (SFQ) [180] is an instrument for both partners. This questionnaire also addresses some of the consequences of female sexual dysfunction for the woman, her partner and their relationship. Both the physical and the

cognitive aspects of sexual response are evaluated within the SFQ items. The Male Sexual Health Questionnaire (MSHQ) [235][235] assesses sexual function and satisfaction in older men with urogenital symptoms of LUTS and sexual dysfunctions.

***C Rated group*:** The Women's Sexual Interest Diagnostic Interview--Short Form (WSID-SF) [228] is used to assess sexual function in adult women with hypoactive sexual desire disorder, The Pelvic Organ Prolapse/Incontinence Sexual Questionnaire, IUGA-Revised (PISQ-IR) [236][236], and the Sexual Health Outcomes in Women Questionnaire (SHOW-Q) [237][237] to assess the impact of pelvic problems on sexual desire, frequency, satisfaction, orgasm, and discomfort.

The choice of which tool to use will be dependent on the type of patient, age, type of pelvic dysfunction and on research hypothesis. For instance, if you wanted to assess impact of OAB on sexual function e.g. arousal in women then the FSFI should be used rather than the SQOL-F because the FSFI has a specific arousal domain whereas the SQOL-F assesses sexual quality of life.

Table 15. Additional Sexual Health and Quality of Life Measures (separate document)

X. RECOMMENDATIONS FOR RESEARCH

1. The selection of a PRO questionnaire must reflect study purpose and objectives.
2. Grade A recommended questionnaires should be used in all clinical trials evaluating treatments
3. The inclusion of the ICIQ modules is preferred in all studies in order to standardize outcome assessment
4. Continued PRO development, refinement, and usage should accurately and adequately report on the methods, samples, statistical analyses and psychometric properties of questionnaires in scientific journals. This includes documentation of validity, reliability and responsiveness and consequently the quality of each study can be assessed.
5. Researchers are encouraged to use existing questionnaires and refine for specific populations when required; such as frail elderly and children.
6. Researchers are also encouraged to participate in collaborative work with the ICIQ project allowing the development and refinement of modules and translations.

INTRODUCTION

This chapter is based on the 'Urodynamic Testing' chapter from the previous (ICI2013) consultation. The fifth consultation, ICI2013, updated the evidence for the technical performance, clinical utility and responsiveness to treatment of UDS for patients with UI. Testing for faecal incontinence was not included in the dynamic testing ICI2013. This ICI2016 chapter starts with a summary of the ICI2013 recommendations and conclusions in each of the paragraphs and

then provides relevant updates where from where we have evaluated the current evidence. Finally, the updated ICI2016 conclusions and recommendations are presented. Outdated references have been removed and new literature references are added. Publications less than one year before the consultation were deemed not to have stood the 'test of time' and so have not been included.

The primary aim of this chapter is to present what tests might be performed to elucidate the mechanism that causes UI in the individual and to make recommendations for practice. To this end, we present an overview of the best available recent scientific evidence about the role of UDS in clinical practice for patients presenting with UI. Based on the above, we provide recommendations, and the strength of the recommendation (A to D), for the current state of diagnostic assessment of the patient, or groups of patients with UI.

Each of the recommendations of the preceding consultation is re-evaluated and the discussion ends with new or renewed conclusions (with a level of evidence that follows the Modified Oxford Scale). Following on from that we present our new (ICI2016) graded recommendation(s) where necessary after considered judgement of the evidence (discussion). Where deemed useful we suggest topics(s) for research. Conclusion, recommendation and suggestions for research are highlighted in the text and are therefore suitable for 'express reading'.

The chapter considers the evidence around UDS for patients with signs and symptoms of UI by reviews of the literature regarding clinical UDS of diverse patient groups with UI; which include the following discrete groups; Women, men, children, neurogenic lower urinary tract dysfunction (NLUTD) and the frail elderly. UDS of voiding dysfunction is not addressed specifically and only described where deemed relevant (more specific: when related to the UI).

I. WHAT ARE URODYNAMIC STUDIES AND WHAT SHOULD, IN GENERAL BE THE ROLE OF URODYNAMIC STUDIES IN CLINICAL PRACTICE?

INTRODUCTION

Urodynamic testing should be performed to objectively measure and document the entire LUT *function and/or dysfunction.* UDS should be done only when it can have therapeutic consequences; will change the patient's management and/or when part of a surveillance or a research program. For this, the individual patient's symptoms, including their impact in terms of bother and degree of hinder they cause as well as the impact of other relevant circumstances (like e.g. comorbidity or operability) should be kept in mind. UDS can show signs, not presented, such as e.g. (significant) postvoid-residual urine (PVR) or detrusor underactivity (DU), which may be relatively unnoticed by the patient, even when neurologically intact. UUT signs (dilatation) can exist or develop without any (new) symptoms, especially, but not uniquely in patients with relevant neurological abnormalities. Furthermore, the patient can present with complaints such as, 'urinary frequency', 'nocturia' or 'recurrent UTIs', which are difficult or impossible to reproduce in the usual UDS- laboratory. Nevertheless, in the usual setting of a UDS a feature of LUT function or dysfunction may be observed/measured that is relevant to these unnoticed phenomena and (therefore) explaining the person's symptoms. Finally, UDS may provide a basis for the prevention of (signs or) symptoms to arise that are at the time of the testing not presented by the patient; e.g. urinary retention or UUT dilatation or deterioration.

UDS allows direct assessment of LUT function by the measurement of relevant physiological parameters (ICS-ST2002[1] [2]) and invasive UDS is defined as any test that is invasive, i.e. involving insertion of one or more catheters or any other transducers into the bladder and/ or other body cavities, or insertion of probes or needles, for example for (needle-) EMG measurement[3] (ICS-GUP2016).

The point of a clinical /biological test is that it will show a result on a continuum between what is considered normal physiology and pathology; and UDS is no exception to this. The key to determining the cause of the signs and/or symptoms of LUTD will be to reproduce the function and the dysfunction of the LUT of the individual patient. The implicit consequence of this is also that ideally at least one complete filling (storage) and pressure-flow (voiding) cycle, that adequately represents the patients problem (e.g. with regard to volumes) including post voiding features, (PVR, or after contraction) should be tested, analysed, and documented, even if only storage or only voiding signs or symptoms have been expressed by the patient. Last but not least: when LUT sensation is altered, as is frequently in patients with NLUT, the symptoms are even less reliable than those of patients with intact sensation, making UDS as an objective evaluation to advise or justify a specific management even more important.

The role of UDS in broad clinical perspective can be:

a. To identify all factors that contribute to the LUT-dysfunction signs (e.g. UI) and/or are the origin of the symptoms (e.g. frequent voiding) and assess their relative importance;

b. To obtain information about all other aspects of LUT function or dysfunction; whether or not expressed as a symptom or recognisable as a sign;

c. To allow a prediction of the possible consequences of LUT D for the UUT;

d. To allow a prediction of the outcome, including undesirable side effects, of a contemplated treatment;

e. To confirm the effects of intervention or understand the mode of action of a particular type of treatment for a LUTD; especially a new and/or experimental (not routine) one;

f. To understand the reasons for failure of previous treatments for UI, or for LUTD in general (after unsatisfactory treatment).

UDS is the gold standard to assess LUT function and dysfunction. Some studies have challenged UDS with a clinical diagnosis as the comparator. Specifically, the 'clinical diagnosis of SUI' was used as a predictor of outcome of suburethral tapes in a very selected group of patients.[4] When this clinical diagnosis – not standardized in general and not for these trials- had been compared with one specific element (filling -cystometry) of the –not (always ICS) standard- UDS diagnosis (and also including patients with DO[5] neither way of diagnosis has been superior for the patients recruited in this study with signs and/or symptoms of SUI-S. The question remains whether the overall outcome of the surgery (or alternatives for some of the patients) could have been better than the ±65% overall success rate (dry, without other symptoms e.g. frequent voiding), when a more structured clinical as well as UDS diagnosis and/or analysis had been used in these studies.[4 6]

CONCLUSION

UDS in clinical practice evaluates a person's LUT function with at least one complete and representative filling-voiding-post voiding cycle by testing with relevant pressures and flowmetry. UDS includes quality control, subsequent analysis, and systematic documentation.

1. UROFLOWMETRY

This is the non-invasive measurement of urine flow rate applicable for both women and men, as well as for children. The general principles are identical although voiding position is relevant,[7] and a small series of young men voiding in the healthy range shows that time after ejaculation may play a role.[8] Uroflowmetry is also relevant for patients with neurological abnormalities, when they are able to (and do) use a toilet in the daily life situation. The patient voids into a flow meter in private, ideally with a normal to strong (but not uncomfortable) desire to empty their bladder.[9 10] Urine flow rate is continuously measured and displayed graphically. Various parameters from the trace are automatically calculated and printed out together with the trace. After control for artefacts in automated calculations, the maximum flow rate, the volume voided and shape of the curve are usually the principal determinants of whether or not the patient is emptying their bladder in a normal way. Flow rate- volume dependency should be considered. If an abnormal voiding occurs, it is good clinical practice to repeat the assessment to attempt to reproduce normal behaviour. Several factors, such as patient apprehension, can give an abnormal recording in patients who have no voiding difficulty. Asking the patient about what she or he thinks about the voiding; whether the voiding was an adequate representation of their usual voiding, (if possible: comparison with the usual voiding diary -volume) must be regarded as good urodynamic practice. Repeating the assessment can remove such confounding factors. Unambiguous and careful instruction of the patient, privacy and a short meatus to flowmeter distance are all inherently relevant.[11]The committee has not found any relevant technical changes or innovations to uroflowmetry equipment since 2013.

2. FILLING CYSTOMETRY

This is the measurement of the pressure inside the bladder to assess its storage capabilities. It is an invasive test which involves a catheter being placed into the bladder, usually transurethrally, and another catheter being placed rectally, vaginally or through an abdominal stoma to measure abdominal pressure. Subtracting the indirectly measured abdominal pressure (p_{abd}) from the pressure measured inside the bladder (intravesical pressure, p_{ves}) gives a representation of pressure changes due to the action of the detrusor smooth muscle, the detrusor pressure, p_{det} ($= p_{ves} - p_{abd}$). During this assessment, the bladder is usually filled with normal saline solution, or x-ray contrast solution in the case of VUDS, either through a separate catheter placed transurethrally or through the filling channel of a dual lumen catheter, if used. Usually the filling rate is much faster than physiological bladder filling (which is 1-2mL/min) and therefore referred to as non-physiological in ICS terms. The bladder will become filled in about 10 minutes when a 10% of 'estimated usual capacity –based on voiding diary (taking into account the PVR whenever possible)-' is taken as the filling rate (mL/m).[3]

The intravesical, abdominal pressure and the calculated detrusor pressure are monitored as the bladder is filled and before the patient has been given 'permission to void'. The storage ability of the bladder is assessed in terms of the volumes required to elicit various sensations from the patient, its cystometric capacity, its compliance (passive muscle adaptation to volume stretch and detrusor muscle relaxation), and the presence or the absence of phasic detrusor pressure rises. The filling (storage) phase of cystometry is the when USUI can be assessed by means of coughing or straining, on the request of the clinician.[12] Good urodynamic practice demands that all three of abdominal, intravesical and detrusor pressures are evaluated to diagnose urinary bladder storage function. The committee has not become aware of any

changes after 2013 in technique of cystometry. Pelvic muscle EMG during cystometry is not ICS standard and not further discussed in this chapter (see chapter on imaging and neurophysiological testing for this). Alternatives for ICS standard water (saline) filled catheters and tubing are being evaluated and will be discussed in a separate paragraph. Specific attention to artefact and errors merits attention and has been included in the update of the ICS Good Urodynamic Practices.[13 14 15]

3. PRESSURE-FLOW STUDIES (VOIDING CYSTOMETRY)

This is a measurement of the mechanics of micturition. When the filling phase of cystometry is complete, the patient is given 'permission to void' and will empty their bladder into a flow meter whilst intravesical, abdominal and detrusor pressures are being recorded. The simultaneous measurement of flow rate and pressure enables voiding to be assessed and pressure flow analysis can help determine whether a slow urine stream is due to BOO or to DU or to a combination of both. Pressure-flow studies can also assist in the diagnosis of detrusor-sphincter dyssynergia and a clearer description of dysfunctional voiding and/or quantification of outlet dynamics during voiding. Similar precautions as for uroflowmetry must be taken regarding representativeness, artefacts and patient apprehension. Since 2013 no new studies have been published about the technique of pressure flow testing. Analysis of pressure flow regarding detrusor (underactive –DU-) contraction or 'contractility' during voiding has received increased attention and is suggested to be of future relevance.[16 17]

4. URETHRAL PRESSURE PROFILOMETRY

This is a test to estimate the urethra and the surrounding structures' ability to maintain a closed bladder outlet, allowing the body system to contain urine within the bladder. A catheter is placed transurethrally into the bladder and then withdrawn along the urethra (usually by a mechanical puller at a constant rate). Catheters that use water perfusion but also catheters with microtip pressure sensors or catheters with air filled ('charged') balloons are used to this aim. The pressure along the length of the urethra is measured and interpreted relative to the pressure inside the bladder or abdomen. The maximum pressure measured in the urethra is assumed to give an indication of the urethral closure function. The clinical relevance of UPP is frequently discussed in the literature and alternative technical systems to measure urethral pressure or function have been published and will be discussed in following paragraphs.

5. ABDOMINAL LEAK POINT PRESSURE

This test estimates the urethra's ability to contain urine within the bladder. Intra-abdominal pressure is measured whilst the patient is asked to increase their abdominal pressure by Valsalva or by coughing. The abdominal pressure required to produce leakage from the bladder gives an indication of the closure function of the urethra. Diverse methods as well as reference pressures are used. New evidence (since ICI2013) for the relevance of LPP measurements and variants of LPP will be discussed in the specific paragraphs of this report.

II. TECHNOLOGICAL INNOVATIONS IN URODYNAMIC STUDIES

1. CATHETERS FOR PRESSURE MEASUREMENT

Traditionally, UDS is done with water-filled catheters and tubing and external pressure sensors and this has become the ICS Standard method. A variety of catheter-tip microtip or optical sensors have been evaluated in the past and new sensors are being developed. Also, sensors that are placed in the bladder wall (not lumen) itself are tested in animal labs. Single-use, air-filled catheters have been developed for clinical use and are discussed here.

Air filled catheters have a small balloon on the tip and a lumen attached to a pressure system. After introduction, the balloon is 'charged' with air and measurement can take place. Air filled catheters (T-Doc® Air charged™ catheters, Laborie, Mississauga, Canada) can be used for intravesical, intra-urethral as well as for abdominal pressure measurement in UDS and are CE (Conformité Européenne) marked and FDA (US-Food and Drug Administration) approved for their technical safety for use in human.

1.1. Conclusions and Recommendations 2013

ICI2013 concluded that air-filled catheters may provide an acceptable alternative to other techniques for measuring the urethral closing pressure, although studies to show whether air-filled catheters provide an alternative to water-filled lines for measuring intravesical and intra-abdominal pressure in UDS were not available at that time. The recommendations of the ICI2013 were that investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check for themselves that they have an equivalent performance to their current system for measuring pressure.

ICI2013 also advised evaluation of how their system compares to the standard reference values for clinical relevant limits of pressures obtained with the ICS standard water-filled systems.

Studies comparing measurement of urethral pressure by air-filled catheters with measurement by microtip catheters have indicated that the values obtained are statistically significantly different, but are more reproducible with the air-filled systems. [18] [19] [20] In laboratory bench-top studies, water-filled catheters were reported to act as an under damped system, and sensitive to motion artefacts, whilst air-filled catheters acted as an over damped system; while less sensitive to artefacts, they were slower in response.[21] Another report concluded however that the signal could be adjusted to compensate for this difference.[22] Air-filled catheters have several practical advantages over water-filled pressure lines because there is no hydrostatic pressure effect (as is occurring in –the tubing of - a water-filled system) to account for, so that there is no need to position external sensors at a standard reference level. (Which is the level of the symphysis pubis by ICS convention.) Air filled system have no requirement to fluid flush the system to exclude air, a process that is essential in a water-filled tubes pressure-sensing environment. Also, there are no pressure (tube wagging or knocking) artefacts produced when the patients move. In order to compare water-filled systems with the air-filled systems during live UDS, two studies conducted pressure measurements in female patients with both systems simultaneously, one study with 20 patients[23] and one with 51 patients.[24] Both studies reported that the systems were not interchangeable, since values obtained from each were significantly different, the larger study stating that p_{det} values could vary between systems by up to 10 cmH_2O (the 95% limits of agreement). Pressure offset, as observed, differences are not particularly relevant in (urodynamic graph) pattern analysis, however when absolute (subtracted) pressures become relevant as in pressure flow analysis or urethral pressure profiles the possibility of clinically relevant differences exists. Studies that refute or confirm this are not yet available. Thus, more recently, a review paper has recommended that further validation of measurement techniques with air-filled systems should be done before its clinical similarity can be established.[25] Further research must be carried out in order to identify what has caused the observed differences in pressure readings obtained, by evaluating the potential sources in the air-filled system however also in the (ICS standard) water-filled system.

1.2. Conclusions

- Air-filled catheters may provide an acceptable alternative to other techniques for measuring the pressure closing the female urethra however normal –or reference- values have not been established. (level 3)
- Studies show that air-filled catheters record different pressure values to water-filled lines in UDS and are therefore not interchangeable. (level 2)
- Air-filled cathters have not been tested in men or in children, or in patients with NLUTD.

1.3. Recommendation (Grade C)

- Investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check for themselves that they have an equivalent performance to their current system for measuring pressure.
- Investigators planning to use air-filled catheters for intravesical and intra-abdominal pressure in UDS are advised to check for themselves how the performance of their system compares to the standard reference values for clinical relevant limits (of pressures obtained with the classical systems).
- Clinicians using UDS should be well aware of the technical demands of measuring with a water-filled –external pressure system and should be able to (prevent and correct and) recognize these, also in post test evaluation.

1.4. Topic for Research

- Studies to compare the performance of air-filled catheters with (ICS- standard) water-filled pressure lines in the measurement of intravesical and intra-abdominal pressure during filling and voiding cystometry, to include 'fast' events such as coughing, in male, neurological and paediatric patients as well as analysis of test-retest reliability.
- Studies to determine the cause(s) of the earlier observed differences in pressure readings between water-filled and air-filled systems.
- Studies to determine the clinical relevance of difference in pressure readings between water-filled and air-filled systems.
- Studies to demonstrate the technical stability and clinical reliability of practice with the water- filled external pressure reference UDS systems.
- Studies to establish standard values for filling cystometry and pressure flow study in women.

2. OBJECTIVE ASSESSMENT OF BLADDER SENSATION

2.1. Conclusions and Recommendations 2013

Based on published results ICI2013 noted that there was a significant variation in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity despite the standardisa-

tion of terms. The committee concluded that strategies to derive bladder filling sensation parameters in a more automated and objective way (with patient controlled electronic analogue scale registration), have been showing plausible and applicable results. ICI2013 stated that these were however not sufficiently tested with regard to reliability, relevance, investigator independency or test retest robustness.

Bladder sensation during UDS is usually recorded by the simple expedient of asking the patient to inform the investigator when they experience different sensations. This is ICS standardised, but subjective, measurement that can be confounded by the investigators inadvertently or deliberately distracting the patient whilst bladder filling is being carried out. Investigators can also bias the measurement by inadvertent prompting, or by causing too much 'concentration' and unrepresentative awareness of the patient.[26] Bladder filling sensation has received increasing attention since urinary urgency and early filling sensation are clinically important and some treatments are believed to influence LUT sensation.[27 28]

A patient-activated, keypad 'urge score' device to measure sensations during bladder filling was introduced[29] that provided reliable and repeatable measures of different bladder sensations, however this never found its way into clinical routine. Filling sensations during conventional UDS were marked on a body map and this study suggested that women's bladder sensations vary in relation to their bladder condition.[30]

Daily life bladder sensation can be evaluated by a sensation related bladder diary and during cystometric bladder filling. 185 women with SUI-S, OAB-S or mixed UI filled out a 3-day bladder diary grading bladder sensation and measuring VV at each micturition. The maximum cystometric sensation (FS and ND) volumes were significantly larger than the diary VVs for corresponding bladder sensations, and this in all groups, leading to the conclusion that symptoms relate more to the diary.[31] In the development of the ICIQ bladder diary, the data from 264 patients diary recordings of urinary urgency showed weak agreement with questionnaire responses and UDS observations.[32] Although cystometry is regarded the gold standard to asses bladder filling sensation there is a paucity of evidence regarding its clinical relevance; also the question whether cystometry or alternative (diary –like) evaluations are more relevant remains unanswered.

Research has provided some in vivo evidence of the specific brain areas that are involved in LUT sensation, control and modulation, but this type of observations cannot yet be regarded as a replacement of cystometry, because up to now no brain pattern has been shown to correlate with a specific UDS abnormality.[33 34]

Many studies consistently show that the correlation between objective and subjective features of detrusor adaptation to volume increment, bladder proprioception and the subjective interpretation of filling is weak.[35 36 37 38 39 40 41] In fact these observations also demonstrate that UDS is adding new and objective diagnostic information to what has been gathered with history, voiding diary and clinical investigation. Both UDS, as well as signs and symptoms, are relevant to select further treatment, for instance in the identification of DU.[42]

2.2. Conclusion (Level 3-4)

- Based on published results, a significant variation exists in clinical practice to determine bladder filling sensation landmarks and maximum cystometric capacity, despite the standardisation of terms.
- Strategies to derive bladder filling sensation parameters in a more automated and objective way, have been published and show plausible and applicable results, however these have not been sufficiently tested regarding reliability, relevance, investigator independency or test retest robustness.

2.3. Heart Rate Variability

Heart rate variability was evaluated to serve as a monitor of the autonomic nervous system as an objective measure (indicator) for LUTD and/or bladder filling sensation, without arriving at a clinical application yet.[43 44 45]

2.4. Conclusions (Level 3-4)

- None of the analysis or testing methods of the autonomic nervous system has, to date, shown any relevance for the objective diagnosis of LUT function in neurologically intact persons.

3. NON-INVASIVE PRESSURE (& FLOW) MEASUREMENTS

Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. ICI2013 concluded (grade B) that non-invasive measurements of bladder or detrusor 'voiding- pressure' can be considered in clinical experiments in order to evaluate voiding function when the male patient is not required to undergo an invasive assessment of the storage function of the LUT. The ICI2013 did not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis UI, or of LUTD. [46 47] Recently a device to measure isovolumic (maximum) pressure during voiding at the location of the fossa navicularis. The pressures obtained correlated with BOOI based on detrusor pressure at maximum flow rate, but have not been tested for relevance for UI.[48 49] Measurement of perineal noise during voiding as another way of non-invasively quantifying male BOO has been evaluated but has also not

demonstrated relevance for the diagnosis of (male) UI.[50]

Transabdominal wall near-infrared spectroscopy was used to detect the haemodynamic changes that are associated with detrusor contractile activity. This has been demonstrable in a highly selective set of feasibility recordings and may lead the way for non-invasive detection of detrusor (over-) activity.[51 52] Another group has however not been able to replicate this.[53] The use of perineal ultrasound to detect turbulent flow in the male urethra has been reported.[54] Both near infrared spectroscopy and perineal ultrasound have not been tested, or are not applicable, for patients with UI.

3.1. Conclusions (Level 3)

- Non-invasive measurements of bladder pressure during voiding in men by the penile cuff or condom catheter have been shown to correlate with traditional invasive measurement of bladder pressure. None of these studies have shown any applicability in the diagnosis of UI.
- Near-infrared detrusor spectroscopy has in very selected recordings shown a relation with detrusor (over)activity but this has not been reproducible in an independent clinical follow up evaluation.

3.2. Recommendation (Grade B)

- The committee endorses that in clinical experiments non-invasive measurements of bladder or detrusor pressure may be considered in order to evaluate voiding function when the male patient is not required to undergo an invasive assessment of the storage (and continence) LUT functions.
- The committee does not recommend condom or penile cuff pressure, nor near infrared detrusor spectroscopy, for the diagnosis of UI, or of LUTD.

4. URETHRAL RETRO-RESISTANCE PRESSURE

In the measurement of urethral retro-resistance pressure (URP), a small meatal plug is inserted just inside the female urethra and saline is pumped into the urethra until the pressure reaches the value sufficient to overcome the resistance offered by the urethra when the fluid flows into the bladder. The pressure required to achieve and maintain an open bladder outlet is taken to be a measure of urethral closure function. The basic principle behind the technique has its origins in 1923 when Bonney made an attempt to measure the efficiency of urethral closure.[55] Slack et al studied 258 SUI-S women with the URP technique in comparison with MUCP and Valsalva LPP. The URP, in a group of 61 women, without symptoms of UI and who had negative standing UI tests, was significantly higher than in a group of women with SUI-S who had been tested previously.[56] This study also provided some test-retest data, which showed that URP measurements were consistent in individuals. Measurements of URP on 165 women with various UDS diagnoses were published subsequently.[57] Women with USUI had significantly lower URP than women with competent urethral sphincters. In the mixed symptoms group, URP mean values were not significantly different from those with DO competent sphincters, or those with USUI. The authors concluded that whilst there are significantly different URP measurements between women with DO and those with USUI, URP is not a diagnostic tool. An analysis of URP in 48 women with (clinical) SUI-S and also USUI, without pelvic organ prolapse (POP) before and after anti-UI surgery (colposuspension n = 8, TVT n = 6, TOT n = 34) and another study to compare URP with 'established measures of UI severity' showed that preoperative URP did not correlate with SUI-S in all women, had no predictive value and did not correlate with the outcome of anti-UI surgery.[58 59] As for women, retrograde pressures are obtainable for men also and have shown to correlate with 24-hour pad test volume.[60]

4.1. Conclusion (Level 2/3)

- After positive first reports of urethral retro-resistance pressure measurements it was shown that this measurement does not give any better information about urethral closure function than the urethral pressure profile or Valsalva LPP.

4.2. Recommendation (Grade B/C)

- The committee recommends that urethral retro-resistance pressure measurements are not used in clinical routine as an alternative to cystometry or (whn deemed necessary for) urethral pressure measurements made with conventional urodynamic equipment to diagnose female UI.

5. URETHRAL PRESSURE REFLECTOMETRY

Urethral pressure reflectometry was evaluated in an in vitro study for the simultaneous measurement of cross-sectional area and pressure in a collapsible biological tube to assess the female urethra.[61] The team postulated that these parameters had the potential to provide more physiological information about the urethra than could be obtained from conventional urethral studies. These investigators compared UPR with urethral pressure profilometry (UPP) in 143 women (105 patients and 38 healthy volunteers).[62] UPR was measured supine, both while relaxed and during 'squeeze', and while upright and relaxed, and compared with UPP using the perfusion technique, with the patient supine and relaxed. Short-term reproducibility and long-term reproducibility were also assessed. The authors showed that UPR measured the same pressure as UPP but the UPR was more reproducible, however clinical relevance of

this observation was not specifically discussed. Subsequently UPR parameters of in 30 SUI-S women and 30 volunteers (23 'continent' and 7 'nearly continent') were reported and compared with UPP.[63] A feasibility study using the technique has now been reported in 10 male patients.[64]

5.1. Conclusion (Level 3)

- Preclinical measurements of urethral pressure reflectometry opening pressure and cross sectional area ('dynamics') have provided some insight into urethral closure function and dynamics, but, as yet have no clinical relevance in the diagnosis of UI.

5.2. Recommendation (Grade C)

- The committee recommends that urethral pressure reflectometry is not used in clinical practice for the diagnosis of UI before clinical relevance, non-inferiority and/or superiority over current UDS has been demonstrated.

6. ULTRASOUND IMAGING

Imaging and ultrasound in relation to UI will be discussed in a separate chapter of this book. We will only give a short summary of ultrasound in relation with UDS observations.

The measurement of detrusor wall thickness has been used in several studies as a screening test for DO or for BOO with a variety of measurement techniques using transvaginal, transabdominal or trans perineal ultrasound. Different protocols were used and measured different parts of the bladder. This has resulted in contradictory data. Some data showed a smaller cystometric capacity in OAB-S -wet or DO, and an association between increased detrusor wall thickness and DO on UDS. Also, observations of an association of ultrasound detrusor wall thickness and BOO have been reported. Most researchers conclude that overlap of the results and the relatively low predictive value should be improved before bladder wall thickness is used in clinical practice.[65 66 67 68 69 70 71 72 73 74 75 76] Especially the specificity of detrusor wall thickness for UI (or DO) is not determined and probably unlikely. Studies of specific (other) patient groups have been reported. One, in SCI patients, concluded that detrusor wall thickness could not be used in such patients[77] and another in nocturnally enuretic children suggested that detrusor wall thickness could be applied as a screening tool to select children with DO.[78]

Twenty men (mean ± SD age 66 ± 6 years) with LUTS were included in a study to evaluate radio frequency ultrasound imaging -detrusor wall strain. This bladder wall strain correlated positively with detrusor pressure in some patients with a (urodynamic) isovolumic and/or voiding detrusor contraction. It has however been difficult to continuously measure the bladder wall in a large proportion of the patients.[79]

6.1. Conclusion (Level 3)

- There is some evidence that detrusor wall thickness is related to BOO as well as to DO.
- There is no evidence that ultrasound detrusor wall thickness analysis can discriminate between DO (with or without UI) and BOO. Detrusor wall thickness has a relatively low predictive value to discriminate from normal LUT function.
- There is a large overlap between normal and abnormal values in detrusor wall thickness and a lack of standardisation in ultrasound detrusor wall thickness measurement.

6.2. Recommendation (Grade C)

- The committee recommends that ultrasound detrusor wall thickness not be used in routine clinical practice for the diagnosis of LUTD related to UI.

III. URODYNAMIC STUDIES: NORMAL VALUES, RELIABILITY AND DIAGNOSTIC PERFORMANCE; REPRODUCIBILITY AND RELIABILITY OF URODYNAMIC STUDIES (ESPECIALLY UROFLOWMETRY CYSTOMETRY AND PRESSURE-FLOW STUDY)

1. CYSTOMETRY: NORMAL VALUES AND TEST RETEST VARIATION

1.1. Conclusions and Recommendations 2013

The ICI2013 concluded that various studies have been helpful in giving normal values and test retest variation of UDS parameters in healthy volunteers. But also, that there has been some evidence that evaluation of filling sensation may be different between laboratories, (thus: 'may be observer dependent'), making data exchange as well as generalization and interpretation of published data difficult. The ICI2013 recommended (Grade B) that investigators and clinicians bear in mind the results of UDS in healthy persons and to recognize 'normal' test-retest variation as well as the differences and/or variations between 'usual lower urinary tract behaviour', ambu-

latory monitoring and office UDS. The ICI2013 furthermore suggested that clinicians should be sufficiently aware of the normal variation, and normal values of LUT function and UDS and recommended further standardisation and a practical objective means of recognizing and recording the parameters relevant to sensation during bladder filling.

The ICI2013 has reported that several studies have been showing test retest variation of ±10-15% for various parameters (volume, pressure or flow) and observations; It was concluded that this can be regarded as the physiological variation of UDS. However also was concluded that various studies demonstrated clinically relevant practice variation and inter-rater/observer variation. In ICI2013 the committee recommended (grade B) that investigators and clinicians consider the inherent physiological variability of UDS and furthermore that investigators and clinicians evaluate the representativeness of the tests (which is an evaluation based on the patient's perception as to how well the tests have reproduced their usual LUTS and (dys)function, helped e.g. by the voiding diary. The ICI2013 had recommended that examiners strive towards maximal representativeness. Also, the ICI2013 recommended the sitting/upright position during cystometry to be most sensitive to reproducing DO. The ICI2013 recommended persistent attention to the standardisation of techniques, to education, and to practice quality evaluation, and consistency of interpretation of results, especially to reduce intra and inter-practice variation and inter–observer variability.

1.2. New Evidence 2016

The committee has not found new evidence regarding normal values of urodynamic tests.

The committee has also not found new evidence about test retest reliability of standard UDS. One health care system has proposed a national quality standard for UDS.[80]

1.3. Conclusions

The committee concludes that limits of normality of urodynamic tests are well established. (level 2)

The committee also concludes that precise limits for abnormal (reduced) compliance are not exactly known. (level 3)

The committee concludes that LPP has many variations (also without cystometry) and that standardization of technique(s) is lacking. (level 3)

1.4. Discussion

Normal function and physiology of the LUT is the basis for diagnosis of abnormality and dysfunction. Based on the commonly accepted limits of normality a specific dysfunction can be diagnosed.

There is a risk for UTI after UDS. A systematic review evaluated nine randomized controlled trials and concluded that prophylactic antibiotics did reduce the risk of bacteriuria after UDS but there was not enough evidence to suggest that this effect reduced symptomatic UTI.[81]

1.5. Recommendations (Grade C)

Persons diagnosing LUT function and dysfunction should be sufficiently aware of normal variation in the results of UDS. Persons should also be sufficiently aware of normal values and normal variation of LUT function and dysfunction.

Routine antibiotic prophylaxis should not be prescribed for UDS testing; the procedure should be performed sterile and aseptic as per good clinical practice.

2. REPRODUCIBILITY OF AMBULATORY URODYNAMIC STUDIES

2.1. Conclusions and Recommendations 2013

At the time of ICI2013 there has not been published data on the reproducibility or test retest differences of ambulatory UDS. Recently test-retest repeatability of the UDS parameters commonly utilized in ambulatory UDS for patients with NLUTD was evaluated on 64 consecutive patients with stable SCI who underwent two AM studies 24 hr apart. AM parameters were reliable for the reproduction of the main UDS parameters investigated in patients with NLUTD, except for the end filling detrusor pressure. Balancing (zeroing) the abdominal and vesical pressures was reported to be a problem in this study.[82]

2.2. Conclusion (Level 3)

One single centre study reported reproducibility of some parameters resulting from ambulatory UDS for patients with a NLUTD.

2.3. Discussion

Movement artefacts, pressure calibrating, and assessment of fill volume as well as prevention of urodynamic catheters to dislocate are challenging in ambulatory monitoring and standardization of the test is likely of relevance.[83]

2.4. Recommendations (Grade B-C)

- The committee does not recommend ambulatory UDS as a routine diagnostic test for patients with UI.
- The committee recommends greater attention to test retest differences of ambulatory monitoring
- The committee recommends standardization of the practice and the (technical quality-) analysis of ambulatory UDS.

3. INFLUENCE OF CATHETER ON VOIDING

3.1. Conclusions and Recommendations 2013

There is evidence that, in general, flow is reduced when voiding with a urodynamic catheter in the urethra and that this reduction is partially caused by the size of the catheter and it has been the opinion of ICI2013 that single catheters 6-8Fr incorporating both a filling channel and a pressure-sensing channel should be used for intravesical pressure measurement during cystometry (i.e. double lumen catheters in the case of using water-filled pressure lines). The ICI2013 recommended that investigators interpret pressure-flow voiding parameters and the subsequent PVR together with the free flow (not catheterised, representative) voiding parameters. Furthermore the 'standard' use of, as thin as possible, 'one-catheter-systems' (dual lumen if water-filled) for filling and pressure recording during UDS was recommended by ICI2013.

The committee found one new study that confirmed differences between free flow and UDS (catheterized pressure) flow. The differences were large and VV differences were not given, nor the voiding position or representativeness were reported.[84] A small single centre series concluded that the effect of a 4Fr catheter has been negligible.[85]

3.2. Conclusion (Level 3)

Recent studies have confirmed that the transurethral catheter that is necessary for pressure flow caused an effect on voiding and flow rate that is more or less proportional to the size of the catheter.

3.3. Discussion

Both test retest variation as well as variation in circumstances (e.g. position; privacy; (pre) VV) play a role in 'dynamic differences' between two flow rates. And especially the potential effect of position (for men) and privacy has not been reported in flow-pressure flow study. Also, differences may be large, especially in relatively high flow rates (>15mL/s) without clinical relevance. The committee considered that a dual catheter system is disadvantageous because of the manipulation just before the voiding as well as for the need for re-cathetrisation when a second test is deemed to be necessary. 6-8Fr catheters are ICS standard and pressure flow categories are based on measurements with catheters or this size, however only in male patients.

3.4. Recommendations (Grade A-B)

- The committee recommends that investigators interpret pressure-flow voiding parameters and the subsequent PVR together with the free flow (not catheterised, representative) voiding parameters when relevant in the diagnosis of concurrent LUTD, together with the complaint of UI.
- Standard of, as thin as possible, 'one-catheter-systems' (dual lumen if water-filled) for filling and pressure recording during UDS are recommended. If such system is not available, a double catheter system with removal of the filling line, before voiding or while testing stress- or DO UI (-LPP) is acceptable.

4. URETHRAL PRESSURE MEASUREMENTS

4.1. Recommendations 2013

ICI2013 concluded that diverse studies have shown considerable test-retest variation of all urethral pressure measurements or parameters and that normal and pathological values of urethral pressure parameters are largely overlapping. Furthermore, it was concluded that urethral pressures depend on the pressure recording catheter used and its orientation within the urethra and depend on patient position, volume of fluid in the bladder and position of the patient. The ICI2013 recommended that investigators and clinicians recognize the poor sensitivity and specificity of urethral pressure measurements and their significant test retest variation. The committee did not recommend urethral pressure measurement as the only UDS in patients with UI either to confirm or to refute USUI and that these measurements are judged in relation to other UDS (such as cystometry) and to the clinical examination.

5. LEAK POINT PRESSURES

5.1. Introduction

5.2. Recommendations 2013

ICI2013 concluded that diverse (definitions and) techniques to determine (urine) LPP exist and also that there is a weak association between abdominal LPP and the patient experienced or measured severity of bother, or amount of UI. Studies have shown that different techniques and patient positions influence the results of LPP. Studies evaluated by ICI2013 showed that the parameters from abdominal LPP measurements are not very helpful as predictors of success from surgery with either tension free vaginal tape or transobturator tape in patients with SUI-S. The ICI2013 did not recommend abdominal LPP measurement as a single UDS in patients with UI either to reject the diagnosis of USUI, or to select treatment and recommended that the result of abdominal LPP, when performed on patients with UI, should be judged in relation to other UDS such as cystometry

and to the clinical examination. The ICI2013 considers 'detrusor leak point pressure' in patients with NLUTD a relevant parameter. This is discussed in section III (neurogenic LUTD) and in section IV (patient evaluation: children).

5.3. New Evidence

Valsalva (abdominal) LPP was used in a study to evaluate the effect of urethral submucosal injection of bulking agent in patients with SUI-S (no –further- UDS was done) but no changes were reported although 50% of patients considered themselves as dry 1 year after the treatment.[86] In another study, to relate preoperative Valsalva LPP tot the outcome of the single-incision midurethral sling procedure in female USIU, 112 patients were evaluated according to preoperative LPP >90cmH_2O (mean 106cmH_2O) and LPP 60-90cmH_2O (mean 75cmH_2O). The overall subjective cure rates were respectively 65% and 63% (P= .744). with 'satisfied' -rates 59% and 69% (P = .600) with identical complication rates. Concluded was that preoperative VLPP values were not predicting outcomes of this treatment.[87] With regard to post RRP UI, Valsalva LPP was evaluated as a predictor of outcome in a retrospective cohort of 87 men. The primary study questioned whether a difference between intraoperative urethral circumference and artificial urinary sphincter cuff size affects postoperative outcomes. But LPP before AUS did not show any relevance with regard to outcome.[88] Valsalva LPP was found to increase while an intravesical balloon was placed but the amount of LPP change was not associated with UI and/or pad-test volume urine loss in a prospective study of 166 women with SUI-S of whom one third received sham treatment.[89]

5.4. Conclusion (Level 2-3)

New studies showed no evidence that (the height of) abdominal LPP is helpful as predictor of success of surgery in patients with SUI-S or patients with post RRP UI.

5.5. Reccomendation (Grade B)

- The committee does not recommend abdominal LPP measurement as a single UDS in patients with UI.

6. FILLING CYSTOMETRY AND SENSITIVITY AND SPECIFICITY OF SYMPTOMS

6.1. Recommendations 2013

Many studies evaluated by ICI2013 showed a weak correlation between symptoms and the result of UDS, especially filling cystometry, in patients with UI. The ICI2013 concluded that the sensitivity and the specificity of the symptoms, when systematically assessed and voiding diary is included, is at best and in the 'most typical patients', around 60-70%, in comparison with the result of the objective results of UDS.

In general, the ICI2013 committee considered the correlation of the SUI-S (expressed, or questioned) with the result of UDS is somewhat better than the correlation of urgency or UUI (expressed, or questioned) with UDS and concluded that especially when frequent voiding, urgency and/or UUI is part of the symptom complex of patients with UI, UDS is of value to obtain an objective (urodynamic) diagnosis, prior to invasive therapy. Taking into account the variation between various institutes and the test-retest variation, the ICI2013 considered it relevant that investigators and clinicians judge also how adequate the results of the performed tests represent the individual patients' symptoms. The ICI2013 recommended (grade B) UDS in patients with UI when an objective diagnosis is warranted. This is commonly the case when symptoms do not exclusively direct to SUI-S, or when (for all types of UI) conservative measures have not been successful, or when relevant co morbidity exist or relevant previous surgery has been performed. The ICI2013 recommended interpretation of the results of the complete UDS in relation with the symptoms, signs from the clinical (or other) examinations in conjunction with the voiding diary in all patients.

6.2. New Evidence 2016

UDS is the gold standard to assess LUT function and dysfunction. Some studies have challenged UDS with a clinical diagnosis as the comparator. Specifically, clinical diagnosis of SUI-S was used as a predictor of outcome of suburethral tapes in the VALUE trial. When this clinical diagnosis – not standardized for these trials- had been compared with one specific element (filling -cystometry) of the –not always ICS-standard- UDS diagnosis, neither way of diagnosis has been superior for the patients recruited in this study with SUI-S.[4] By doing UDS, it was reported in an abstract[5] (only, not in the published VALUE-study[4] report) that a significant proportion of patients had DO demonstrating the poor specificity of the clinical diagnosis even in expert centres.

Distinguishing or defining characteristics of detrusor overactivity

6.3. Recommendations 2013

Studies summarized in ICI2013 have not been able to show relevant differences in patterns or characteristics of DO whether the cause of overactivity (associated with UI- or not) is neurogenic or idiopathic and diverse studies have not been unable to reliably quantify the severity of DO (with or without UI), in a clinically or scientifically applicable way. The ICI2013 recommended (grade C) that neither the cause (neurogenic or idiopathic) nor the severity of DO is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

6.4. New Evidence 2016

No further evidence about quantification or objective reproducibility of the detrusor filling phase pattern, related to the diagnosis of the LUTD leading to UI, has been published.

6.5. Recommendation (Grade C)

- The committee recommends that neither the cause ('neurogenic' or 'idiopathic') nor the severity of DO is diagnosed on the basis of parameters from urodynamic investigation (cystometry).

7. PROVOCATIVE MANOEUVRES

7.1. Recommendations 2013

A systematic review available at ICI2013 concluded that more DO is seen when the patient is in the sitting position during cystometry, when compared to the supine position. There has also been some evidence that moving to a toilet, and also hand washing, is strongly provocative of DO.

Evidence suggests that ice-water cystometry can be applied to elicit DO in patients with NLUTD and that a detrusor contraction during filling with ice-water can be interpreted as a sign of pathologic (existing only in patients with relevant neurology) C-fibre reflex activity. It has, however, also been shown in this regard that false-negative tests do occur.

The ICI2013 recommended that the results of provocative cystometry are interpreted in the light of the patients' symptoms and to bear in mind whether the results obtained are representative. The ICI2013 recommended the performance of UDS in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the greater possibility of representative voiding and better patient comfort. The ICI2013 recommended that the position of the patient during filling cystometry is always taken into account because it can influence the demonstration of DO and recommended that repeating the cystometry in a different position can be helpful when it is deemed clinically necessary.

7.2. New Evidence 2016

The committee has not found new evidence regarding the position of the patient during cystometry.

7.3. Recommendations (Grade C)

- The committee recommendes that the results of provocative cystometry are interpreted in the light of the patients' symptoms and to bear in mind whether the results obtained are representative.
- The recommendes the performance of UDS in the sitting position whenever possible, because of the better sensitivity for filling phase abnormalities, but also because of the greater possibility of representative voiding and better patient comfort.

8. CLINICAL APPLICATIONS OF URODYNAMIC STUDIES

8.1. Women with Urinary Incontinence

The diagnostic rationale for UDS in women with UI in association with the currently changing management paradigm has been debated for some time. The think tanks of the International Consultation of Incontinence Research Society (ICI-RS) have discussed this diagnostic rationale and suggest that the patients' presentation can be more precisely delineated as syndromes. E.g. that the SUI syndrome (SUI-S), the overactive bladder syndrome (OAB-S), and the neurogenic LUT dysfunction syndrome (NLUTD-S) are suggested as more precise and descriptive terms that can be used to delineate categories of patients based on symptoms and signs. The diagnostic process for patients with LUTD should be carefully implemented and personalized to rationally select patients for invasive UDS and improve the outcome of initial management.[90]

8.2. Urodynamic Evaluation is Recommended

- When a patient presents with symptoms and signs of LUTD (especially UI) that are not typically 'SUI-S' or 'overactive bladder (wet) syndrome' or not (typical) nocturnal enuresis (syndrome).
- When a patient presents with new or persisting symptoms and signs of LUTD after initial (or subsequent) management or when a patient, after initial management expresses the wish for alternative (and/or more invasive and/or irreversible) management.

IV. STRESS URINARY INCONTINENCE SYNDROME

1. URETHRAL PRESSURES AND SEVERITY OF STRESS URINARY INCONTINENCE

1.1. Recommendations 2013

Various studies have shown a weak association between UI severity and urethral function tests (LPPs and urethral closure pressures) and cohort studies have shown that UI volume and intravesical volume at leakages are poorly associated with symptoms' severity and/or with patients' quality of life. Furthermore, ICI2013 concluded that studies have shown that ure-

thral function tests (LPPs and urethral closure pressures) are of very little value in predicting the outcome of treatment with suburethral tapes. Studies to demonstrate any relevance of urethral function tests (LPP and urethral closure pressures) in predicting the outcome of non-surgical or other treatments for SUI-S are lacking.

The ICI2013 recommended (grade C) that urethral function measurements of LPPs and urethral closure pressures are not used as a single factor to grade the severity of UI and therefore did not recommend the use of contemporary urethral function tests for prediction the outcome of any surgical treatment for SUI-S.

1.2. New Evidence 2016

A new study published showed, validating the earlier evidence, that urethral pressure and/or LPP did not have a predictive value towards outcome after 6 months of TVT surgery, apart from the 6% patients with very low urethral pressures (<20cmH_2O).[91]

Two expert opinion reviews have discussed the lack of evidence specifically for the management of patients with very low urethral, (leak point or closure) pressures and both have concluded that the many possible surgical solutions do not differ very much in outcome.[92] [93]

1.3. Recommendation (Grade C)

The committee does recommend that LPP and urethral closure pressures are not used as a single factor to grade the severity of UI

The committee does not recommend the use of contemporary urethral function tests for prediction the outcome of any surgical treatment for SUI-S.

2. ASPECTS OF URODYNAMIC STUDIES RELEVANT TO THERAPY FOR STRESS URINARY INCONTINENCE

2.1. Conclusion and Recommendations 2013

ICI2013 reported that it has been concluded in a model study, based on a selected retrospective cohort that UDS is not cost effective in the *primary* health care setting for women with predominant SUI-S symptoms. The model demonstrated however also, that in a *referred* population UDS is the most accurate way to obtain an objective diagnosis in an individual patient with UI symptoms. The ICI2013 summarized that it has been concluded in retrospective and prospective cohort studies that symptoms of 'pure SUI' do not exclude other LUTD.

2.2. New Evidence 2016

Mixed UI has repeatedly been shown to have a poorer outcome than SUI-S alone in surgical trials.[94] Despite this in one study OAB-S symptoms were reported to be more likely to improve rather than deteriorate after TVT in one study.[95] However 'de novo' OAB-S symptoms were reported to arise in another.[96] A study found in follow up of 200 patients after 10 years that persisting or new onset OAB-S is an important reason for dissatisfaction.[97]

The question is whether there is any role in predicting outcome other than differentiating mixed from pure USUI. Detrusor opening pressures have been investigated in outcome for colposuspension and fascial slings and found not to help[98] whereas another study[99] suggested opening pressures were predictive of outcome of retropubic tape surgery. These findings were supported by a further study the following year.[100] A recent systematic review asked the question 'does preoperative UDS improve outcomes of women undergoing surgery for SUI-S?' [101] This review was importantly influenced by the VALUE study and concluded that the current evidence suggests that UDS does not influence the outcome of SUI-S surgery. The review supported the need for new properly constructed RCT's for this. They highlighted the results of the VALUE study where, in a non-inferiority design, 93% of the 630 patients underwent surgery.[4] They did demonstrate that 18 patients had the choice of surgery changed based on UDS, although the protocol -design intended to omit the UDS results. A second study was again a non-inferiority design looking expressly at where the UDS findings were discordant with symptoms including 578 patients of which 268 were discordant. 126 women were randomised to surgery direct or individual tailored therapy.[6] A further secondary analysis of the women VALUE study concluded that UDS did significantly change clinical diagnosis but that UDS –as was planned- infrequently changed treatment plan or influenced surgical decisions.[102] This position has been further evaluated by the INVESTIGATE 1 study.[103] This study was designed to demonstrate the feasibility of a RCT into the role of UDS for patients with SUI-S. The investigators concluded such a trial was feasible and their pilot data indicated that there was a change in practice based on UDS with 80% versus 95% undergoing surgery. The study wasn't powered to demonstrate significance and the authors concluded that 450 patients would be needed in each arm to answer the question, which is more than the 2 (prospective) studies which have reported to date.

ICI2013 Initial assessment –committee has suggested 'a simplified accurate and reproducible system for anatomic changes and establishing the likelihood or presence of SUI' (p377-378: General recommendations in the female patient) as a research recommendation. In the absence of such system, to date, it is impossible to establish the need for UDS in a reliable manner. At present the predictive value of a clinical diagnosis towards the selection and the outcome of management are unknown. UDS can only be disputed (or discarded) as the gold standard when prospectively compared to its alternative; a (reproducible)systematically derived clinical assessment or

a well-defined 'stress urinary incontinence syndrome', and/or a precisely defined 'urgency urinary incontinence syndrome' (or 'overactive bladder –wet syndrome').

2.3. Recommendation (Level B)

The committee recommends that UDS is kept in mind when discussing costs (risks, harm) and benefit (objectivity of the diagnosis) of the various methods (clinical or UDS) of diagnosis for (LUTD and/or) UI, in relation to the method of treatment.

3. PREDICTION OF FAILURE OF SURGERY

3.1. Recommendations 2013

ICI2013 found that LPPs are reported not to correlate with failure (or success) rates of colposuspensions, transobturator and retropubic suburethral, bone-anchored suburethral slings and that there is conflicting evidence that low urethral closure pressures are associated with poorer success rates of sub-urethral slings. The ICI2013 recommended that measurements of urethral function (LPP and urethral closure pressures) are not used to predict the likelihood of success after surgical treatment for women with uncomplicated primary SUI-S.

3.2. New Evidence 2016

ICI2016 did not find any new evidence. The committee, however, reviewed some studies that commented on the new onset or persistence of OAB-S in women with mixed symptoms of UI. An extensive review of the outcome of all little invasive surgical techniques after minimal 2 years showed that 'storage LUTS' and 'voiding LUTS' had an overall similar prevalence of about 15%.[104] A –very- long-time follow up study observed that the likelihood of being storage symptom- free declined steadily after each year until ±30% after 10 years, whereas voiding symptoms stabilised after the first year but further increased in prevalence after 6 years.[105]

4. VOIDING DIFFICULTIES AFTER SURGERY

4.1. Recommendations 2013

ICI2013 concluded that female voiding dysfunction has been defined in many ways thoughout the many publications, with consistency in UDS criteria- and analysis lacking. ICI2013 also concluded that test methods have been unable to reliably predict which patients will develop voiding difficulties after surgery for SUI. In particular, normal UDS do not predict absence of voiding difficulties after sub-urethral tape. However, it was found that flow rates, if abnormal, may be useful in predicting post-operative voiding dysfunction and retention following retropubic and transobturator suburethral slings. ICI2013 recommended that patients are informed that it is difficult to predict who will develop voiding difficulty following surgery for SUI and recommended that patients with poor flow rates before (intended) surgery are informed that they have a higher likelihood of having voiding problems following suburethral tape placement for USUI.

4.2. New Evidence 2016

A review has confirmed the ICI2013 conclusions.[106]

5. POSTOPERATIVE URGENCY, MIXED SYMPTOMS OF INCONTINENCE, OR OVERACTIVE BLADDER SYNDROME

5.1. Recommendations 2013

The prospective studies that were available at ICI2013 indicated that OAB-S, mixed symptoms of UI and/or DO during UDS at presentation have a negative effect on the outcome of (all available) surgical interventions for SUI-S. ICI2013 concluded that test methods have been unable to reliably predict which patients will develop de-novo urinary urgency (OAB-S) after surgery for SUI-S. Post hoc evidence suggests that procedures for the treatment of SUI-S which are more 'obstructing' produce a higher chance of de novo urinary urgency (OAB-S).

The ICI2013 recommended (grade B) that patients with SUI-S are informed that the chance of developing urinary urgency (OAB-S) following surgery is unpredictable and recommended also that patients are counselled before surgical intervention regarding the possibility of a lesser success rate when OAB-S and/or (UDS) signs of DO (or reduced compliance and/or cystometric capacity) exist.

5.2. New Evidence 2016

A new study showed that also patients with 'obvious' symptoms of SIU-S may have DO, and that these patients are successfully managed without surgery.[107] Another recent study demonstrated that when TVT-O was done only in patients with USUI without (UDS-) DO the cure rate after 10 years was markedly higher (95%) than the usual reported ±75-80%.[108]

6. THE ROLE OF URODYNAMIC STUDIES IN PREDICTING URINARY INCONTINENCE IN WOMEN AFTER

SURGICAL MANAGEMENT OF PELVIC ORGAN PROLAPSE

6.1. Recommendations 2013

Various studies summarized for ICI2013 have shown that symptoms of SUI can appear after surgery for POP. A variety of methods to uncover 'occult stress urinary incontinence' in women with POP had been reported and in prospective studies it has been demonstrated that all have different sensitivities and specificities. Standardisation of these tests was considered necessary. The ICI2013 recommended that patients with POP are informed about the relatively unpredictable chance of developing SUI after surgery for POP.

6.2. New evidence 2016

Two recent studies added to the body of evidence regarding the unpredictability of SUI after POP repair.[109] [110] A systematic review found that voiding problems were more incident after combined and/or preventive surgery.[111]

6.3. Conclusions (Level 2-3)

Prospective studies showed that cystometry does not predict outcome of suburethral tape surgery (continence or not) when patients are selected for surgical intervention on the basis of the 'clinical diagnosis' SUI.

UDS is referred to as the gold standard for the diagnosis of LUTD in all teaching books. (level 1) However it is yet not precisely determined in which type of patients a urodynamic diagnosis ('above' clinical diagnosis) is needed for long term -effective and safe management.

Specific reproducible and uniformly agreed upon criteria for clinical diagnosis of SUI are not available, also not specific criteria for complex or complicated SUI.

6.4. Discussion

Earlier consultations have recommended UDS for all patients with symptoms of SUI. Based on the recent trials' conclusions, but also already without or before the publication of those trials many patients underwent suburethral tape surgery for diagnosis of SUI established on the basis of signs and symptoms. Systematically collected long term follow up is scarce, difficult, because of patients lost and the now available publications usually report single centre expert outcomes. Nevertheless, there is also not much –epidemiological- evidence that the management of patients with 'clinical uncomplicated SUI' without UDS is very risky. It should be borne in mind however that the recruitment rate for the published trials evaluating the need of UDS, notably, in the expert centres, has been fairly low. This seems to allow the interpretation that the incidence of patients with 'uncomplicated SUI' has been relatively low and that a large percentage of patients with the complaint of UI, or with SUI symptoms plus other LUT-symptoms, signs and or (complicating) factors, deserves UDS.

6.5. Recommendations (Grade 2)

- The committee recommends to consider to manage a patient with SUI-S without UDS diagnosis, and to individually discuss the likelihood of success and or the possibility of side effects or failure of surgical management (with suburethral tape) based on the available clinical diagnosis.
- The committee recommends to consider to manage a patient with SUI-S not without UDS diagnosis when clinical signs of not typical or not uncomplicated or complex SUI exist.
- The committee recommends to consider to include the complete and systematically gathered results of UDS in the management plan for patients with SUI-S when UDS is done.

V. URGENCY URINARY INCONTINENCE AND OVERACTIVE BLADDER SYNDROME

1. FREQUENT VOIDING AND URGENCY; OVERACTIVE BLADDER SYNDROME

1.1. Recommendations 2013

Studies have not been able to show a strong association between OAB-S and DO. Various studies have directly or indirectly concluded that the individual prediction of the response to treatment for OAB-S, on the basis of the characterization or quantification of DO during UDS, is impossible. The ICI2013 recommended (Grade B/C) that investigators and clinicians discuss with patients with DO that neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches.

1.2. New evidence 2016

A single centre retrospective study with good power confirmed the lack of association between subjective symptom severity and bother and objective measurements reinforcing the need for objective assessment, especially in proof of principle studies. However, it was also observed that UDS cystometric capacity, compliance as well as onset of first contraction were associated with perceived severity of symptoms.[112] Another well powered multicentre study demonstrated that subjective symptom assessment for women with LUTS was not reliable to uncover the pathophysiology that caused the symptoms.[113]

1.3. Recommendation (Grade B)

- The committee recommended that investigators and clinicians discuss with patients with OAB-s that neither the quantity nor specific characteristics of OAB-S predicts the response to any of the therapeutic approaches.
- The committee recommended that investigators and clinicians discuss with patients with OAB-S that when UDS is performed neither the quantity nor specific characteristics of DO predicts the response to any of the therapeutic approaches, but that the absence of DO is relevant for further management.

VI. URGENCY URINARY INCONTINENCE

1. RECOMMENDATIONS FOR URODYNAMIC DIAGNOSIS IN WOMEN WITH URINARY INCONTINENCE

1.1. Recommendations 2013

The ICI2013 recommended non-invasive UDS (voiding and UI diary, PVR, and possibly uroflowmetry) for all patients with UI and suggested that non-invasive and simply reversible treatment based on symptoms and signs is offered in situations where one of the two types of UI is likely to exist, without invasive UDS, if the patient accepts the uncertainty margins of the diagnosis and there is no symptom or sign for coexisting dysfunctions or complicating factors. The ICI2013 provided the following examples:

- Uncomplicated symptoms of SUI with normal bladder diary, normal uroflowmetry and without relevant PVR. (Symptomatic pure SUI with no symptoms or signs of voiding difficulties), for treatment with pelvic floor muscle training.
- Uncomplicated symptoms of UUI or OAB-S, with a bladder diary in accordance with these symptoms, with normal uroflowmetry and without relevant PVR. (Symptomatic pure UUI with no symptoms or signs of voiding difficulties), for treatment by bladder training with or without combined pharmacotherapy.

The ICI2013 has recommended that, whenever surgical intervention is planned, whenever there is doubt about the pathophysiology, or about whether the UI is uncomplicated or not, that invasive UDS should be performed in order to provide the knowledge on which rational treatment decisions and prognosis can be based. The ICI2013 also recommended UDS for patients that have had failed first therapies. The investigation should be tailored to the individual patient; typically, this means that it will be a comprehensive examination of multiple aspects of storage and voiding function, and not just of the UI itself.

1.2. New Evidence 2016

New studies have attempted to better define the role of clinical diagnosis in women with (predominant) symptoms and signs of SUI[4 6] but have regrettably not been very generalizable (or reproducible) because of little standardisation in both experimental arms (clinical diagnosis as well as UDS), because of preselection (inclusion) and also because of crossing over within the trial.

1.3. Recommendations (Grade B)

- The committee recommends that that invasive UDS should be considered for women with SUI-S or in order to provide the knowledge on which rational treatment decisions can be based.
- The committee recommends to perform UDS whenever there is doubt about the pathophysiology causing (UI, the SUI-S or) the LUTS, whether the UI is uncomplicated or not.
- The recommendeds UDS for patients that have had failed first (pragmatic) therapy.
- The recommendeds (complete, standard) UDS for women that have LUTS and or UI and representative ineffective voiding (significant PVR) and or reduced flow rate.

VII. PATIENT EVALUATION: MEN

1. URODYNAMIC TESTING OF MEN WITH SYMPTOMS AND SIGNS OF LOWER URINARY TRACT DYSFUNCTION

1.1. UDS for Male LUTS and / or UI

1.2. Conclusions and Recommendations 2013

Epidemiologic studies have shown that LUTS in men >50 years of age are highly prevalent and that storage LUTS are relatively more reported than voiding or post-micturition symptoms. Case series available at ICI2013 indicate that in male patients, OAB-S -wet is associated with (a UDS diagnosis of) DO. OAB-S dry might involve other LUTD or be the result of obstructed and/or ineffective voiding. Guidelines at that time suggested that the initial treatment for male LUTS could be based on the predominant symptoms, without UDS and recommend, on the basis of expert opinion, UDS when the initial management fails to resolve the storage LUTS.

Various studies indicate that male LUTS including UI may be due to detrusor dysfunction and/or BOO and that DO and urethral sphincter dysfunction should also be considered in young men with LUTS or in men with a small prostate. Mono and multi-centre cohorts show that although UDS do not unequivocally predict outcomes of pharmacological or surgical treatment, treatment results are, however shown to be better predicted in patients who have had objective UDS and objective evidence of BOO. ICI2013 recommended (grade C) that all elderly male patients with UI should receive a complete UDS when conservative measures fail, to understand the problem.

1.3. New Evidence 2016

OAB-S and LUTS associated with prostate enlargement and BOO in men increase with age.[114] [115] Coexistence of UI in men with BOO and DO increases with age and with the degree of BOO.[116] In addition to BOO associated UI, other pathological conditions such as nocturnal enuresis and post-micturition dribble are also clinically relevant in men.[117] Evaluation for men with LUTS and UI starts with symptoms assessment,[118] further discussed in the diagnosis chapter of this book. The best independent predictors of USUI, apart from clinical history were the patient's age and the ICIQ-UI-SF.[119] ICI questionnaire and 3-day bladder diary have been shown to be valid, reliable, and responsive to change.[120] Non-invasive investigations such as uroflowmetry and measurement of PVR are easy to perform but cannot distinguish BOO from DU. [121] [122]

Surgical intervention, to relieve BOO and associated LUTS, based on UDS diagnosis of outflow obstruction resulted in an improvement of flow rate and reduction of symptoms.[123] Preoperative UDS diagnosis of DO is associated with significantly more storage symptoms than the patient without DO.[124] Multivariate analysis revealed that a low MUCP at baseline UDS was the independent predictor of de novo UI after HoLEP (laser prostate enucliation) for BPH-BOO.[125] In an expert group discussion, it was concluded that UDS is indicated for proof of principle and for the evaluation of effectiveness of new treatment modalities for elderly male patients.[126]

DO can be characterized as phasic DO and terminal DO. Phasic DO has been reported to occur more frequently in young individuals with OAB-S.[127] For patients with OAB-S without response on empirical treatment, UDS can provide definite information that can identify associated pathologies and/or alter the treatment course.[128] Clinically, video-UDS or UDS had also been used to evaluate the (continence) function of the (intracorporeally reconstructed orthotropic) U-shape ileal neobladder,[129] and the Studer orthotropic ileal neobladder,[130] or investigation of pouch UI. The functional length, static and dynamic closure pressure and pouch capacity.[131]

A retrospective study of UDS involving men with OAB-S (with or without UI) revealed that 43% of men with OAB-S had evidence of BOO. There was weak correlation between (OAB-S) symptoms and UDS findings, underscoring the relevance of UDS.[132] An assessment of UDS patterns in post stroke UI found UDS patterns vary depending on timing of the study, suggesting spontaneous changes, and the relevance of UDS-timing, but also test retest variability.[133]

Although there has been no definite definition of reduced and increased bladder sensation (which may be associated with OAB-S), it was considered helpful in one single centre study when reduced bladder sensation was defined as a bladder volume at first sensation >300 mL and increased bladder sensation as bladder volume at the first sensation <100 mL.[134]

Retrograde LPP has been introduced to test the tightness of virtue quadratic sling for post RRP UI while prepubic tensioning, and after transobturator and prepubic arms were secured in place.[135] The efficacy and clinical application of current urethral function tests were however recently also discussed by the ICI-RS and this committee reported that each of the methods currently in use has limitations as to its use and proof of reliability.[136]

Ambulatory UDS is sensitive for the detection of DO, however prone to artefacts and time consuming. Nevertheless, the method is considered valuable by some experts when all other diagnostic means have failed.[137] This was demonstrated in patients with suspected detrusor acontractility on UDS and UI of unclear origin; however, the UDS graphs with this manuscript do also show significant technical flaws.[138] Ambulatory UDS has been shown reliable for the reproduction of the main UDS parameters in patients with NLUTD-S, except for the end filling detrusor pressure.[139]

1.4. Conclusions

UDS for (elderly) men with LUTS has demonstrated relevance for the diagnosis of bladder sensation, and volume adaptation (bladder compliance and detrusor relaxation) it has also demonstrated relevance in the quantification of BOO.

UDS is in all guidelines referred to as the gold standard test to evaluate men with signs and symptoms of LUTD.

Most elderly men who present with OAB-S have voiding symptoms also and a consistently reported large percentage has – UDS - evidence of BOO.

BOO, DO, reduced cystometric capacity, PVR and/or DU can occur in any combination per individual, independent of the symptoms presented, and can all be quantified on the basis of UDS.

Specific evidence that UDS improves outcome is limited, and pragmatic or 'symptom oriented' management is demonstrated to be very well possible in many men. Nevertheless, UDS is the bais for therapy when it is desired to be directly aimed at the pathophysiology that is responsible for the symptoms if the patient and/or the physician consider that relevant.

1.5. Recommendations (Grade C)

- The committee recommends invasive UDS for a patient for which objective elucidation of the pathophysiology of the LUTD is deemed relevant.
- In general, this shall be relevant when invasive management is considered. But it may also be relevant in relatively symptomatic men with relatively young age and/or relatively small prostates and/or relatively good flow rates and/or with relatively large volume of PVR, when initial management fails.
- The committee recommends invasive UDS for patients that have experienced failure of surgery for LUTS.

2. LUTS AND OAB-S IN MALE PATIENTS

2.1. Conclusions and Recommendations 2013

ICI2013 concluded that symptoms and signs of "new onset" UI or nocturnal enuresis in men are unspecific with regard to the underlying dysfunction, also when large PVR or retention are excluded and recommended UDS of men with symptoms and signs of UI.

2.2. New Evidence 2016

OAB-S symptoms (with or without UI) are highly prevalent in men and the prevalence increased with age.[140] [141] LUTS, believed to represent bladder storage (dys)function were more prevalent than voiding -symptoms or post-micturition –symptoms in men. The most prevalent LUTS was nocturia.[142] [143] A longitudinal study showed that OAB-S and UI symptom severity progresses over time.[144] The overall incidence of DO was 76% in male patients with OAB-S symptoms, 63% of men with urgency (OAB-S dry) had DO, while 93% of men with urgency and UUI (OAB-S wet) had DO.[145] [146] Men who received invasive UDS were less likely to undergo surgery as treatment for LUTS.[147] Urethral closure pressure had a significant association with BOO and also micturition urethral pressure profilometry, but not with UI in men.[148] Most of patients with BPH and (urodynamically demonstrated) BOO have OAB-S which can be relieved after TURP, however, one study found that the presence of preoperative terminal (end filling-) DO might be negatively associated with the improvement of OAB-S and or UI.[149] In patients who received vaporisation of the prostate for BPH-BOO, a study found the number of patients with moderate to severe storage LUTS decreased from 60% to 49% at week 6 to 12% at month 6 but DO has not been a predictor in this series.[150]

UDS has been used to evaluate outcome of medical treatment for OAB-S in men and may demonstrate objective improved LUT function, or not. In a study including both genders, combined low and standard dose trospium and solifenacin has shown to provide good clinical effects associated with UDS changes.[151] On the other hand, in evaluation of the therapeutic efficacy of once daily tadalafil in men with LUTS, a randomized, placebo controlled 12-week clinical trial revealed that, although there had been a symptom response, no objective UDS changes were found. Especially no change in any of the relevant cystometric (DO) or pressure flow study parameters (BOO) was observed.[152]

Systematic review of percutaneous tibial nerve stimulation (PTNS) concluded that PTNS has been efficacious for symptoms of frequency and/or UUI in most cohort studies.[153] 77% of participants with an initial positive response to 12 weekly PTNS treatments safely sustained symptoms improvement to 3 years with an average of 1 treatment per month.[154] PTNS treatment also leads to improvement in open label uncontrolled studies patients with multiple sclerosis[155] which was observed to persist for one year in one recent study.[156] A review shows that UDS proof of (PTNS-) effects is observed (evaluated) in a very limited number of studies and patients and has demonstrated some improvement of cystometric capacity and occasionally reduction of DO.[157]

In a systematic review of the mean outcomes for the use of BoNT-A in the management of LUTD it was shown that the cystometric capacity increased 60% and maximum filling phase pressures reduced by 40%, with its clinical relevance demonstrated in voiding (emptying) diary parameters.[158]

EAU guideline advised initial treatment of LUTS and OAB-S is conservative and of empirical nature, including lifestyle interventions, physiotherapy, physical therapy, pharmacotherapy.[159]

AUA/SUFU guideline for diagnosis and treatment of non-neurogenic OAB-S in adults has provided expert opinion supplement from the 2012 original version to 2015 version with recommendations for refractory OAB-S[160] however with an undefined role of UDS, and with ambiguous definitions of 'treatment resistance'.[161]

2.3. Conclusions

LUTS in men >50 years of age are highly prevalent and storage LUTS are frequently reported. In male patients, OAB-S wet symptoms are associated with DO. UI in elderly male may be due to DU /urinary retention and/or BOO.

UDS has been demonstrated to be able to differentiate storage dysfunction (DO reduced compliance) and outflow dysfunction (bladder neck obstruction, DU and BOO) or combinations of these, in men with LUTS.

LUTS –storage symptoms, with or without (U)UI, diminished gradually over time after vaporisation of the prostate. Patients with preoperative terminal DO might have lesser rapid improvement of OAB-S symptoms after TURP.

Epidemiology shows that non- urologic causes for nocturia are prevalent and nocturnal polyuria can be diagnosed with a 24 h frequency-volume chart.

UDS in elderly men indicate however that DO and BOO with ineffective voiding may play a role in a proportion of patients with nocturnal enuresis and or UI.

UDS has shown that use of a phosphodiesterase inhibitor initiates no objective changes of the LUT function in men, although it does affect symptoms.

New onset, night time UI, in an elderly male, warrants urgent urodynamic pressure-flow analysis.

2.4. Recommendations 2016

- The committee recommends UDS for objective diagnosis of male LUT function, especially in elderly men with UI or in (young) men with LUTS and relatively small prostates not responding to management or medical treatment based on clinical examination.
- The committee recommends to consider UDS for objective diagnosis of LUT function in men with prostate enlargement to ensure specific management of the dysfunction causing the LUTS.

3. URINARY INCONTINENCE AFTER TRANSURETHRAL RESECTION OF THE PROSTATE AND OPEN PROSTATECTOMY FOR BENIGN DISEASE

3.1. Conclusions and Recommendations 2013

Case series have concluded that UI after prostatectomy may be attributed to bladder storage dysfunction and can exist in association with (neo-bladder neck) BOO although the most prevalent cause is sphincteric dysfunction. Retrospective studies have shown that UDS cannot predict which patient will develop SUI or DO (with or without UUI) after surgical treatment for prostatic BOO. Studies have shown that UDS can identify the aetiology(ies) of UI (or other LUTD) after surgical treatment for prostatic BOO, however the predictive value for the outcome of subsequent treatment is unknown. Good evidence shows that more than 90% of post prostatectomy UI is SUI, with or without co-existing LUT dysfunction.

The ICI2013 recommended (grade C) to consider UDS for the diagnosis of concomitant LUT dysfunction in patients with clinical stress UI after prostatectomy, but especially if further surgical or invasive treatment is considered. The ICI2013 committee also recommended definition of UDS cystometric capacity (technique, 'end of filling' and evaluation) specific for patients with post prostatectomy UI.

3.2. New Evidence 2016

The most common aetiology of UI after surgery for BPH-BOO was sphincter weakness or deficiency, followed by sphincter weakness plus DO, reduced compliance alone.[162] [163] Approximately 1% of patients who have undergone TURP or laser TURP suffer from UI. [164] [165] Kuo urodynamically evaluated 185 men aged from 55 to 91 years who had variable LUTS after TURP and found that UI was present in 74 patients (40%), BOO and DO with DU were the most common findings associated with UI, followed by DO.[166] UDS in UI showed no significant change in filling or voiding parameters when suburethral male-slings were implanted.[167]

3.3. Conclusions 2016

Many case series show that sphincter weakness is the most common aetiology of male UI after prostatectomy (TURP). However, case series and reviews show that other LUTD besides sphincter incompetence play an incident role in post prostatectomy UI.

Case cohorts show conflicting evidence whether DO before prostatectomy is an important indicator for the postoperative persisting incidence of UI, or for the outcome of interventions to treat the UI.

3.4. Recommendations

- The committee recommends UDS when elderly male patients have persisting LUTS and/or UI after surgical treatment for prostatic BOO if further surgical or invasive treatment is planned.

4. (ROBOT ASSISTED) RETROPUBIC RADICAL PROSTATECTOMY

4.1. Conclusions and Recommendations 2013

Case series and reviews show that the main cause of UI after RRP is sphincter weakness and that DO contributes in only a small proportion of those patients and show also that higher maximal urethral closure pressures or abdominal LPPs, indicating greater urethral sphincter resistance is not of utmost clinical relevance. UI after RRP will improve with time. A study concluded that postoperative urethral pressure profile after 6 months may be predictive for persistent UI. The ICI2013 recognised that UDS for UI after RRP is not particularly important for the diagnosis of sphincter dysfunction (SUI) in patients with post RRP UI. However, the ICI2013 recommended that UDS is considered in patients where other dysfunctions of the LUT (obstructed voiding, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of signs and symptoms.

4.2. New Evidence 2016

UI after retropubic (robotic assisted) radical prostatectomy (RRP) is prevalent despite improvement in surgical techniques. Changes of the detrusor and

urethral function after RRP deserve attention to improve continence. Approximately 10-14% of patients, suffer UI 2-5 years after RRP.[168] UI after brachytherapy was reported by 4 to 6% of patients at 1 to 2 years after treatment.[169] Comparative studies indicate that UI is the most common adverse effect of RRP.[170] Preoperative DO was not associated with worse post RRP UI outcomes, or increased incidence of UI. Single centre observations suggest that even if DO is present in men with USUI after RRP they may be considered for a male sling procedure.[171] After RRP, Q_{max} was reported to increase, and detrusor voiding pressure and the urethral resistance factor to decrease significantly. In univariate analysis, DO was found in 34% of patients who were still incontinent 6 months postoperatively and only in 5% of patients who were not.[172] After RRP, the functional profile length (FPL) decreased by 64%, because the prostate was removed, but also maximum urethral closure pressure (MUCP) decreased by 41% on average. Non-nerve sparing technique was a prognostic factor for a higher relative decrease of MUCP after RRP.[173] UDS can identify aetiologies of post RPP UI such as sphincter weakness. Neo bladder neck outflow obstruction, DO and mixed symptoms of UI may also be contributing to post RPP UI.[174] UDS parameters change after RRP by reducing BOO without affecting overall detrusor contractility. Urinary continence rates were gradually improved to a satisfactory level in more than 80% of patients by 12 months after RRP.[175] DU is relatively common in patients with post RPP UI, 40% of patients demonstrating an isovolumetric detrusor pressure of <50 cmH_2O.[176] Although DU was found in 49% of patients preoperatively, DU did not affect UDS parameters and LUTS improvement after RRP.[177] Another large cohort study also demonstrated DU and Valsalva voiding was observed in 41% of patients after RRP, which might reduce (longer term) success of treatment for post RPP UI.[178] In a longitudinal observational cohort study, patients with bladder neck contracture after RRP presented with preoperative DU.[179]

Urethral sphincter insufficiency was the most common UDS abnormality after RRP (88%), followed by DO, neo bladder neck obstruction, impaired detrusor contractility, and normal findings.[180] Co-existing detrusor dysfunction had to be taken into consideration, as well as intrinsic sphincter deficiency, in order to properly treat persistent post RPP UI[181] [182] but also postoperative UPP after 6 months may be predictive for persistent UI.[183] The abdominal LPP was considered a relatively poor predictor of UI severity and, therefore, is reported to have limited value in the UDS evaluation of post RPP UI.[184]

Preoperative UDS may help to estimate the likelihood of postoperative UI[185] [186] [187] although it remains undetermined how to clinically implement this knowledge.[188] In robot-assisted RRP series, the outcomes of continence rate improved from 75% to 93% for cases 501-700, suggesting that surgeons experience is relevant (or 'confounding' UDS evaluations).[189] The role of UDS on predicting continence outcome after RRP remains controversial. Small cohort studies drew different conclusions that preoperative UD DO may have influence on post RPP UI.[190] [191] Investigation before and after RRP revealed 25% of patients had DO in associated with decreased bladder compliance, diminished FPL and MUCP after operation, 22% of patients had detrusor hypoactivity.[192] Nerve sparing (NS) RRP significantly affected urine loss immediately after RRP compared with non-NS surgery.

Increased urine loss immediately after RRP was noted in 86% of patients, which could be attributable to decreased MUCP and abdominal LPP.[193] In addition to a lower MUCP, a reduced bladder compliance was shown in 27% and idiopathic DO in 31% of patients with post RRP UI.[194] Chronological UDS of patients with UI after RRP revealed that LUT worsens immediately after RRP and recovers over time.[195] In one small cohort study, 21% of patients had UI at 1 year after RRP. Bladder compliance <28ml/cmH_2O, MUCP<50 cmH_2O and BOO are reported to be independent UDS factors correlating with UI after RRP.[196]

The aetiology of UI following RRP, either stress or UUI, also cannot be predicted by the ICIQ-UI-SF survey.[197] UDS have been done to demonstrate the UI in many reports but also recently, to better show the detrusor storage function, mimicking the situation after AUS placement (and preventing incontinence during cystometry). In practice, this may be more relevant than the demonstration of UI in patients with post RRP UI.[198]

In patients receiving radiotherapy for prostatic cancer, patients with larger prostatic volumes (> 35 mL) and/or with UDS confirmed BOO were more prone to problems after brachytherapy.[199] A high PVR (> 100 mL) is associated with slower resolution of voiding symptoms, prolonged (more than 3 days) catheter dependency, and increased post-brachytherapy surgical intervention for BOO.[200] Men after brachytherapy were, in a single centre retrospective cohort, reported to have a relatively high incidence of DO, prostatic and urethral strictures and prostatic urethral stones.[201] Compared to patients with prostate cancer receiving RRP, high dose external beam radiation therapy and brachytherapy iodine implantation as monotherapy had a better rate of urinary continence and sexual function however more bowel and urinary irritation.[202]

UDS prior to AUS implantation revealed that DO was much more prevalent in the group with radiation (26%) than in group without radiation (5%). Post-operative urinary urgency with or without UUI was found in similar proportions of the 2 groups, suggesting that pre-operative DO did not predict outcome in this group.[203] Patients with post RRP UI, with adverse UDS findings such as DO, low compliance, low detrusor contractility, or decreased cystometric capacity and first sensation of filling were reported to have similar outcomes after AUS implantation to those just with USUI.[204] [205] The presence ofLUTD was also not predictive

of surgical outcome in one other series and preoperative use of few pads, less severe post RPP UI, and a longer interval between RRP and post RPP UI surgery were associated with a successful outcome.[206] Patients with postoperative retrograde LPP < 50 cm H_2O and DO were however seen to be associated with failure in another series.[207] The transobturator - tape for treatment of post RPP UI was shown to be effective with an improved mean MUCP and high cure rate.[208] UDS after a bulbourethral composite suspension revealed a significant increase of MUCP (40 v 58 cmH2O), and functional urethral length (31 v 40 mm), the Q_{max} was slightly reduced (16 v 12 ml/s); however pressure flow study was reported to show not obstructive voiding in all patients.[209] A functional pelvic cine-MRI study in patients with a bulbourethral composite suspension revealed that this procedure was associated with an increase in urethral length, urethral coaptation zone and bladder neck elevation, implying a non-compressive mode of action. However, no difference on imaging was noted between patients showing clinical success or failure.[210] [211] Using the Argus T adjustable system for treatment of post RPP UI, at 30 month follow-up 88% of patients were dry or improved. The retrograde LPP increased from 18 to 35 cmH_2O after intraoperative adjustment. Transient inguinal or perineal pain was reported by 61% of patients and postoperative infection occurred in 6%.[212] The overall cure rate for the AdVance and AdVanceXP transobturator male sling was reported to be 80%. This procedure was safe and efficient in patients with mild UI after RRP.[213] Using an Advance transobturator male sling for post RRP UI, among 38 patients 28 (74%) reported successful 3 months after operation. A small cystometric capacity was reported to have potential impact on the success of the procedure.[214] Patients with a preoperative Valsalva LPP of >100 cmH_2O have a high degree of predictability for success for AdVance sling procedure.[215] Among 35 patients who underwent AUS implantation for post RPP UI, 16 (46%) had postoperative urinary retention requiring CIC but this resolved within 7 days with no reported effect on continence outcome.[216] A cadaver model demonstrated that a tandem cuff as such did not improve retrograde LPP, but that proximal bulbar urethral circumference was greater than distal circumference and therefore the addition of a more proximal cuff was improving efficacy.[217] In men who failed to demonstrate incontinence during intubated UDS prior to AUS placement for post RRP UI a high rate of anastomosis stricture (and history of radiotherapy treatment) was observed, but anti-incontinence outcome for these was not affected by this.[218] However, another study showed, although transobturator male sling provides good continence outcomes for post RPP UI on average, previous pelvic irradiation seems to compromise the effectiveness of the procedure.[219] Volume adjustable balloons implantation was used to treat post RPP UI with a success rate of 37/49 (75%). A longer duration of UI, the use of >5 pads daily, and a small cystometric capacity predicted unsuccessful clinical outcome of this technique.[220]

4.3. 2016 Conclusions (Level 2-3)

The main cause of UI after RRP is sphincter weakness, but reduced compliance and DO with or without neo-bladderneck outflow obstruction contribute in an unknown proportion of those patients.

UDS have demonstrated value to identify the aetiology of LUTD after surgical or radiotherapy treatment of prostatic carcinoma.

Both urethral and detrusor (adaptation) function are prone to be affected after retropubic or RRP. Decreased bladder compliance, lower detrusor pressure during voiding, higher Qmax, and reduced maximal urethral closure pressure are noticeable immediately after RRP.

DU is commonly observed in patients with UI after RRP, and may be a risk factor for the development of neo- bladder neck (stricture).

Leak point pressures and urethral pressures, measured in their various ways, are consistently reported to be improved after anti -incontinence treatment using the various surgical techniques, and their improvement is associated with cure or reduction of UI volume and/or pads use.

Clinical indicators for reduced chance of success of post RPP UI -surgery are lesser amounts of urine loss, less pad use, and higher preoperative Valsalva LPP however precise action limits for these are not available.

Anastomosis stricture (may also prevent UI to be demonstrable during UDS), reduced compliance and DO as well as Valsalva voiding are urodynamic predictors of failure although with unknown specificity.

Retrograde LPP may be a good tool for adjustment of male sling tension to balance the resistance during post RPP UI -surgery.

Anti-incontinence male sling, composite suspension apparatus and AUS device have been shown good surgical outcome for post RRP UI.

4.4. Recommendations (Grade 3)

- This committee recommends that UDS should be performed when RRP UI has not spontaneously improved and conservative measures have failed.
- The committee recommends that UDS for patients with RRP UI is not only done to evaluate USUI but that it is also done specifically to evaluate bladder storage function. (Thus: to do cystometry with the prevention of early/massive leakage during the test and with filling until practically acceptable volumes, e.g. 3-400mL, to 'predict' the situation after regaining continence).

5. UDS FOR PATIENTS WITH POST (RADICAL) PROSTATECTOMY

URINARY INCONTINENCE AND PERSISTENT SYMPTOMS OF LOWER URINARY TRACT DYSFUNCTION AND OR FAILED SURGICAL MANAGEMENT

5.1. Conclusions and Recommendations 2013

ICI2013 concluded that studies LPPs and urethral pressures, measured in their various ways, are consistently reported to be improved after anti -incontinence treatment using different surgical techniques, and their improvement is associated with cure or reduction of UI volume and/or pad usage. Most single centre reports conclude that UDS variables, used to evaluate voiding, do not show clinically significant change after suburethral sling procedures or AUS implantation. The ICI2013 committee recognised (grade B) that UDS for UI after RRP is not particularly important for the diagnosis of sphincter dysfunction (SUI) in patients with post RRP UI but recommended that UDS is considered in patients where other dysfunctions of the LUT (BOO, valsalva voiding, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of signs and symptoms.

5.2. New Evidence 2016

Other dysfunction may be more prevalent in patients with persistence of LUTS and or UI after surgical management of their post RRP UI. The committee has however not found specific (new) evidence. Recent series and reviews have little or not elaborated on UDS evaluation for recurrent LUTD and or UI after RRP.[221 222 223 224]

Recommendation

- The committee recommends that UDS is considered in patients with post RRP UI.
- The committee recommends UDS for patients with post RRP UI when co-existing dysfunctions of the LUT (neo bladder neck BOO, valsalva voiding, significantly reduced bladder compliance and/or DO) cannot be excluded on the basis of clinical history, e.g. radiotherapy, signs and/or non-invasive UDS and symptoms.

6. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

6.1. Recommendations 2013

The ICI2013 found expert agreement, on the basis of many case series, that UDS is of great relevance to establish the management and to achieve the best long term clinical outcome for patients with NLUTD and found also that VUDS is necessary when anatomical information is deemed clinically relevant. ICI2013 concluded that case series have indicated that it is possible to monitor patients without anatomic abnormalities (absence of a high likelihood of VUR and or bladder diverticulae) of the LUT (especially adult age SCI and unaffected LUT function before the lesion) with cystometry and ultrasound of the UUT.

No specific reports about the optimal frequency and techniques of follow –up UDS in patients with NLUTD has been available at the time of ICI2013. No conclusive evidence exists about the predictive value for treatment with regard to ice-water testing, or of ambulatory monitoring of patients with NLUTD. Some evidence from centres of excellence indicates that 'one channel, cystometry' can be applicable in the monitoring (follow-up) of a selected group of patients with complete SCI.

The 2013 committee recommended that patients with signs and symptoms of LUTD and relevant neurological abnormalities should receive UDS (including filling and voiding cystometry) if initial treatment will be affected as a consequence of the diagnosis, or if 'simple' first line diagnosis and management have been unsuccessful.

This committee also recommended that at least at a baseline, to establish the state and function of the LUT in patients with NLUTD, VUDS evaluation is indicated if relevant anatomical abnormalities are to be expected.

The 2013 committee recommends that the frequency of testing and the techniques applied in the follow –up of patients with NLUTD be critically analysed and optimised, and recommended to develop guideline recommendations on the basis of those analyses. The committee recommended that UDS in patients with NLUTD be done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

6.2. New Evidence 2016

Any disturbance of the nervous system, can result in signs and symptoms of LUTD. The extent and location of the neurological dysfunction will determine the type of LUTD, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function.[225]

Neurogenic lower urinary tract dysfunction applies to a spectrum of clinical conditions and refers to the presence of LUTD symptoms 'when there is a relevant neurological condition'.[226] UDS can measure LUTD caused by a lesion in the brain and or spinal cord or peripheral nerves; associated with a congenital condition (e.g. MMC), an acquired, stable condition (e.g., stroke, SCI), or an acquired, progressive condition (e.g., multiple sclerosis [MS], Parkinson's disease, dementia).[227] Because not all patients with neurogenic conditions develop LUTD or have abnormal UDS findings, a specific understanding of the dysfunction in each individual is a prerequisite for the

correct choice of therapy. The aim of the diagnostic tests is to describe the (dys)function of the bladder, the urethra and the pelvic floor, their coordination during filling and voiding and their influence on other conditions (e.g. autonomic dysreflexia) or organ systems (e.g. renal function). Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of LUTD.[228]

6.3. Urodynamics in NLUTD

A lesion above the lumbosacral cord level (e.g., due to SCI or MS) is characterized by UI due to NDO and the loss in voluntary control of micturition, initially, in the spinal shock phase, leading to an areflexive bladder and urinary retention due to detrusor sphincter spasm.[237] In the case of suprasacral lesion above the lumbosacral cord level, the patient will lose voluntary and supraspinal control of micturition, and this usually leads to NDO which is characterized by spinal reflex pathways mediated by formerly silent capsaicin-sensitive unmyelinated C fibres.[229] In these cases, bladder contractions are poorly sustained and there is dyssynergia between the urethra and bladder.[237]

DO in association with neurological disease, may lead to UI. Observed during UDS, this type of UI is termed *neurogenic DOI*. The corresponding clinical sign or symptom is however variable: if the DO is accompanied by sensation (desire to void) it might be termed UUI; frequently however any sensation is absent, and so the term *urgency incontinence* is an incorrect description of the situation. For this reason, the term *'reflex incontinence'* was introduced by Abrams in 1988,[230] implying uncontrolled but complete emptying of the bladder without sensation. However, this term is no longer recommended.[254] NDO is often accompanied by DSD, which is a neurogenically determined failure of pontine coordination of detrusor and bladder outlet. In DSD the failure of the urethral sphincter and/or the pelvic floor to relax completely and sustained, when the detrusor contracts, causes a dynamic type of BOO which may not only prevent complete bladder emptying, but can also lead to chronic and/or intermittent high detrusor pressures observable with UDS. 'Overflow incontinence'[263] is another term that is no longer recommended.[254] It meant continuous or intermittent (-stress 'like') leakage from a constantly overdistended bladder.[263] However, neither what constitutes 'overdistended' nor the cause of the leakage are defined by the term 'overflow incontinence'. The presenting symptom is usually characterised by small amounts of UI, exacerbated by increased abdominal pressure, together with an inability to empty the bladder by voiding. Whilst UI appears as a problem of LUT storage function, 'overflow incontinence' originates from a dysfunction of voiding. Overflow incontinence can exist in combination with BPE and BOO but also exists in conditions with relevant neurologic pathology. Incontinence due to neurogenic DU (or acontractility) or DSD, with incomplete emptying, and neurogenic incomplete voiding with UI, are clinical (UDS) descriptions and have not been officially defined in the current standardization documents.

During UDS a frequent observation is low compliance and little or no detrusor activity until it reaches a pressure value sufficient to overcome urethral resistance and open the urethral sphincter with urine loss as the consequence. Clinically, this variable is usually reported as the detrusor LPP. If this pressure is elevated, and if similar pressures are attained during UI in daily life, then renal function is endangered because the constantly high detrusor pressure hinders outflow of urine from the ureters into the bladder. Conventionally, DLPP's of 40 cm H_2O or more are believed to increase the likelihood of UUT deterioration. There is evidence (mostly from paediatric studies with children with MMC) that UUT deterioration is more probable when DLPP is elevated above that 40cmH_2O.[231] However, the evidence for a cut-off at 40 cm H_2O seems less clear and an expert opinion appears to introduce 'as low as reasonably achievable' and a 'safe' detrusor pressure of below 20 cmH_2O, over the entire 'daily' volume range, when CIC is part of the treatment, is advised.[232]

Except in diseases where empirical, conservative therapy can safely be instituted (e.g. post-stroke or Parkinson's disease, some MS patients), UDS is usually deemed to be required, based on clinical practice guidelines and expert reviews. In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic LUTS after proper office evaluation for common aetiologies. Relevant investigations include; voiding diary, UDS (cystometry EMG, VUDS, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrography and ultrasonography.

Urodynamics is advised to provide the understanding of the situation on which rational treatment must be based. UDS is the only method that can objectively assess the function and dysfunction of the LUT. In patients, with NLUTD, UDS may be more provocative than in patients without relevant neurology. Even when empirical therapy is instituted without UDS, experts usually agree that the patient must be carefully monitored to determine whether and when UDS is needed.[227 233 234 235] UDS involve functional and dynamic assessment of the LUT and are used to assess detrusor and bladder outlet function.

In patients at risk for autonomic dysreflexia, it is advisable to immediately stop filling when this occurs, and it may be prudent to measure blood pressure during the UDS.[236] The rectal ampulla should be empty of stool before the start of the investigation. All UDS findings must be reported in detail and performed according to ICS technical recommendations and standards.[227 236 237]

A large proportion of patients with congenital neurological conditions show anatomical abnormalities that

involve the LUT, especially those born with abnormal neurology (MMC-see in children section of this chapter), and do have congenital relevant 'end organ (LUT)-sequelae' that can be demonstrated by imaging. VUDS is the test of choice usually advised on the basis of expert opinion when anatomic information is needed to establish treatment.[268] VUDS combines a fluoroscopic voiding cystourethrogram with multichannel UDS, allowing anatomic and functional assessment of the bladder and outlet. VUDS importance has been recently underlined by Marks et al who assessed that it should be considered in patients with neurologic findings or diseases as well as those with obstructed voiding, congenital genitourinary anomalies, or a history of genitourinary reconstruction.[238]

6.4. Special Tests

LUT function or dysfunction can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the 'ice-water test') is sometimes used in an attempt to identify NDO or to demonstrate the integrity of the detrusor muscle function and/or its innervation.[239] [240] Patients develop a detrusor contraction reaction on cooling if the detrusor and or the reflex pathway are intact. Patients with myogenic dysfunction or (iatrogenic) detrusor muscle damage, will not demonstrate contraction. Hüsch et al in their recent review assessed that the ice-water test is a reliable possibility to identify NDO subsequent to standard cystometry,[23] the clinical relevance of the ice-water test is however undetermined and in patients with high level SCI the test can aggravate autonomic dysreflexia.[241] [242]

A positive bethanechol test (detrusor contraction >25cmH_2O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given inconclusive results.[243]

One channel cystometry is reported to be feasible and reliable in patients with complete SCI that do not generate much (abdominal or other) muscle activity below the lesion level. Intravesical pressure will reasonably adequate represent detrusor (relaxation or) activity and allow cystometry pattern analysis in this situation.[244]

6.5. Reproducibility and Reliability of Tests

Since many patients with NLUTD have infra-pontine neuropathy, the influence of the emotional (limbic) nervous system on LUT function is reduced or eliminated; thus, UDS observations may be less influenced by the test circumstances than those made in individuals with an intact nervous system.[245] Nevertheless, the test conditions (e.g. the rate of filling the bladder) do affect the results, and should be chosen carefully.[246] Some advocate ambulatory monitoring to increase the representativeness of cystometry.[247] However, tests of longer duration with natural filling, did not relevantly assist in the diagnosis and selection of treatment in patients with SCI in a single centre prospective comparison.[248]

6.6. Does Urodynamic Testing Help to Select (Optimal) Treatment?

The aims of therapy for NLUTD are to achieve the most physiological filling and voiding conditions possible, as well as a management situation acceptable to the patient in their daily life. Long periods of elevated detrusor pressure during bladder storage phase or (abnormally prolonged and/or high pressure) voiding put the UUT at risk.[230] [249] The primary aim of therapy in patients with such problems is conversion to a low pressure bladder during filling,[233] [250] achieve continence, and to manage incomplete emptying due to (medically induced) DU or detrusor acontractility, with CIC.[268]

The primary aims for treatment of neuro-urological symptoms and their priorities can be summarized as follows:[251]

- protection of the UUT
- achievement (or maintenance) of urinary continence
- restoration of the LUT function
- improvement of the patient's QoL

Adequate management depends on whether the detrusor is overactive or has reduced compliance, and only UDS can answer those questions. Timely and adequate diagnosis is of paramount importance for the patient's QoL, as well as for safety.[252] [253] There is expert agreement that UDS is essential to monitor the effects of any treatment and in the follow up of any sequelae of the disease and its management. UDS is certainly needed to document the effects of new treatments or management strategies for patients with NLUTD. Changes in UDS do not always relate to clinically relevant improvements in these patients.[241] [246] A retrospective study shows with 80 SCI patients and a minimum follow-up of 5 years that it is possible to manage continence and preserve (100% of) UUT with ultrasound monitoring and repeated UDS.[254] Another retrospective observation indicates, in a series of 200 children with various types of NLUTD, that the intensity (frequency) of UDS follow up can be adapted according to the estimation of the risk for UUT deterioration on the basis of UDS parameters achieved at a baseline.[255]

6.7. Conclusions Level 3:

- Case series indicate that it is possible to monitor patients with NLUTD, without anatomic abnormalities of the LUT (especially adult age SCI) with cystometry and ultrasound of the UUT.
- Uncontrolled cohort studies indicate that non-invasive tests are less sensitive to relevant abnormalities in comparison with UDS and investigators have concluded that UDS is necessary when

LUTS arise in patients with neurologic abnormalities.

- No specific reports about the optimal frequency and techniques of follow –up UDS in patients with NLUTD exist
- No conclusive evidence exists about the predictive value towards better diagnosis or (the outcome of) treatment with regard to ice-water testing or ambulatory UDS of patients with NLUTD.
- Nocturia, nocturnal enuresis or LUTS may be the first, or an early, sign of Parkinsonism in elderly male patients, and may occur also in patients e.g. with MS, or other neurology and UDS is of value to establish a diagnosis of the LUT dysfunction(s) responsible for the symptoms.
- LUTD in male patients with Parkinsonism (or MS, or other neurology) can be the result of DO, (benign prostatic) BOO, dyssynergic voiding or PVR or any combination thereof.
- DO and DU, with or without urethral sphincter dyssynergia, are commonly found in male patients with Parkinson's disease.
- BOO is not specific to Parkinson's disease. For male patients with Parkinson's disease and LUTS(D), UDS and evaluation of prostate size are recommended to select appropriate treatment strategy.

6.8. Recommendations 2016

- This committee recommends that UDS evaluation should be considered at the time of first evaluation of patients with signs and symptoms or with suspicion of NLUTD and that VUDS is considered when anatomical abnormalities with the NLUTD are not unlikely.
- The committee recommends that the frequency of testing and the techniques applied in the follow up of patients with NLUTD be critically analysed and optimised, and continues to recommend that guideline recommendations on the basis of those analyses should be developed.
- The committee recommends that UDS in patients with NLUTD is done with special attention to the specific needs of the patients. It is highly preferable that all professionals involved are specifically trained for that purpose.

6.9. Recommendations for Research

- Comprehensive UDS should remain an integral part of the evaluation of new therapies and management strategies for NLUTD whether conservative, medical or surgical. The first goal of this should be to monitor the safety of the (developed) approach for the patient and the secondary goals of this UDS should be the efficacy outcomes (preferably on predefined UDS criteria).
- The frequency of UDS in the follow up of patients with NLUTD should be evaluated and optimised in the different neurologic conditions.
- Specific UDS diagnosis categories and diagnostic techniques need to be developed to quantify detrusor sphincter dyssynergia and neurogenic DU. Diagnostic techniques need to be developed to objectively evaluate bladder sensation.

VIII. PATIENT EVALUATION: CHILDREN WITH URINARY INCONTINENCE

1. INTRODUCTION

1.1. Conclusions and Recommendations 2013

ICI2013 concluded that retrospective and prospective studies have shown that symptoms and signs (in UI) do not adequately represent LUT dysfunction and UDS diagnosis in children. This is observed in otherwise healthy children with LUT signs and symptoms, in children with MMC, with ARM, with SCI, spinal cord tethering, cerebral palsy / spasticity, sacro-coccygeal teratoma, and also in children with urethral valves, VUR or bladder extrophy. Retrospective and prospective studies have shown that management of children with MMC is depending on UDS diagnosis and expert consensus exists in this regard and single centre retrospective (selected) series have shown that UDS-diagnosis is frequently relevant in children with the above -mentioned pathology but also that initial conservative management of (otherwise healthy) children with UI is possible without UDS-diagnosis.

No good evidence existed in 2013 to support optimal selection of VUDS (versus UDS) in most situations of children with UI, apart from MMC and VUR or to support individual decisions regarding UDS or VUDS (technique and timing) for follow-up in children. At the previous consultation also no positive evidence existed for the routine use of any of the new non-invasive UDS methods in children. Some (expert and/or single centre) evidence has been emerging for flow + EMG evaluation and follow-up in children.

The 2013 committee recommended managing children with UI,with a minimum of a bladder diary plus 3 representative flow-PVR –measurements and to use this information also to act as a reference for cystometric capacity and/or filling rate.

The committee also recommended to consider VUDS (only) when relevant anatomical abnormalities are (to be) expected and recommended the need to improve pelvic patch EMG technique, standards and evaluation/reporting.

The 2013 committee recommended that patients with symptoms and signs of LUT dysfunction with relevant

neurologic abnormalities receive (V)UDS when it is considered possible to initiate treatment as a consequence of the diagnosis based on the (V)UDS and when first line management has failed. The committee recommended to use bladder diary as the basis for cystometry but for patients with relevant neurological abnormalities also or specifically to use the catheterisation volumes (also). The ICI2013 committee does not recommend routine use of non- invasive UDS or ambulatory UDS in patients with relevant neurological abnormalities.

The committee recommends that UDS in patients with NLUTD is done with special attention to the specific needs of these patients and recommended specific (V)UDS -practice guideline(s) and training for (V)UDS in patients with (LUTD and) relevant neurological abnormalities.

1.2. New Evidence 2016

The indications for UDS evaluation in children are usually neurological, anatomical and/or functional abnormalities, with the types of studies to be performed being based on the presumed underlying patho(physio)logical conditions rather than on the presenting symptoms. UI in children is relatively more often seen (compared to adults) in combination with other LUT (or lower bowel or pelvic floor) dysfunctions. On the other hand, urinary continence and the development of 'full-grown' LUT function are the result of a normal maturation process that can be delayed in some, and may 'spontaneously cure' (or 'resolve') without requiring medical intervention. UDS is used to establish as clearly as possible the baseline situation where needed, so that changes as a result of treatment and/or growth can be assessed, and some guidance is obtained in the choice of treatment. Perhaps more clearly than in any other patient group, the aim of UDS in children is to provide objective knowledge about LUT function and dysfunction as well as to provide understanding to the care-giver and to the patient (and her or his parents).

Paediatric UDS implies a different approach than in adults and applications are unique in this population. Nevertheless, there has not been a validated guideline on the use of UDS in children but a publication of 2015 by the International Children Continence Society summarized the available evidence and expert based knowledge, and provided expert recommendations.[256] Also a specific standardized expert report for VUDS was presented in 2016.[257]

More extensively than in other ages, non-invasive UDS are initially explored, not only because they are more easily accepted and more applicable for children, but also to have comparable parameters during follow-up, and to exactly identify those children and clinical conditions that will benefit from further invasive exams. Essential are a meticulous and complete history, physical examination including clinical neurological testing and assessment by voiding diaries. The exact role and reproducibility of uroflowmetry have been strongly under consideration during the last years, especially if associated with pelvic floor EMG. Additionally, flow plus EMG is recommended in the ICS- Childrens Good Urodynamic Practices.[256]

Furthermore, ultrasonography is considered a useful tool with acceptable reproducibility for initial assessment when evaluating LUTS in children. Ultrasound LUT-studies in children include not only PVR and bladder volume but also bladder wall thickness (BWT).[258 259] The use of ultrasound is not only limited to a morphological analysis of the LUT, but also a dynamic one, with evaluation of the full and of the empty bladder,[260] and evaluation of the pelvic floor muscles movements and contraction endurance.[261]

2. NEUROGENIC LOWER URINARY TRACT DYSFUNCTION

2.1. Myelodysplasia

2.1.1 ICI2013 Conclusions and Recommendations

Retrospective and prospective studies have shown that the UDS diagnosis of (neurogenic) DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms. Many retrospective and prospective studies have shown that regularly repeated UDS in patients (children) with MMC reveals clinically relevant results regarding medical and surgical management. Based on expert opinion, VUDS testing is preferable above UDS without X-ray video; however, the exact advantage (e.g. in repeated investigation) is not substantiated. Various studies have shown that LUT function in children with MMC may change over time and with physical growth. No studies have been published that are a help to determine the optimal timing and frequency of UDS follow-up.ICI2013 recommended (grade B/C) that comprehensive UDS is advised in all patients with MMC throughout the entire life on a regular basis from earliest childhood and further that on indication, unscheduled UDS should be considered when relevant lower body half and/or LUT clinical or neurological signs or symptoms arise or when significant management, medical or surgical treatment changes have been instigated.

ICI2013 also recommended that the advantages and disadvantages of the addition of x-ray to UDS should be considered in children with MMC on an individual basis. Timing and technique of UDS in patients with MMC must be selected on an individual basis. To help identify children at risk for subsequent UUT and/or LUT deterioration or a changing neurological picture, initial UDS, very early in the neonatal period, are recommended for children with MMC. The ICI2013 recommended on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with LUT function in children with MMC (see also the chapter on faecal incontinence).

2.1.2 Discussion and New Evidence 2016

Treatment of NLUTD by intradetrusor BoNT-A injection gained growing consideration, also in children, with the mechanism of action now better known[262] Despite studies attesting to the good results of BoNTA in adult neuropathic DO and FDA approval, studies on its effectiveness on NLUTD in children remain controversial, and only scarce reports comment on the specific features of the disease process among patients and reasons for failure in some.[263 264] The evidence from uncontrolled studies was recently reviewed.[265] In a study aiming to investigate UDS parameters that predict outcome of intradetrusor BoNT-A injection in 37 children with NDO, preoperative bladder compliance (P .030) and open bladder neck (P .031) were found as important predictors of poor response at a regression analysis of outcome.[266] In another well conducted study on 16 children with NDO, who underwent intradetrusor BoNT-A injection, the patients with typical DO showed a significant increase in both the cystometric capacity (from 53% to 74% of age related capacity) and the compliance (from 4.7 to 8.6 ml/cm H2O) This resulted in 56% of patients with complete dryness between CIC. Among the patients that displayed (very) low compliance and no detrusor contraction at all, none demonstrated any notable clinical improvement.[260]

Another point is that, also because of the extensive use of BoNT-A, some less aggressive surgical procedures (i.e. without bladder augmentation) are attempted, and they may require preoperative UDS. In a cohort of 79 patients studied by UDS before bladder neck surgery without augmentation for neurogenic sphincteric incompetency, despite sustained pressures >40 cmH_2O and then assessed at 3 years, UUT changes developed in only 35% of patients, and resolved with medical management or minimally invasive interventions. This provided evidence for a statement that end pressures should not be used as an independent indication for augmentation.[267]

For children followed since birth, initial UDSin the neonatal periodhad been recommended for children with myelodysplasia, the basis being that they help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture.[268 269] This concept has been confirmed by the recent ICCS recommendations for initial diagnostic evaluation and follow-up of congenital neuropathic bladder.[270] Approximately 90% of children born with MMC will have a preserved UUT at birth. Over time, many children who have not received proactive urological care develop UUT and/or LUT deterioration, as an acquired phenomenon secondary to the development or progression of various LUT hostility factors such as DO, reduced bladder compliance, detrusor-sphincter dyssynergia and/or high LPP. The main identified risk factors from UDS which relate to increase of the occurrence and grades of UUT dilatation are decreased bladder compliance of <9 mL/cmH2O, increased DLPP of >40 cmH2O and acontractile detrusor.[271] The presence of severe bladder trabeculation has been coined as a parameter of BOO in incontinent children with NLUTD.[272] Bladder wall thickness measurement was also found as a predictor of LUT impairment in a case-control study on 80 children with myelodysplasia, decreasing the need for UDS.[273] When conservative treatment - as CIC, anticholinergic drugs and BoNT-A injections – are not sufficient, bladder augmentation is performed to relief or prevent UUT deterioration and/or VUR, usually without necessity of simultaneous anti-reflux repair.[274] Cystometry follow-up should be used to evaluate the effect of this treatment.[275 276]

Single centre studies suggest that prevention of high bladder filling pressure (before UUT dilatation is observed) is necessary and feasible even before any UDS diagnosis.[277 278] Expert reviews have recommend periodic cystometry when new onset hydronephrosis, VUR or UI develops.[279 280] A considerable number of myelodysplastic children can develop a change in neurological impairment, early in infancy or as they grow up and reach puberty, thus they need UDS follow-up to check changes[281 282] however, the interval and frequency of follow up UDS are not precisely established. In closed MMC, as lipomeningocele, UDS and the presence of neurological impairment were considered to have had crucial roles in determining the optimal timing of surgery in patients with lipomeningocele, and in diagnosing the onset of tethered cord, [283] UDS is also reported to be more relevant towards the outcome of neurosurgical interventions (untethering) than pelvic floor muscle needle EMG.[284]

In a long-term perspective of drugs use, UDS has been relevant to evaluate the treatment efficacy and tolerability of propiverine[285] and, over a period of 15 years, intravesical oxybutynin treatment showed adequate suppression of detrusor activity, cystometric capacity increase from the 5% percentile to the 25-50% percentiles for age, mean end-filling pressure from 24.5 ± 14.4 cm H2O, had returned to the safe zone.[286]

Because renal transplantation in patients with myelodysplasia and persistent LUT dysfunction carries increased (post –renal) risks for the grafted kidney, the existence or creation (augmentation cystoplasty) of a UDS confirmed low pressure bladder with adequate cystometric capacity before transplantation is deemed necessary.[287]

2.2. Occult spinal dysraphism

Lumbar cutaneous stigmata in infants may be associated with occult spinal dysraphism and often prompt urological evaluation, including UDS is needed. Series of children with occult spinal dysraphisms have documented abnormalities in striated urethral sphincter function (denervation and/or detrusor-sphincter dyssynergia) in 20 - 35% of babies under 2 years of age with normal neurological examinations in; thus emphasising the need for UDS in these children.[288 289 290] There is however also a correlation of 70–90% between an abnormal neurological examination and

the likelihood of finding an abnormality on UDS in older children.[291] [292] In the past, several studies demonstrated the usefulness of UDS to diagnose sacral cord function; better EMG activity (in up to 60% of the children corrected before 2 years of age) and or progressive changes in urethral sphincter function with very few of these patients having detectable alterations on physical examination.[293] [294] [295] A UDS before neurosurgical intervention was found to identify LUTD in clinically silent cases and also identified deterioration in these patients.[296] The usefulness of UDS in detecting lesions and during follow-up in children with known spinal cord abnormalities and/or tethered cord is still controversial. The association between abnormal UDS findings and need for tethered cord release was studied in a large series of 123 children, mainly (91%) non toilet trained infants. 19% of these had abnormal UDS, 85% abnormal spinal MRI and 96% abnormal spinal ultrasound: a significant association was found between abnormal UDS (P .002) and MRI (P .05), while ultrasound of the spine, was not associated with intervention for tethered cord release (P 1.0).[297] Taking into account the large spectrum of spinal cord lesions, a multivariate analysis was carried out on a uniform set of 59 patients with a fatty filum terminale and/or low-lying cord: UDS results were categorized by three urologists, blinded for the neurological diagnosis and it was found that pre and post untethering UDS do not predict continence status.[298] In a retrospective study on 149 tethered cord patients, operated also if asymptomatic when primary and also the symptomatic ones with re-tethering, UDS and prone MRI were considered to be the best tools for screening those patients at risk of symptomatic retethering.[299] The utility of UDS in preoperative work-up, monitoring for retethering, and long-term urologic follow-up is confirmed but requires further examination.

2.2.1 Conclusions (Level 2/3)

- Retrospective and prospective studies have shown that the UDS diagnosis of (neurogenic) DO and/or reduced detrusor compliance in patients with myelodysplasia or (occult) spinal dysraphism is not predictable on the basis of clinical signs or symptoms.
- Many retrospective and prospective studies have shown that UDS in patients (children) with meningomyelocele or (occult) spinal dysraphism, both initial as well as in the follow-up reveals clinical relevant results with regard to management and surgical or medical treatment.
- Evidence for the optimal interval and frequency of (V)UDS follow –up in patients with children with NLUTD is lacking.
- On the basis of expert opinion, VUDS testing is preferable above UDS without x-ray video, however the exact advantage of repeated VUDS in the follow-up of children with known (morphological or anatomical) abormalies is not substantiated.
- Various studies have shown that LUT function in children with myelodysplasia or (occult) spinal dysraphism may change over time (and physical growth) (Level of Evidence: 3)
- No studies have been published that help to determine the optimum of timing and frequency of UDS follow-up.

2.2.2 Recommendations (Grade B/C)

- Comprehensive UDS is advised in all patients with myelodysplasia or (occult) spinal dysraphism throughout the entire life on a regular basis from earliest childhood.
- UDS should be also be considered by a change in signs and symptoms, when relevant lower body half and/or urinary tract) clinical or neurologic signs or symptoms arise or when significant (surgical or medical) treatment changes have been instigated.

2.2.3 Recommendations (Grade C)

- The advantages and disadvantages of the addition of video (x-ray) to UDS should be considered in children with myelodysplasia or (occult) spinal dysraphism on an individual basis.
- Timing and technique of UDS in patients with myelodysplasia or (occult) spinal dysraphism must be selected on an individual basis.
- To help identify children at risk for subsequent urinary tract deterioration or a changing neurological picture, initial UDS very early in the neonatal period (e.g. starting from 3 months age), should be considered for children with myelodysplasia or (occult) spinal dysraphism.
- The committee recommends on the basis of expert opinion that anorectal function or dysfunction is simultaneously evaluated with LUT function in children with myelodysplasia or (occult) spinal dysraphism (see also the chapter on faecal incontinence in the book).
- The committee recommends research to determine the optimum of interval and frequency of follow up UDS in children with NLUTD.

2.3. Sacral Agenesis

2.3.1 ICI2013 Conclusions and Recommendations

ICI2013 concluded (Grade 3) that case series have shown that UDS evaluation of LUT function in children with (partial) sacral agenesis reveales a substantial incidence of clinically hidden dysfunction. It is shown that approximately one third of children with

ARM have spinal dysraphism and/or tethered spinal cord associated with UDS demonstrable LUTD.

ICI2013 recommended that clinicians should consider UDS in children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma, and that clinicians must consider that in children with LUTD, otherwise clinically silent sacral agenesis can exist.

2.3.2 Discussion and New Evidence 2016

No significant new evidence or observations arose during the last 3 years. Sacral agenesis, absence of the lower most vertebral bony segments, is a rare lesion that can be missed in infancy because of its sometimes subtle, clinical manifestations, with generally no loss of lower extremity motor and sensory function.[300] Urinary and/or faecal incontinence usually manifests at an older age when the child fails to toilet train on time. A careful physical examination noting flattened buttocks and a short gluteal crease is pathognomonic for the diagnosis. UDS studies had been shown to be 90% accurate in delineating the neurological deficit, which could not be predicted by the level of absent vertebrae. Sacral agenesis also shows variable association with ARM and/or spinal cord anomalies.[301] [302] [303] These studies reveal that 30 to 40% of these patients have a lesion type with DO and an intact, but dyssynergic, sphincter while 25 to 50% have areflexic detrusor and denervation in the sphincter, but 15-20% may have have normal LUT function.[304] MRI is for the evaluation of all patients that have sacral agenesis in the basis of a single expert centre review,[336] confirmed by another team, who found the extension of the sacral defect as a prognostic factor for retethering.[305] When MRI shows sacral or spinal cord anomalies, UDS should be considered, preceded by neurological exam and considering neurophysiological (evoked potentials) testing. The authors of this and subsequent studies recommend a non-invasive evaluation for all other children, and UDS when NLUTD is suspected.[306]

2.3.3 Conclusions (Level 3)

- Case series have shown that UDS of LUT function in children with (partial) sacral agenesis reveals a substantial incidence of clinically hidden dysfunction.
- It is shown that approximately one third of children with ARM have MMC and/or tethered spinal cord have UDS demonstrable and clinically relevant NLUTD.

2.3.4 Recommendations (Grade C)

- Clinicians should consider UDS in all children with sacral agenesis and also after (surgery for) sacrococcygeal teratoma. (see section f – Tumours)
- Clinicians must consider that in children with LUTD, otherwise clinically silent sacral agenesis can exist.

2.4. Spinal Cord Injury

2.4.1 ICI2013 Conclusions and Recommendations

Retrospective studies have shown that UDS of all children with SCI is relevant. Retrospective studies have shown that UDS of children with SCI results in diagnoses and treatment similar to adults with SCI. The ICI2013 recommended that UDS in children with SCI is planned on an individual basis, but no earlier than 6 weeks after injury

2.4.2 Discussion and New Evidence 2016

No further studies with evidence are available during the last three years. The scarcity variability of SCI in children makes it difficult to propose any one treatment program unless the specific type of LUT function is known on the basis of UDS.[307] It is important to measure detrusor compliance in order to determine the potential risk for VUR and hydroureteronephrosis**.**[308] All studies are single centre, retrospective and use historical controls for comparison. In the presence of elevated UDS filling and voiding pressures, a 30% incidence of UUT deterioration can be expected,[309] while effective voiding with pressures below 40 cm H_2O in the absence of detrusor-sphincter dyssynergia ensures a stable UUT.[310] UDS monitoring has been demonstrated to be relevant in the follow up and prevention of UUT deterioration.[311] In another study on 17 children aged 6 months-18 years with cervical (4), thoracic (8) and lumbar (5) SCI, all but one showed DO on first evaluation, which was changed to acontractile and/or compliant detrusor pattern by medical treatment; 7 had increased cystometric capacity and 8 decreased DLPP at follow-up; only 2/17 developed minor UUT impairment.[312] UDS, undertaken no earlier than 6 weeks after injury, allows for the manifestation of the extent of the neurologic injury.[313] As in adult patients autonomic dysreflexia can occur also in children and adolescents.[314]

Conclusion (level 2/3)

- Retrospective studies have shown that UDS of all children with SCI is relevant.
- Retrospective studies have shown that UDS of children with SCI results in diagnoses and treatment similar to adults with SCI.

2.4.3 Recommendations (Grade C)

- The committee recommends that UDS in children with SCI is planned on an individual basis, but no earlier than 6 weeks after injury.

2.5. Cerebral Palsy

2.5.1 ICI2013 Conclusions and Recommendations

ICI2013 has concluded on the basis of cohorts with historical/ literature -control groups that clinically unexpected LUTD – predominantly dysfunctional voiding and reduced cystometric capacity - can occur in

children with cerebral palsy an has recommended that clinicians should carefully evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected. ICI2013 reccomended that UDS is considered in all patients with spastic cerebral palsy.

Discussion and New Evidence 2016

A recent systematic review on 27 studies, describing prevalence of LUTS or UDS findings, found that 55% of the patients have at least one LUTS: storage symptoms are more common, and patients with pelvic floor overactivity are more prone to progress to UUT dysfunction in adult life.[315] Bladder (cystometric) capacity is decreased in most children with cerebral palsy, and PVR is present in an important proportion. Uroflowmetry and PVR are considered first line evaluation of LUT function in children with cerebral palsy.[316] UDS can direct management; Negative prognostic factors are the spastic subtype with quadriplegic distribution, moderate to severe functional impairment (Gross Motor Function Classification System [I-V; V= Severely handicapped/wheelchairbound] III or higher) and severe cognitive impairment.[317] A careful study by uroflowmetry on 57 patients showed that the symptomatic children (52%) had lower Q_{max} (P .013) and abnormal flow rate curves (P .022),[318] indicating non-invasive testing as a good screener tool. The vast majority of the children with cerebral palsy tend to gain normal LUT function, but often at an age that is later than expected for from DO.[319] A meta-analysis of UDS performed in 117 children with either persistent UI despite frequent toileting, or UTI, revealed normal function in 15% or DO in 73%.[320 321] In some recent studies, detrusor-sphincter dyssynergia was present in higher prevalence then earlier reports (11% versus 5%),[322 323] and normal function was less prevalent (only 15%) in the more recent case series.[324] Therefore, it has been suggested on the basis of expert opinion that cystometry and sphincter EMG are to be considered, but only when frequent toileting or anticholinergic therapy fails to control incontinent episodes, the child develops UTI from ineffective voiding, or when ultrasonography reveals hydronephrosis.

VUDS assessment can be considered in all patients with infantile cerebral palsy. The decision should not be based on clinical symptoms because at least half of the children with spastic cerebral palsy have clinically silent bladder dysfunction. 100% of children had clinical improvement postoperatively (selective dorsal rhizotomy), 71% who were incontinent preoperatively became continent and none had deterioration on UDS.[325 326] There is a spectrum of clinical and UDS LUT (dys) function in children with cerebral palsy; e.g. 77% void spontaneously but have UI. Children with UI have a significantly lower age related cystometric capacity,[312] and also lesser than expected for age voided volumes on uroflowmetry (plus PVR).[313]

2.5.2 Conclusion (Level 3)

- Some studies have shown that clinically unexpected LUTD can occur in children with cerebral palsy, especially when voiding symptoms are present.
- Observation and non-invasive testing are helpful, but UDS should be considered when UTIs or UUT dilation occurs in children with cerebral palsy.

2.5.3 Recommendations (Grade C)

- Clinicians should evaluate voiding in children with cerebral palsy and should consider complete UDS when dysfunction is suspected.
- UDS is to be considered in all patients with spastic cerebral palsy. Undiagnosed and untreated patient's bladder dysfunction remains pathological and potentially dangerous, and may damage the UUT.

2.6. Tumours

2.6.1 ICI2013 Conclusions and Recommendations

According to ICI2013, it was shown in single centre cohorts that UDS testing is relevant after resection of a sacrococcygeal teratoma. A study showed that all children with central nervous system tumours can have LUTD regardless of the location of the tumour.

LUTD exists after sacrococcygeal teratoma resection and recently again it was proposed, on the basis of a single centre cohort, that UDS is necessary for those children.[327 328] A recent study showed that children with central nervous tumours can have UDS abnormalities, whether the tumour is in the spinal cord or not. A single centre and selected cohort study concluded that a child with a central nervous system tumour needed urological investigation including UDS regardless of tumor location.[329]

2.6.2 Conclusion (Level 3)

- It was shown in single centre cohorts that UDS is relevant after resection of a sacrococcygeal teratoma.
- A study showed that all children with central nervous system tumours can have LUTD regardless of the location of the tumour.

3. ANORECTAL MALFORMATION AND PERSISTENT CLOACAL ANOMALIES

3.1. ICI2013 Conclusions and Recommendations

ICI2013 concluded that various studies have shown that a significant proportion of children with an ARM

have primary or secondary dysfunction of the LUT and/or LUT innervation abnormalities or pelvic floor dysfunction. ICI2013 recommended that clinicians should consider UDS in children with imperforate anus or ARM when clinical signs of LUTD exist and also should consider UDS in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological structural abnormalities exist, before and/or after reconstructive surgery independent of (the existence of) LUTS.

3.2. Discussion and New Evidence 2016

In the past, imperforate anus repair for high lesions frequently resulted in (stress-) UI due to a pudendal nerve injury that often occurs from surgical perineal approach. With the advent of the posterior sagittal anoplasty this complication has been eliminated as a cause for subsequent UI, although bladder neck incompetence may be a consequence of extensive mobilisation of the sigmoid colon to transfer the rectum to its final location.[330]

UI and LUTD may result from iatrogenic injury or from a pre-existing congenital neurological lesion. UI after definitive repair is reported as to be the result ineffective emptyingcausing 'overflow urinary incontinence' and underactive or acontractile detrusor, rather than urinary sphincter injury. Similarly, it has been reported, on the reconstruction of cloacal anomalies, that the main clinical characteristic of bladder dysfunction was a failure to empty,[331 332] presumably due to iatrogenic injury from extensive dissection, which can lead to peripheral nerve damage. In 2004, Warne et al prospectively studied the effect of surgical reconstruction by posterior sagittal approach and total urogenital mobilisation in either causing or worsening bladder dysfunction, in new patients with cloacal anomalies and ARM: those with cloacal malformation had a high incidence of innate LUTD, and a significant deterioration (frequently a change to DU) in bladder function.[333] In a prospective study on children with ARM, prior to, and following definitive procedure, only 9 of the 19 patients had normal UDS pre-operatively, and LUT function worsened postoperatively.[334]

UDS is required to evaluate LUTD in patients following repair of ARM (and Cloacal anomalies). The reliability and reproducibility of findings among the various studies analysed confers an important role for VUDS as an integral part of the evaluation and management of these children.

Moreover, reports of spinal MRI's reveal a 35% incidence of distal spinal cord abnormalities in children with an imperforate anus[335] NLUTD occurs in 50%,[336] and 40-60% of those patients who have tethered cord needed untethering.[337] Evaluation of all patients with ARM using MRI is recommended and when MRI shows sacral or spinal cord anomalies, non-invasive should be done, and UDS when NLUTD is suspected.[338] To detect spinal cord abnormalities in neonates, spinal ultrasound has been largely used as a screening test up in children to 5 months of age; a study on 244 ARMs showed a 100% specificity but a very low sensitivity (15%), thus stating that ultrasound is not suitable as a screening test for MMC in ARM, with MRI being necessary when symptoms occur.[339]

In summary; imperforate anus may occur as an isolated lesion but also in conjunction with spinal cord pathology and/or sacral anomalies (and associated cardiac, esophageal, bony ones), which was reported to occur in 38% of cases of ARM.[340 341] By combining the incidences in 3 studies it was found that the presence of an abnormal sacrum increases the likelihood of LUTD to as high as 76% (38 of 50 children).[342 343 344] When the rectum ends above the levator ani muscle there is a much greater chance of LUTD than when it ends below the pelvic floor[345] and the older the child is at the time of UDS the more likely he/she is to have abnormal LUT function.[346]

3.3. Conclusions (Level 3)

- Various studies have shown that a significant proportion of children with ARM has primary or secondary dysfunction of the LUT, LUT innervation abnormalities or pelvic floor dysfunction.

3.4. Recommendations (Grade C)

- Clinicians should consider UDS in children with imperforate anus when clinical signs of LUTD exist.
- Clinicians should consider UDS in children where, on the basis of an MRI, or on the basis of clinical examination, relevant neurological abnormalities exist, before and/or after reconstructive surgery independent of (the existence of) LUTS.

4. ANATOMIC ABNORMALITIES

4.1. ICI2013 Conclusions and Recommendations

ICI2013 has observed that many case series have demonstrated frequent UDS abnormalities, predominantly DO and reduced bladder compliance or large capacity bladder with impaired filling sensation, in children with PUV, urethral stricture, ectopic ureterocele, VUR or bladder exstrophy and that proper UDS has been shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities. ICI2013 concluded that the use of UDS has aided in an objective measurement of success or failure of treatments for these abnormalities.

ICI2013 recommended that clinicians should consider complete UDS of the filling and voiding phases, at least once, in children with PUV, urethral stricture, ectopic ureterocele, VUR or bladder extrophy and also that clinicians should consider regular uroflowmetry and PVR assessment in the follow-up and further management of children with PUV, urethral stricture ectopic ureterocele, VUR or bladder exstrophy.

4.2. Discussion and New Evidence 2016

No further major evidence arose during last 3 years regarding usefulness of UDS in congenital anatomical anomalies, apart from the general tendency to use non-invasive tools as much as possible in conditions which are not treated with surgical correction (i.e VUR and/or valve patients); while major abnormalities (i.e. extrophies or ARM or clocal anomalies) need UDS evaluation prior to decide complex corrections. The evidence still consists of uncontrolled case series and expert opinions although many clinicians now feel its usefulness is beyond question.

4.3. Posterior Urethral Valves

In the past UDS had been essential to understand (functional) obstruction, LUT dysfunction, persistence of UI and UUT (and renal) impairement evolution in boys with PUV.[347] [348]

The importance of bladder neck secondary obstruction remains one of the principal issues,[349] which may require further intervention on the basis of the UDS observation that DO and high maximum voiding detrusor pressures decreased consistently after bladder neck incision.[350]

In a series of UDS after valve ablation, the type of bladder function observed, correlates with the time elapsed from surgery; DO was the predominant pattern initially,[351] but changes are noted in both DO and compliance over time.[352] [353] [354] Myogenic failure, in conjunction with increasing capacity and poor emptying, are primarily a later phenomenon, and are most likely to be secondary to increased urine production and decreased frequency of voiding with advancing age.[355] Despite early valve ablation, a large proportion of boys treated for PUV have gradual detrusor 'decompensation' and/or secondary bladder neck outlet obstruction leading to obstructive voiding and finally DU or acontractility.

The persistence of UUT changes is related to the bladder's unresponsiveness to medical therapy for the DO and/or for DU(usually CIC). However, it is possible that this condition is secondary to insufficiently frequent voiding in the face of increased urine production. BOO from a secondary hypertrophied bladder neck can also occur, requiring further intervention.[356] Several studies have shown the predictability of the development of renal failure based on specific detrusor patterns seen on UDS: persistent poor compliance, high detrusor pressures, BOO and/or chronic failure of the detrusor to adequately contract during voiding with increased PVR.[357] [358] The extended use of antenatal diagnosis selected a 'new generation' of patients with PUV, who undergo proper early ablation of obstructing valves allowing normal cycling, which helps 'bladder healing'.

Nowadays, knowing the LUT conditions which are at risk for UUT deterioration, it is reasonable to follow the patients who underwent neonatal valve ablation and aggressive and early bladder training, by non-invasive UDS exams. In a case-control study two age-matched group of patients were followed by cystometry and pressure-flow study at least every 3 years or were monitored annually by non invasive tests from age 5: neither the prevalence of LUTD nor late onset renal failure differed significantly between the two groups.[359] In another multivariate analysis study, detrusor thickness greater than 1.3 mm was considered the only independent risk factor for later impaired bladder function.[360] Noninvasive UDS seems to be as safe and effective as invasive UDS in the long-term management of boys with PUV, and invasive UDS may be reserved for cases of progressive deterioration of LUTD or renal function.

4.4. Bladder Exstrophy

Once the exstrophied bladder is closed it may be difficult to manage persistent UI, UUT dilation or VUR. Whether and when to further improve continence function and whether to perform augmentation cystoplasty for a small capacity, poorly compliant bladder are challenging issues. In addition, as more children undergo complete primary repair of the exstrophic bladder in the neonatal period, the most accurate assessment of bladder function is by UDS; compliance reduces in up to 50% after surgery.[361] [362] Studies have correlated UI with age related cystometric capacity, compliance, DO and/or LPP.[363] UDS remain helpful to evaluate LUT before (and after) further surgical procedures and for research matters. To check potential injury to pelvic neurourological anatomy after complete primary repair of bladder exstrophy, needle -EMG was done on 13 children to evaluate the external urethral sphincter response to sacral reflex stimulation and during voiding, finding normal individual motor unit action.[364]

4.5. Ectopic Ureterocele

UDS in babies with an ectopic ureterocele had shown that several cases had a larger than normal cystometric capacity and DU,[365] but in a multicentre analysis of 616 children it was found that LUTD is present only in ectopic ureterocele.[366] Recently, there is an increasing agreement in favour of conservative management of paediatric duplex system ureteroceles, by mean of simple endoscopic puncture followed by close surveillance: VUR can resolve spontaneously in a significant number of patients, and bladder function should be conserved,[367] and even if secondary bladder surgery is needed, significant bladder dysfunction is rare.[368]

4.6. Vesicoureteral Reflux

It had been shown that VUR may be a secondary phenomenon resulting from LUT dysfunction and not (only) a primary anatomic abnormality at the ureterovesical junction in a significant proportion of children.[369] [370] [371] There is evidence that DO may lead to VUR in a marginally competent ureterovesical junction mechanism.[372] [373] This DO may be a natural phenomenon in the infant bladder, especially in boys,

due to the presence of higher voiding pressures[374 375] and/or a learned dysfunction in older children. DO tends to resolve with increasing age[376] going from an immature pattern with high pressure levels in the first two years or life, to a high capacity bladder with incomplete voiding.[377] Among UDS parameters, *high bladder pressure* at the onset of VUR was found a positive prognostic factor for spontaneous resolution of VUR (P .0005), independently of VUR grade.[378] The highest degree of VUR was found associated with highest detrusor pressure (P .038) in the group with 'urgency syndrome',[379] and no differences in resolution rates observed from grades I to V VUR in children with LUT conditions, patients with dysfunctional voiding having the most improvement and greatest (70%) resolution of VUR.[380] Another prognostic finding regarding the spontaneous resolution of VUR is intravesical volume at the onset of VUR: large cystometric capacity correlated with VUR during filling, while VUR at voiding correlated with low cystometric capacity, with the first pattern showing a lower resolution rate within the third year of life, in a longitudinal study by videocystometry.[381] There is ample evidence to show that treating the DO and/or voiding dysfunction leads to a faster rate of resolution of VUR (63-92% within 1 year)[382 383] than treating only with antibiotics (25-54%).[384] UUT damage is more likely to occur in children with abnormal LUT function.[385] In this setting, history taking about voiding habits and accurate non-invasive UDS evaluation become paramount. Question remains if cystometry with pressure flow studies in older children are advised. In a study on 40 patients, VUDS showed LUTD in 76% of the children,[386] and in a recent prospective study of 147 children with high grade VUR, normal patterns were found in only 23% of them.[387] In patients who had post-treatment UDS, biofeedback, pelvic floor muscle training and treatment with antimuscarinics effectively decreased detrusor pressure, increased cystometric capacity and maximum flow rate, and reduced the grade of VUR.[388] It is nowadays reasonable to diagnose LUTD by non invasive tests and to consider VUDS in therapy resistant patients, paying attention to bladder neck dysfunction, which was shown to be relevant in a randomized trial.[389] Many clinicians advocate UDS especially for those patients that still have UI, renal damage, or who are about to undergo surgical correction,[390 391] even if precise UDS (pressure flow) criteria for outlet conditions in children are still undefined.

4.7. Urethral Stricture

Urethral stricture disease in boys is rare, usually arising from a previously unsuspected straddle injury or the late result of hypostadias repair. Uroflowmetry can accurately predict the presence of a urethral stricture in 88% of affected males.[392] A urethral obstruction after hypospadias repair may develop asymptomatic and uroflowmetry can be helpful [393] demonstrated by significantly different pre- and post-meatotomy findings of Q_{max} (P .001) and voiding times (P .03).[394] Follow-up uroflowmetry, analysing and complaring the maximum flow rate, voiding times and curve pattern may alert the clinician to early signs of (re-)stricturing but the precise interval, frequency (and efficacy) of periodic uroflowmetry testing in these patients have not been corroborated.[395]

4.8. Conclusions (Level 3)

- Many case series have demonstrated frequent UDS abnormalities, predominantly DO and reduced bladder compliance or large cystometric capacity with impaired filling sensation, in children with PUV, urethral stricture, ectopic ureterocele, VUR or with bladder exstrophy.
- Proper UDS has been shown to be of help to determine when further medical or surgical management is indicated in children with these abnormalities.
- The use of UDS has aided in an objective measurement of success or failure of treatments for these abnormalities.

4.9. Recommendations (Grade C)

- Clinicians should consider complete UDS of the filling and voiding function, at least once, in children with PUV, urethral stricture, ectopic ureterocele, VUR or with bladder extrophy.
- UDS in children should be done with special attention to their specific needs, and with careful attention to minimize mental trauma and to ensure representativeness as much as possible.
- Clinicians should consider regular uroflowmetry and PVR assessment in the follow-up and further management of children with PUV, urethral stricture ectopic ureterocele, VUR or with bladder exstrophy.
- Clinicians should consider the necessity of follow-up UDS on an individual basis and as less frequent as possible.

5. FUNCTIONAL DISORDERS OF THE LOWER URINARY TRACT

5.1. ICI2013 Conclusions and Recommendations

ICI2013 found that various studies had been showing that treatment of children with functional UI (and of the, frequently associated, bowel elimination problems) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and (free) uroflowmetry with PVR assessment. Furthermore various studies, reviews and guidelines agree on the relevance of UDS in children with UI and nocturnal enuresis resistant to initial (conservative) treatment.

The ICI2013 recommended (Grade B) uroflowmetry and PVR assessment (until -for the individual child-representative values are obtained, if possible) as ‘non-invasive urodynamic’-screening and evaluation

in all children with LUTS, UI and/or with nocturnal enuresis resistant to first line therapy. ICI2013 suggested urological signs and symptoms assessment in children with chronic constipation and ICI2013 recommended complete UDS in children with UI and/or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

5.2. Discussion and New Evidence 2016

When assessing functional disorders involving the LUT in children, one must take into account the dynamics of the maturing nervous system, learned habits of elimination for bladder and bowel function and social influences

5.3. Diurnal Incontinence

UDS (invasive) has a limited place in diurnal (day and night) UI. This condition is not considered worrisome before age 5 or 6.[396] UI in children can have many causes, and history and clinical investigation are very important in this regard. Therefore, it is imperative to formulate a 'urodynamic question(s)' following a comprehensive history, careful physical examination, and standard urological investigations, possibly with the aid of validated questionnaires.[397] [398] [399] It is well known since several years that UI can also coincide with dysfunctional voiding and/or bowel elimination problems.[400] Treating these bladder and bowel dysfunctions, with behavioural modification, biofeedback training, drug therapy, is necessary before considering UDS. Nowadays, the expression 'Elimination syndrome' has been substituted by Bowel/Bladder Dysfunction (BBD), to better underline a clinical condition involving abnormal habits and dysfunction of both the lower urinary and bowel tracts.[401]

Uroflowmetry with a PVR urine and simultaneous EMG determination are the the tests of choice, and results from uroflowmetry should be compared with information from the

patient's Frequency/Volume Charts. Bladder volume may affect uroflowmetry: it was theorized that Q_{max} is physiologically dependent on bladder volume, thus researchers are trying to identify other factors that may be more important in what determines Q_{max}.[402] Sonographic estimation of PVR volume should complete the assessment: in children <6 years, a repetitive PVR of >20 ml or >10% cystometric capacity is considered elevated; while in children >7 years, repetitive PVR >10ml or 6% cystometric capacity is regarded as elevated.[403] Some (expert and/or single centre) evidence is emerging for uroflowmetry + EMG evaluation and investigators have looked at the time differential between relaxation of the external urethral sphincter (as measured by patch perineal electrodes) and the opening of the bladder neck on VUDS. This parameter (labeled 'lagtime') was not corrected for meatus to flowmeter distance but was nevertheless considered a sign of DO, when prolonged >2 seconds and it was suggested that this lag time could also indicate bladder neck dysfunction if the time exceeded 6 seconds.[404]

In all children with non-neurogenic LUTS non-invasive UDS is warranted to determine the presence of different forms of LUTD, and to assess bowel dysfunction as well. Bowel dysfunction, in the absence of any anatomical or neurological deficit, often affects LUT function and contributes to UI in a number of ways. Constipation had been shown in the past to be associated with DO and a reduced functional bladder capacity.[405] Understanding and eliminating this possible aetiology can normalise LUT function, as stated by the report from the Standardisation Committee of the International Children's Continence Society[406] In a recent prospective study from urological and gastroenterological clinics in one center, 68% of subjects referred with UI, and/or constipation and/or faecal incontinence and included, had at least a 50% reduction in number of daytime UI episodes and 27% became completely urine -continent by successful relief of bowel (constipation and/or faecal incontinence) dysfunction.[407]

Persistent daytime and night-time UI, resistant to conventional therapy may require (V)UDS. In several reports over 20 years, different UDS findings had been found, with DO (in 57%), dysfunctional voiding (in 22%)and also normal findings in 14%.[408] [409] Dysfunctional voiding was also reported associated with DO in up to in incidence of 76%.[410] [411] Many of those studies use terms that are outdated now and those should be replaced ('transformed' where possible) with the new.[412]

Apart from the above mentioned NLUTD , co-morbidities other than bowel dysfunction may be present such as psychiatric and psychosocial ones. Several recent studies well designed by validated questionnaires, were conducted, including a case-controlled one on autism spectrum disorders which showed a significant incidence of LUTS, with a total problem score of 70% (versus 2% in controls) and concluded that screening for UI and, if indicated, treatment of the dysfunction(s) is recommended.[413] In a study on 68 children with attention deficit-hyperactivity disorder (ADHD), the total dysfunctional voiding score in the ADHD symptoms group was significantly higher (P .05) than in non-ADHD children.[414] Other social and behavioral conditions were investigated in children referred with sings and symptoms of LUTD, such as obesity or underweight;[415] bullying (a quarter of American school children are regularly bullied);[416] and sexual abuse and found these to have a higher LUTS-score and/or a higher incidence of UI.[417] Regarding bullying, UI is more frequent in females and in those children with higher bulling scores; physical forms of bullying accounted for worse voiding severity scores.[418]

Greater attention has been recently paid to check the prevalence of LUTS and UI in a series of genetic dis-

orders with cognitive/behavioral or potential neurological problems, in order to reassure the families and to screen the cases which may require treatment. For example, in a case-control study, out of 326 children with Down's syndrome, it was found that there is a marked delay in toilet training (average 5.5 years), and UI was reported in 46% of (versus 24% in controls) previously toilet trained children.[419] Children with Williams syndrome, which comprises mild intellectual disability, have high rates of daytime UI and enuresis, reducing with age: daytime UI decreased from 18% in children to 0% in adults, while enuresis (45% in children) persisted in 4% of adults.[420]

UDS has clearly improved our understanding of the aetiology of diurnal UI but no study has shown that UDS characterisation of any abnormality has improved the efficiency of treatment for these children. In any case, pretreatment UDS is considered to be required before invasive treatments in children with therapy resistant diurnal UI. Sacral neuromodulation has been demonstrated to improve refractory bowel bladder dysfunction,[421] with more benefit if DO is shown on UDS.[449] [422]

5.4. Enuresis (Nocturnal)

Night-time wetting (nocturnal enuresis) is a condition that is common in children aged 5 years but which improves with time, so that less than 15% of pubertal boys and 5% of pubertal girls continue to be affected.[423] Multiple causes for the persistent wetting have been implicated, ranging from genetic factors, to maturational delays, sleep disturbances, social causes, psychiatric conditions (as attention deficit disorders),[424] to LUTD and/or abnormal vasopressin secretion.[425] [426]

It is now commonly considered essential to discriminate Monosymptomatic Nocturnal Enuresis (MNE) from Non -Monosymptomatic one (NMNE). According to the ICCS definitions, NMNE consists of two different disorders: nocturnal enuresis and LUTD identical to those with daytime UI except that daytime UI does not occur.[427] It is generally not necessary to conduct UDS until adolescence, to determine why the UI has not abated. Non-invasive exams are important for enuresis subtyping, relevant for selection of treatment modality.[428] An abnormal micturition history, or dysfunctional voiding symptoms like squatting and/or abnormal voiding charts, predicted abnormal UDS results correctly, with a sensitivity of 81% and specificity of 86%.[429] A bladder volume and bladder wall thickness index less than 70 was a predictor for the presence of DO at cystometry in one cohort.[430] A bladder capacity at night (enuretic capacity) was significantly less in those with nocturnal enuresis versus those without.[431] A recent study from a series of 720 children showed significant differences between MNE and NMNE patients as both maximal VV and nocturnal urine volume, which were lower ($P < 0.001$) in NMNE patients. Out of 500 patients who were initially referred as desmopressin resistant, 33% of these became dry on desmopressin monotherapy, demonstrating how relevant is the UDS diagnosis of enuresis subtyping for selection of treatment.[432] On this regard, it was shown that treating the non monosymptomatic child using antimuscarinic agents can be very effective (as high as 77% cure) when based on the findings of UDS.[433] [434]

An emerging issue which requires further research, is the progression of enuretic children into adulthood. Enuretic children were found more likely to have nocturia and urinary urgency if they had nocturnal enuresis when > 12 years of age.[435] In a retrospective case-control study, 57 women were investigated using a validated questionnaire. The results demonstrated that the prevalence of LUTS was much higher (mainly UI, P .0001) in patients who initially presented for LUTS/UI in childhood than in age-matched controls (school nurses).[436]

5.5. Conclusions (Level 2/3)

- Various studies show that treatment for children with functional UI (and of the, frequently associated, bowel dysfunction) can be initiated on the basis of history, clinical exam, bladder diaries, bladder ultrasound and uroflowmetry with PVR assessment.
- Various studies, reviews and guidelines agree on the relevance of UDS in children with UI and nocturnal enuresis resistant to initial (conservative) treatment.
- There is evidence from epidemiological studies, carried out by validated questionnaires, that several neurological/cognitive/behavioural disorders (i.e. genetical diseases, autism, ADHD) have a an association with LUTS and UI.
- There is evidence that also social and/or behavioural conditions (i.e. obesity, bullying) have a significant incidence of high LUTS-score and/or UI.
- The neurological diseases and social conditions with potential LUTS and UI should be evaluated at least by bladder diaries and questionnaires, possibly by non-invasive UDS.
- The potential risk factor for adult women to have UI if they suffered from LUTS as girls may require long-term accurate follow-up.

5.6. Recommendations (Grade B/C)

- The committee recommends uroflowmetry with pelvic floor EMG and PVR assessment as 'non-invasive urodynamic'-screening and evaluation in all children with LUTS, UI and/or with nocturnal enuresis resistant to first line therapy.
- The committee suggests urological signs and symptoms assessment in children with chronic constipation and/or fecal incontinence.

- The committee recommends complete UDS in children with UI and/or with nocturnal enuresis resistant to conservative treatment, if invasive or clinical (dry-bed training) treatments are contemplated.

5.7. Suggestion for Research

- The committee suggests that further integrated approaches to the diagnosis (and management) of children with bowel dysfunction, in combination with LUTD are undertaken.
- Longitudinal studies on persistence of LUTS/UI in adults are suggested, to be integrated with retrospective studies in adults suffering of UI, in order to evaluate if having LUTS in children is a risk factor for UI in adulthood.

6. TECHNICAL CONCERNS: RELIABILITY AND REPRODUCIBILITY OF TESTS

6.1. ICI2013 Conclusions and Recommendations

The ICI2013 concluded (on the basis of various studies to determine normal and test retest values for UDS in children) that, within the limits also provided for adults, UDS in children is reliable and reproducible. Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values can not be given and the influence of the transurethral catheter size on (children's) voiding is unknown. The ICI2013 concluded that standards for pressure flow analysis in children are lacking.

The ICI2013 recommended (Grade C) that the specific demands of children, physically, as well as psychologically, be taken into account, before UDS is carried out, as well as during the testing. The ICI2013 advises specialised workers, units and equipment to ensure this. The ICI2013 recommended that invasive diagnostic tests should be done if indicated by the results of non-invasive procedures and should be done only when the outcome will or can alter management and recommended that clinicians take into account the variability and test retest differences of UDS in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child's behaviour, and the implications for the results of the tests.

6.2. Discussion and New Evidence 2016

Often, differences in UDS parameters exist from one study to another. In pediatric patients there is concern that the reliability of measurements could be influenced by development effects and measurement variability, as well as by the unfamiliar clinical environment. A recent study, comparing (conventional) UDS with Ambulatory UDS: even if flow rates were similar between methods, more diverse voiding patterns were identified in AU, suggesting that UDS may not be sensitive enough to the variability of LUT pathophysiology in children.[437] 'Functional' bladder capacity (as derived from the voiding diary, without the first void in the morning) is presented as a relevant parameter for the clinician in the ICCS definitions.[438] Confirmed by the subsequent ICCS revised document.[439]

In the UK health care system a minimum number of tests is considered of relevance for the maintenance of sufficient expertise which is also specified for the number of children (30 /annum) to ensure quality.[78]

Following the above clinical assessment by diaries - as underlined in the paragraph 'Diurnal Incontinence - efforts have been done in the recent years to better standardize non-invasive tests. Uroflowmetry, which is the indispensable first-line test for children with suspected LUT dysfunction, must be accompanied by ultrasound PVR measurement. Uroflowmetry should be evaluated according to precise criteria and may be performed in conjunction with pelvic floor EMG. More accurate nomograms were recently stated for uroflowmetry analyzing, 721 records,[440] and for PVR, analyzing (single and dual) PVR in healthy school children.[441] Unfortunately, there is still a tremendous amount of intra- and interobserver variation in defining the shape of curves, but studies are showing how uroflowmetry-analysis can be more reproducible using standardized evaluation and using a 'flow index'.[442] Uroflowmetry may be also more reliable if performed with simultaneous EMG;[443] [444] [445] inter-rater agreement in a study on 84 uroflow-EMG studies was suboptimal and disagreement may be lowered by simplifying diagnostic criteria and allowing assignment of multiple diagnoses.[446] Ultrasound bladder wall thickness measurement is gaining interest: in a prospective study on 324 children; healthy and dysfunctional voiders, a good sensitivity (based on anterior wall thickness: 67% and based on posterior wall thickness 83%) for symptoms of dysfunctional voiding was obtained.[447] Another study in children with BOO (PUV), found detrusor thickness greater than 1.3 mm in a multivariate analysis as the only independent risk factor (P .004) for later impaired bladder function.[448] Dynamic pelvic floor ultrasound is under evaluation for normative values of endurance and direction of pelvic floor movements.[449] A cut-off diagnosis for specific non-neurogenic dysfunction for any of the non-invasive tools would be desirable.

Invasive UDS are considered to be indicated when non-invasive investigation raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (i.e., PUV), genitourinary abnormalities (i.e., exstrophy, epispadias), profound non-neuropathic detrusor-sphincter dysfunction (children with dilating VUR and recurrent febrile UTI), or significant PVR of unknown cause.[450] To assess the voiding phase, pressure flow studies are performed immediately after filling cystometry. In children, the

transition from filling to voiding is not as easily managed as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements should preferably be performed as one continuous study. Available reports on detrusor pressure during voiding in symptom free children is reported to give a wide range, that is between ± 50-60 cmH_2O in one study.[451] In infants the average detrusor pressure at voiding was reported another study to be 127cmH_2O in boys and 72 cmH_2O in girls on standard fill cystometry,[452] similar to what found in another study by natural fill cystometry.[453]

When filling by catheter, slow fill cystometry (5–10 percent of estimate bladder capacity per minute, or <10 ml/min) is recommended, as compliance (predominantly) and DO (possibly) may be significantly altered by faster rates of filling.[454] [455] [456] In infants, temperature of the infusate may influence cystometric capacity and DO; however, its clinical relevance remains unknown.[457] Most children readily tolerate a 6- or 7- Fr. double lumen transurethral catheter to fill the bladder and record pressure. In selected cases, a suprapubic catheter may be inserted under general anesthesia the previous day or several hours earlier on the same day, but risks need to be juxtaposed against benefits of this approach.[458] It has been postulated that transurethral catheters (6 or 7 Fr.) do not significantly obstruct the urethra.[459]

Avoiding general anesthesia is important as this affects the natural state and eliminates the chance for voiding.[460] Most children can undergo UDS without pre-medication; only the most agitated may require some degree of sedation.[461] To reduce anxiety, the study may also be performed with the child seated, watching a video or DVD and accompanied by one or both parents. Following previous consultation recommendation,[462] [463] [464] the ICCS standardiation on UDS studies of the LUT in children confirmed that UDS in children are best performed under the auspices of a knowledgeable urologist or trained urodynamacists; so that children should receive comprehensive UDS in a laboratory that is specialised in paediatric UDS with appropriately trained personnel.[465] [466]

6.3. Conclusions (Level 3)

- The committee concludes (on the basis of various studies to determine normal and test retest values for UDS in children) that within the limits also provided for adults, UDS in children is reliable and reproducible.
- Non-invasive tests are gradually achieving more evidence level, by constructing normative values and more standardized performing of the tests
- Although it is plausible and considered useful to reduce filling speed and catheter size in relation to patient size, the exact values cannot be given and the influence of the transurethral catheter size on voiding is unknown in children.
- The committee concludes that standards for pressure flow analysis, and information on non-invasive PFS in children are lacking.

6.4. Recommendations (Grade C)

- The committee recommends that the specific demands of children, physically as well as psychologically are taken into account, before UDS is carried out as well as during the testing. The committee advises specialised workers, units and equipment to ensure this.
- The committee recommends that non-invasive diagnostic tests should be preferred, and invasive ones should be done only if indicated by the results of non-invasive procedures, in neurogenic lesions to discover risk conditions, and when the outcome will or can alter management.
- The committee recommends that clinicians take into account the variability and test-retest differences of UDS in children and also take into account the effect of the (apparent psychologically stressing) laboratory-situation on the child's behaviour, and the implications for the results of the tests.

6.5. Suggestion for research

- The committee suggests to elaborate on standardisation of UDS evaluations and on criteria to judge how the 'laboratory' circumstances have influenced the child's (LUT) behaviour, with the aim to better include how well UDS have represented the actual LUTD, in the evaluation of the test.
- The committee suggest to verify if, how and when non-invasive tests can substitute UDS in the accuracy of diagnosis of functional LUTD in children.

IX. PATIENT EVALUATION: FRAIL ELDERLY

1. INTRODUCTION

1.1. 2013 Recommendations and Conclusions

ICI2013 concluded that UI in the frail elderly commonly has diverse and multiple coexisting factors. Retrospective ('clinical cohort') single centre reports confirm that general health, mobility neurologic diseases, medications and 'direct' effect of aging on the LUT all have effect on LUT function. Also in the frail elderly, symptoms and signs are unreliable to predict LUT (UDS) dysfunction. The committee concluded that bedside UDS (one channel cystometry) has inherent unreliability and no evidence exists to quantify the risks (of false positive diagnosis) versus the advantages ('simplicity'). The committee concluded also

that determination of PVR is considered relevant in all frail elderly with LUT dysfunction on the basis of expert opinion and good clinical practice -guidelines.

The 2013 committee recommended that frail elderly, with UI, are evaluated by a clinician skilled in the care of those patients and that all contributing factors are managed, before further urological diagnostics are started. The committee recommended also that (standard) UDS should be offered to all elderly regardless of the comorbidity (not responding to relevant management) if specific further treatment is deemed appropriate (possible).

1.2. New Evidence 2016

Also in the elderly UI is associated negatively with HRQoL and with similar impact in both men and women, mostly noticed in the dimensions of energy, social isolation, and physical mobility.[467] OAB-S is common in older adults and associated with impairment in mental health and HR-QoL, but rates of treatment seeking behavior are low.[468] OAB-S and UUI symptoms severity progress dynamically and are also sustained over time, although in a 5 years period also symptoms reduction may be observed.[469] Elderly patients with OAB-S and DU might also develop a large PVR volume after antimuscarinic treatment.[470] The role of urothelium is, also in the elderly, considered of relevance in the pathophysiology of LUTD[471] and urinary inflammatory proteins have generated some attention.[472] The frail elderly are reported to have a higher risk of developing DO and/or DU.[473] UDS findings in the (frail) elderly tend to demonstrate DO,[474] [475] even in individuals that do not spontaneously report symptoms or bother. There may also be a reduction in cystometric capacity, urinary flow rate and detrusor contractility.[476] The invasive nature of conventional UDS becomes a relatively more important factor in the old or frail elderly, who may be more vulnerable to any intervention than younger people. There was a significant association between age and the presence of asymptomatic bacteriuria before cystometry and between the bacteriuria and urinary urgency (without DO) on cystometry.[477] Elderly patients with DU may have large bladder volume, but small VV and large PVR volume, suggesting diminished central sensitivity to volume afferent activity in the aged bladder.[478] In patients with DM, the PVR volume was significantly increased, in addition to OAB-S in the elderly.[479]

Some recent reviews have summarized medication use, especially polypharmacy and the effect on the lower uinary tract. Contrary to, or before adding another medicine (or management) in a frail elderly person with LUTS or LUTD, it might be wise to consider reducing other medication to ameliorate medicine (side effect) associated -LUTD and symptoms.[480] [481] [482]

UDS is reserved for patients in whom conservative management and medical management, directly or indirectly aimed at LUT-function improvement, has failed or has proved inadequate, and in whom more intensive or invasive therapy is being considered. The place of UDS in the frail elderly with UI is less precisely established. There is very little objective evidence for or against clinical UDS in this population group. UDS should be performed in the workup of vulnerable elders when surgical intervention is considered according to the guideline of American geriatrics.[483]

- As UI in frail elderly people may be the result of a number of contributory factors, many of which are reversible by simple measures, such patients should be first evaluated by a clinician skilled in the care of older people before any invasive investigations or more potentially harmful medications are given.
- There is direct and indirect evidence that UI in the (frail) elderly often has diverse and/or multiple coexisting factors.
- Apart from general health, mobility, neurological diseases and medications, the LUT is directly affected by aging of the detrusor, and the detrusor muscle function can be(come) both overactive during storage as well as underactive during voiding. Furthermore growth of the prostate; aging of the bladder outlet and decline in striated pelvic floor muscle function are commonly of relevance.
- In common with all patients, but maybe even more relevant; symptoms are not synonymous with the abnormalities that can be measured with UDS.
- Every test or (invasive) procedure can cause harm in the (vulnerable) elderly but there is no published evidence that UDS cause significantly more harm in the elderly.
- Simple bedside UDS has an inherent unreliability, and it is unclear whether the risk of misdiagnosis outweighs the ‘simplicity’ over conventional UDS.
- Especially, but not exclusively, male elderly patients, with central neurological disease, can have urologic disease (e.g. prostatic BOO) as a cause for UI or other LUTD.

1.3. Recommendations (Grade B-C)

- PVR measurement by a non-invasive method is recommended before institution of pharmacological or surgical treatment ofUI. It should be repeated to monitor the effect of such treatment. Uroflowmetry should be used to screen for voiding abnormalities prior to invasive treatment in the elderly.
- Simple cystometry can be considered as a ‘screening test’ for non- invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management.

- The committee recommends offering comprehensive UDS to all elderly, with due consideration to any co-morbidity, that may have not responded to management of relevant contributing factors, and/or behavioural or pharmacological therapy, and in whom further invasive therapy is considered.
- Frail elderly patients are more vulnerable to complications and UDS -data specific for the treatment of OAB-S in the frail elderly is limited.

1.4. Urinary Urgency Incontinence in Frail Elderly Patients

1.4.1 Recommendations 2013

In non-systematic reviews on pharmacotherapy UDS do not play an important role to initiate treatment for OAB-S in the frail elderly.[484] [485] [486] Among the frail elderly, UI is the paramount troublesome symptom, in both men and women, with a steeply rising incidence after age 80.[487] The type of UI appears to be predominantly UUI.

The symptoms of UUI are, also, or especially, in elderly women, frequently the result of DO, which can be shown with filling cystometry. The reason to perform UDS might therefore be to confirm this abnormality but identification of coexisting or alternative abnormalities may be of importance. Two industry supported reviews have found a paucity of specific evidence for the risks and efficacy of pharmacotherapy for DO or OAB-S in the frail elderly but have also not found that pharmacotherapy or conservative (behavioural) management is very risky in these patients.[486] [488] Reduced bladder sensation or 'awareness' in the frail elderly may lead to reduced warning (time) of impending leakage, and it is postulated that a (cognitive/cerebral) neurological cause may be co-existing and responsible for LUT symptoms in the elderly.[489] [490]

In symptomatic elderly people, UUI frequently coexists with incomplete bladder emptying. Incomplete emptying may be a sign of impaired bladder contractility, now termed by the ICS as detrusor underactivity. The UDS abnormality underlying UUI with incomplete emptying (assuming no BOO) has been introduced some decennia ago as 'DHIC (detrusor hyperactivity with impaired contractile function)' .[491] Its significance is that the standard pharmacological treatment of UUI – with antimuscarinics – may affect bladder emptying thus reducing the effect on symptoms of frequent voiding, by increasing PVR. In frail elderly women, DO is reported to be the commonest UDS diagnosis in a large retrospective series of referred elderly women.[492]

With regard to male elderly patients, a total of 185 men who had persistent LUTS after TURP were evaluated with VUDS in one single center study. A normal VUDS tracing was found in 9%, pure DO in 10%, DU in 19%, DHIC in 14%, poor relaxation of the urethral sphincter in 19%, and recurrent or remaining BOO in 28%.[493] A significant proportion of patients might develop (transient) de novo UUI after photoselective vaporization of the prostate. Pretreatment UDS demonstrated that small bladder volume at first desire to void and small maximal cystometric capacity are predictive factors for this.[494] Older age was, apart from UDS predictors also a risk factor for posttreatment UUI in this study but transurethral laser treatment is not considered extremely risky in the very old in another evaluation.[495] A lower long-term success rate and an increased risk of large PVR after intradetrusor BoNT-A injection for refractory idiopathic DO has however been noted in frail elderly patients although safety and short time efficacy were similar between elderly patients without frailty and younger patients.[496]

1.4.2 Conclusions

- No evidence exists that age by itself or frailty are contraindication to UDS and guidelines recommend UDS for the elderly following the principles similar to the younger; in general UDS is reserved for patients in whom non-invasive diagnosis and conservative and/or medical management have failed and in whom more intensive or invasive therapy is being considered.
- DO, DU and/or reduced filling sensation may coexist also in elderly or frail patients with UI. In addition, elderly men (and lesser prevalent, women) may have BOO.
- It has been shown that voiding efficiency and PVR should carefully be monitored in the elderly patients and especially in frail elderly men during treatment with antimuscarinics as well as with intradetrusor BoNT-A injection.

1.5. Stress Urinary Incontinence in Frail Male Elderly Patients

Among older men, SUI is almost entirely confined to RRP patients. Approximately 1% of patients who have undergone TURP or laser TURP suffer from post RPP UI.[497] [498] The majority of SUI after RRP is caused by urethral sphincter damage during operation the effect of exercise programs was not observable in urethral pressure profile measurements.[499] UDS in post RPP UI showed no significant change in filling or voiding parameters when suburethral 'male'-slings were implanted.[500] Sequential UDS evaluation of patients with post RRP UI revealed urethral sphincter and bladder function worsen immediately after RRP and recover over time.[501] The urinary continence rates were gradually improved to a satisfactory level in more than 80% of patients by 12 months after RRP.[502] In addition to a lower MUCP, a reduced bladder compliance, de novo DO, and DU are commonly observed in patients with post RRP UI.[503] [504] However, DU did not affect UDS parameters and LUTS improvement after RRP.[528]

1.6. Conclusions

- UI in elderly men may be the consequence of ineffective emptying and BOO.

- UI in elderly is however also frequently iatrogenic; caused by RRP or transurethral resection of the prostate.
- UI after prostate surgery may recover spontaneously and/or with conservative management within a period of 12 months in the predominance of men.
- Patients with post RPP UI might have a low MUCP, a reduced bladder compliance, de novo DO, or DU, and UDS may have an important role in identifying the bladder and urethral dysfunction in patients with prolonged post RPP UI in order to establish appropriate treatment strategy.
- UDS may have a role in identifying the bladder and urethral dysfunction in patients with prolonged post RPP UI in order to establish appropriate treatment strategy.
- There is paucity of evidence about reproducibility and reliability of UDS in the elderly.

2. TESTS IN THE GERIATRIC OR FRAIL ELDERLY POPULATION

2.1. Filling Cystometry

In a prospective 3 arm study with oxybutynin, biofeedback-assisted behavioural training and a placebo control condition in women with a mean age of 67 years, UDS parameters (filling sensation, cystometric capacity and voided volumes) improved in all. The improvement in UI was however related to the UDS changes observed in this small series, probably because of diverse UDS diagnoses at inclusion, as well as a consequence of the variability of the UDS outcome.[505]

2.2. Post-Void Residual Urine

PVR is believed to depend on the presence of BOO as well as to relate to DU.[506] Thus, in a man, the presence of substantial PVR (> 100 mL), in the absence of a large prostate, and/or severe BOO, may suggest that the increased PVR is mainly due to a reduction in detrusor contractility.[507] PVR volume varies in a given individual and can wax and wane over time. Significant daily variations have been observed in elderly patients of both sexes, with larger PVRs (up to 40% greater) being measured in the early morning.[508] Elderly patients with DU may have small VV and large PVR volume, suggesting diminished central sensitivity to volume afferent activity in the aged bladder.[509] In patients with diabetes mellitus, the PVR volume was significantly increased, which might increase the distress of voiding dysfunction, in addition to OAB-S in the elderly.[510]

2.3. Pressure-Flow Studies

Driving a contraction to its maximum load (and zero contraction velocity) is a manner to evaluate muscle force, and stop-flow test is the practical way to do this. Voluntary stop test are not clinically validated to evaluate DU, but occlusion stop tests can be of relevance to evaluate the effect of treatments that affect detrusor voiding contraction in the elderly.[511]

3. EVIDENCE THAT PERFORMING URODYNAMIC STUDIES IMPROVES CLINICAL OUTCOMES IN THE GERIATRIC POPULATION

Pre-operative UDS was not able to predict the outcome of a popular SUI procedure in older women in this single centre uncontrolled cohort.[512] Regarding the diagnostic evaluation of LUTS in older men, an International Consultation on New Development in Prostate Cancer and Prostate Diseases concluded that the frequency volume chart is recommended when nocturia is a bothersome symptom to exclude nocturnal polyuria. The use of UDS and transrectal ultrasound can be limited to situations in which the results are likely to benefit the patient such as in selection for surgery.[513] DO or LUTD with or without BOO are present in patients with Parkinson's disease. UDS is recommended for men with Parkinson's disease with symptoms of LUTD since early and effective treatment can improve the bladder function and quality of life.[514]

The therapeutic efficacy and tolerability of a beta 3 adreno antagonist (mirabegron) were similar between patients with >65 and >75 years of age with OAB-S (with and without UI); UDS evaluation was not performed In this study.[515] In a randomized trial for men with LUTS and BOO, mirabegron was demonstrated not to adversely affect voiding UDS (maximum urinary flow and detrusor pressure at maximum urinary flow) compared with placebo after 12 weeks of treatment.[516]

4. THE PRACTICAL INDICATIONS FOR URODYNAMIC STUDIES AND WHICH TESTS ARE NEEDED

4.1. Post-Void Residual Urine

In the elderly, PVR urine measurement is indicated before treatment of UI either with anticholinergic medication or by SUI surgery. A consistently large PVR certainly is a reason for caution, and careful monitoring of bladder emptying is needed.[517] After intradetrusor BoNT-A injection for OAB-S, large PVR volume (greater than 150 ml) after BoNT-A injection was significantly higher in the frail elderly group than in the non-frail elderly or younger patient groups (61% versus 40% and 36%, respectively, (P .018).[518] PVR monitoring was considered to be relevant after intradetrusor BoNT-A injections in the frail elderly.

4.2. Uroflowmetry

Uroflowmetry is a simple and non-invasive test. A normal uroflowmetry pattern without much PVR probably rules out significant BOO or DU, but this finding is unusual in the elderly. Uroflowmetry (with PVR measurement) may be a useful screening tool prior to instituting therapy. However, in a retrospective study of hundred women tested, the first free flow was inconclusive in 44% but was interpretable in 91% on the second free flow.[519]

4.3. Pressure-Flow Studies

There is weak evidence to suggest that prostatectomy may improve the continence if UDS shows 'severe' BOO in Parkinson's disease patients.[520] If BOO is equivocal or absent, then there is little point in performing surgery in an attempt to alleviate the signs and LUTS (presumed to be) 'related to BOO'. After screening with uroflowmetry and PVR measurement, pressure-flow studies may be indicated in older men in whom BOO cannot be ruled out otherwise and surgery is at least contemplated.

4.4. Recommendations (Grade C)

- PVR measurement by a non-invasive method is recommended before institution of pharmacological or surgical treatment of UI. It should be repeated to monitor the effect of such treatment.
- Uroflowmetry should used to screen for voiding abnormalities prior to invasive treatment in the elderly.
- Filling cystometry, as a single investigation, has limited value in this patient population. 'Simple cystometry' is not recommended.
- Simple cystometry can be considered as a 'screening test' for non- invasive, or other low risk treatments, when a urethral or suprapubic catheter is already present for management. However, the low specificity and sensitivity towards complete UDS diagnosis must be taken into account.
- The ICI2013 recommended offering comprehensive UDS to all elderly, with due consideration of any co morbidity, that have not responded to management of relevant contributing factors, and/or behavioural or pharmacological therapy, and in whom further invasive therapy is considered.
- The ICI2013 recommended that comprehensive UDS be performed in centres with a special interest in UI in the frail elderly, by trained and certified staff who frequently perform UDS of patients referred with suspected LUTD.
- To maintain adequate expertise in this difficult-to-examine patient population and to provide a background of 'regular' patients against whom specific patients can be judged , it is essential that centres examine substantial numbers of patients for LUTD; frail elderly as well as 'routine' patients.

5. THE URODYNAMIC PARAMETERS IMPORTANT IN VARIOUS GERIATRIC CONDITIONS

UDS can be of relevance to determine the most important cause of the LUTS in the elderly, where central nervous system disease is a frequently occurring comorbidity and where clinical signs and symptoms of LUTD are regularly more difficult to obtain or to isolate. Brain disorders such as stroke, Parkinson's disease and white matter disease may decrease the tolerance of bladder filling and also increase the prevalence of OAB-S in the elderly population.[521] [522] In a community health survey, 31% of patients with central nervous system disease reported OAB-S, and the overall prevalence of neurogenicOAB-S was 1%. Patients with neurogenicOAB-S have a poorer HR-QoL compared to patients with idepathic OAB-S.[523] The pathogenesis ofOAB-S in cerebral events involves not only sensory perception but also the impairment of detrusor (voiding) contractility. Patients with a cerebrovascular accident or Parkinson's disease have DO and inadequate contractility or DU resulting in increased PVR volumes.[524]

5.1. Parkinson's Disease

DO associated with Parkinson's disease is reported to occur at smaller bladder volumes than DO in BOO-related DO. The duration and severity of Parkinson's disease were reported not be related to the UDS results. Patients with Parkinson's disease have a higher risk of falls and falls, but not the frequency of urination were associated with urinary urgency in a prospective observational study.[525]

DO or LUTD, with or without BOO, are present in patients with Parkinson's disease. UDS is recommended in men with Parkinson's disease with LUTD. Early and effective treatment can improve theLUT function and quality of life.[526] Another group found that the majority of patients with Parkinson's disease (72%) or multiple system atrophy (100%) had symptoms of LUTD. DO was more common in Parkinson's disease and DSD was reported to be specific for multiple system atrophy in this cohort. BOO (pressure flow BOOI> 40) was more common in Parkinson's disease than in multiple system atrophy. DU was less common in Parkinson's disease than in multiple system atrophy and PVR (> 100 mL) was only present in (47%) patients with multiple system atrophy.[527] By correlating the LUTD and motor function impairment in patients with Parkinson's disease, detrusor weakness was found relevant to motor impairment, and OAB-S were found relevant to (disease specific) quality of life.[528]

5.2. Other CNS Disorders

Acute urinary retention and/or voiding difficulty are frequently encountered signs of LUTD in stroke patients. The majority of stroke patients (±60%) had remained able to void spontaneously at –rehabilitiation-admission. During rehabilitaiton this percentage increased, partially because UDS had provided the arguments to remove the indwelling catheter. At discharge ±20% of the patients depended on intermittent or indwelling catheter or on condom conduit.[529]

The most common type of UI in patients with Alzheimer's disease is UUI. In a cohort of 144 Alzheimer's disease patients with UI, DO was found in 58% of patients on UDS. The presence of DO could be predicted using Clinical Dementia Rating and Barthel's Activity of Daily Living Score.[530]

Patients with central nervous system lesion and OAB-S might also have DU. One recent study of 100U BoNT-A injected to the detrusor, including the trigone, in 20 patients with Parkinson's disease with PVR <50% on free flowmetry, demonstrated a small reduction of voiding frequency, a reduction of voided volume and some increase of PVR, however without the need for CIC.[531] The efficacy and safety of intradetrusor 100U BoNT-A treatment was also evauated in 40 elderly patients with chronic LUTD after cerebrovascular accident or Parkinson's disease and/or dementia. Intradetrusor BoNT-A injections reduced OAB-S and UUI. The treatment resulted in UDS cystometric capacity increase, with modest change in pressure flow parameters and some increase of PVR, but without the occurrence of urinary retention. An increased need to strain- void was noted in the (23) patients with LUTD after cerebrovascular accident. The long-term effects had been comparable to a retrospectively assessed cohort of patients with OAB-S managed with 'standard' treatment in the same clinics. Nonetheless the authors of this study stress the need for careful evaluation before choosing intradetrusor BoNT-A injections for this very vulnerable population.[532]

5.3. Topics for research

- Establishment of the reproducibility and reliability of UDS specific for the frail elderly.
- Further investigation of the associations between clinically observed LUTD and UDS assessed DO; DU and/or PVR in the frail elderly.

I. INTRODUCTION

The Committee was given the task of updating the evidence on imaging, neurophysiological testing and other tests in the field of urinary and anal incontinence. The Medline, Embase and Cochrane databases were searched for the relevant subjects from February 2012 to January 2016. All references obtained from the database search were screened for relevance, full text papers were obtained and reference list were used as additional source of evidence where appropriate.

The chapter covers different issues including: imaging, neurophysiological testing, and other investigations (laboratory tests, tissue analysis and pad test) in the paediatric and adult population, male and female subjects, neurogenic and non-neurogenic patients.

The following keywords were used for the difference subjects:

- Imaging: the Medline database was searched using the following keywords: imaging, urinary incontinence, continence, anal incontinence and faecal incontinence; the search has been limited to period from 2012 to 2016.
- Neurophysiology: clinical neurophysiology, conventional urodynamics, neurourology, urinary dysfunction.
- Other investigations: keywords including urinary incontinence, continence, pad test, urinalysis, urine culture, cystoscopy and tissue analysis were used.

Members of the committee were allocated the different topics of the chapter based on their specific expertise in the field. The first draft of the chapter was reviewed by all committee members, the final draft was then edited first by the Committee Chair and then by the book Editors.

Diagnostic techniques were evaulated with reference to the technique and its standardisation, intraobserver and interobserver variability, diagnostic accuracy, cost/benefit ratio and clinical benefit. The level of evidence was graded taking into consideration that imaging, neurophysiological testing and the other tests pertain to the area of “diagnosis” and the quality of the published papers was graded according to the criteria specific for this area. Areas of future research were identified.

Notwithstanding the large body of evidence, research on imaging in anal and urinary incontinence, its clinical benefit remains questionable. Test-retest, intraobserver and interobserver accuracy are often provided for diagnostic tests although diagnostic accuracy is difficult to evaluate due to a lack of a gold standard. When ultrasound is used to measure bladder volume, catheterisation can be used as a reference standard and accuracy can be easily calculated but when sphincter volume is calculated with ultrasonography, there is no solid reference standard except another imaging technique (e.g.: MRI) or the validity of an imaging measurement is tested against another weak test such as Valsalva Leak Point pressure or the maximum urethral closure pressure. Imaging can either be performed to better understand the pathophysiology of incontinence and pelvic organ prolapse and it may be of importance, although no immediate clinical benefit is evident (e.g.: calculation of sphincter volume with ultrasound). It can be performed as a diagnostic test in patients undergoing surgery so that quantification of the clinical benefit requires complex clinical trials (e.g.: MRI of pelvic organ prolapse in patient undergoing prolapse repair) in which different reference standards can be used (e.g.: physical examination or anatomic finding during surgery). Although imaging can sometimes offer a better understanding of the anatomy underlying the condition (e.g.: presence of an enterocele) the clinical benefit of this additional information may not be observed in all patients.

Although imaging is clearly a difficult area for research, the consensus regarding introduction of a diagnostic test into our daily practise must rely on the evidence of clinical benefit in terms of safety, outcome or cost-benefit ratio.

Imaging studies belong to the area of diagnostic studies, they should follow the suggestions of the STARD initiative and they differ substantially from other types of clinical trials (1). The aim of clinical studies of diagnostic tests should be to provide information regarding the diagnostic accuracy of the proposed test although, this is not always possible.

A few considerations regarding the levels of evidence in imaging studies may be instrumental in reading this chapter and are summarised herewith.

Imaging of parameters with known prognostic value (e.g. PVR)

- The first issue is to prove that imaging studies image what they are supposed to image. Although the issue may be trivial in case of PVR imaging or anal sphincter imaging, the issue is relevant in other areas (eg: enterocele imaging) and should be approached by using imaging in cadavers or other approaches such as intraoperative confirmation of the observed condition as a gold standard.
- When the imaging is quantitative, accuracy versus a quantitative gold standard technique should be provided. When the imaging is qualitative (e.g. presence or absence of vaginal vault prolapse) the diagnostic value should be provided (sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variablity).
- Once validity has been proven, one can assume that the predictive value of the imaging study is

equal to that observed for the parameter measured with the gold standard. The same applies to its value for patient management.

Imaging of parameters with unknown prognostic value (e.g. MRI of the pelvic floor)

- When the imaging is qualitative (eg: intact versus damaged levator ani), once validity is proven, the diagnostic value should be investigated providing sensitivity, specificity, positive and negative predictive value, accuracy, interrater and intrarater variability in cadavers or patients undergoing surgery.
- Once validity is proved, the prognostic value for patient management should be investigated.
- Confirmation of the proposed imaging study by independent groups is required ideally for both validity and prognostic value or at least for the latter parameter (we can assume that confirmation of the prognostic value is obtained, validity of the imaging technique can be inferred).

II. IMAGING IN URINARY INCONTINENCE AND PELVIC FLOOR DYSFUNCTION

This is a broad area that often requires a multiprofessional and muldisciplinary approach. The patient population is heterogenous including children, female and male subjects suffering congenital malformation of the genital and urinary tract, neurogenic disorders, iatrogenic conditions and traumatic lesions. Clinical guidelines always refer to the so called “standard patient” but the majority of subjects referred to secondary and tertiary referral centres cannot be defined as such and their management sometimes requires deviation from guideline recommendations. The large variability and the uniqueness of the observed cases may justify the adoption of a knowledge-based management in the absence of proven clinical benefit. Research on imaging of urinary incontinence (UI) and genital prolapse remains very active. Although all guidelines recommend not to use imaging in the evaluation of the standard patient, many clinicians believe this is an ideal adjunct to physical examination in evaluating the anatomical condition of the individual subject.

1. IMAGING OF THE UPPER URINARY TRACT

Urinary incontinence is defined as the complaint of any involuntary leakage of urine, it can be urethral or extraurethral (1). This latter condition either results from congenital anomalies such as ectopic ureters (inserting in the female distal urethra or vagina), iatrogenic or traumatic conditions such as fistula. In some patients, lower urinary tract dysfunction (LUTD) causing UI, might compromise the transport of urine from the kidneys to the bladder resulting in hydronephrosis and renal failure. The relationship between high bladder storage pressure and renal deterioration was first identified in myelodysplatic children and then considered to apply in all neurogenic patients (2) and automatically transferred to male and female patients with or without neurogenic problems; the value of 40 cmH2O of bladder pressure as threshold value at which the upper urinary tract (UUT) is at risk should therefore be used with caution. In male patients, chronic retention of urine can be associated with UI and lead to chronic renal failure. Lewis et al. reported that renal function at baseline and at the time of catheterisation were significantly worse in patients with chronic retention than with acute retention (3). Therefore, UUT imaging is needed in patients with urinary retention, especially with chronic retention. In women, severe urogenital prolapse may cause angulation of the pelvic ureter by the uterine arteries leading to hydronephrosis (4)

1.1. Indications

Generally speaking, there is no need for UUT imaging in patients with UI unless any of the previously described conditions is suspected or diagnosed. In children with extraurethral incontinence imaging of the UUT helps to identify the underlying cause.

The objectives of UUT in the incontinent patient are as follows:

Evaluation of the UUT when the presence of an ectopic ureter or ureterovaginal fistula are suspected.

Evaluation of the kidneys whenever UI is related to bladder dysfunction with high storage pressures (e.g. in neurogenic voiding dysfunction, chronic retention with overflow or low compliance bladders)

Exclusion of hydronephrosis in cases of UI associated with severe uterine prolapse.

1.2. Techniques

UUT imaging modalities include intravenous urography (IVU), ultrasound sonography (USS), computerized tomography (CT scan), magnetic resonance imaging (MRI), and isotope scanning. No data regarding reproducibility, specificity, sensitivity, positive and negative predictive value in relation with the diagnosis and management of UI are available. The choice of the imaging modality also depends on availability, expertise, and local management policies. Generally speaking, low cost and low risk techniques such as USS are preferred. Unless otherwise described, the following considerations regarding the different imaging modalities are based on expert opinion.

1.2.1 Ultrasonography

USS is the gold standard technique for primary imaging of the UUT because of the relatively low cost of the equipment and the examination, its wide

availability, the lack of any exposure to ionizing radiation. Renal USS is independent on kidney function and provides a good evaluation of kidney morphology. Concomitant renal disorders such as urinary lithiasis and neoplasms can also be diagnosed. In patients with LUTD, the detection of hydronephrosis is of importance and it can be related to either vesico-ureteral reflux or obstruction. USS is used for the first line evaluation of the UUT conditions in neuropathic patients. Sixteen percent of chronic spinal cord injured patients with hyperreflexic bladder had UUT deterioration revealed by USS, while 17.5% of patients with areflexic bladder also had it (5). UUT deterioration more frequently occurred in hyperreflexic bladder with higher reflex detrusor contraction pressure (115 vs. 72 cm H2O) mostly accompanied by type 3 detrusor external sphincter dyssynergia, and in areflexic bladder with higher storage detrusor pressure (58 vs. 24 cm H2O). In patients adequately managed with clean intermittent catheterization annual USS monitoring without routine urodynamic testing wassuggested to be an effective surveillance strategy (6). UUT deterioration was demonstrated in 70 of 193 myelodysplastic patients who underwent USS, voiding cystourethrography, DMSA scan, and urodynamics at three years old (7). The sensitivity and specificity for UUT damage were 91.4%and 22.3% in DLPP >20 cm H2O, 77.1% and 32.0% in DLPP>30 cm H2O, and 52.9% and 51.8% in DLPP >40 cm H2O, respectively. Therefore, a DLPP cut-off value of 20 cm H2O showed a higher sensitivity to predict UUT damage instead of 40 cm H2O. In the cross-sectional survey of Dutch urologists 91.5% of them performed USS at least once every 1-5 years during the follow-up of adult myelodysplastic patients (8).

USS is also used to detect hydronephrosis in prolapse patients. Hydronephrosis was revealed by USS in 5%-50% of patients with pelvic organ prolapse (POP) that reconstructive surgeries were indicated for (9). The proposed mechanisms for hydronephrosis are 1) ureteric compression between the uterine body and the urogenital hiatus, and 2) ureteral kinking caused by the cardinal ligament (9). It was reported that hydronephrosis occurred in 12.6%-22.4% of patients with severe ureterovaginal prolapse as well as 3.9%-7.1% of patients with severe vault prolapse, indicating that hydronephrosis developed after hysterectomy (10, 11). It was supposed that the ureters may be pulled down and kinked by the downward traction of prolapse upon the bladder (9). Dancz et al. reported that 30.6% of their POP patients had hydronephrosis, and that Ba-point (OR 1.68, 95% CI, 1.22-2.12), not C-point, and maximum cystometric capacity (OR 1.50, 95% CI, 1.08-2.07) were associated with hydronephrosis on a multivariate analysis (9). On the other hand, Beverly (11) and Gemer (12) reported that 7.7% and 17.4% of patients, respectively, had hydronephrosis, and that uterine prolapse was associated with hydronephrosis on multivariate analysis (OR 3.8, 95% CI, 1.4-10.5 and OR 1.9, 95% CI, 1.1-3.2, respectively). The presence of hydronephrosis do not affect the surgical procedures for POP repair and hydronephrosis improves in 70-100% of patients after surgery (10, 13). Therefore, USS should be performed in women with advanced POP, especially when surgical intervention is not indicated or delayed (9).

Although, no strict correlation exists between the degree of dilatation and the severity of obstruction, the grade of hydronephrosis is correlated with the extent of cortical damage (14). In children, kidneys with a pelvic diameter >20 mm are considered to be at risk for deterioration and require intervention (15). Measurement of the resistive index in the interlobar and arciform arteries of the kidney has been proposed for the diagnosis of urinary obstruction but this is rarely used in the evaluation of the incontinent patient (16). Whenever hydronephrosis is diagnosed on USS, other imaging modalities are often used to evaluate renal function, the degree of obstruction or vesico-ureteral re ux. USS is an ideal technique to follow the degree of hydronephrosis over time or the response to treatment.

1.2.2 Intravenous Urography

IVU is the original radiographic examination of the UUT which allows evaluation of UUT anatomy and function. Recent Canadian guidelines recommended that a serum creatinine level (SCr) should be obtained, and an estimated glomerular filtration rate (eGFR) should be calculated within 6 months as an outpatient who is stable or within 1 week for inpatients and patients who are not stable (17). Patients with an eGFR of ≥60 mL/min have an extremely low risk of contrast-induced nephropathy (CIN) (17). Fluid volume loading remains the single most important measure, and hydration regimens that use sodium bicarbonate or normal saline solution should be considered when GFR < 45 mL/min in patients who receive intravenous contrast (17). Patients are most at risk for CIN when eGFR< 30 mL/min (17). Additional preventative measures include the following: avoid dehydration, avoid contrast medium (CM) when appropriate, minimise CM volume and frequency, avoid high osmolar CM, and discontinue nephrotoxic medications 48 hours before administration of CM (17). Also, Japanese guidelines showed that chronic kidney disease (CKD, eGFR< 60 mL/min/1.73 m2) is the most important risk factor to predict the risk of CIN in patients receiving iodinated contrast media (18). In addition, aging and diabetes associated with CKD are risk factors for the development of CIN (18). Recent systematic review recognised pre-existing CKD, diabetes, age, and cardiovascular comorbidity as risk factors (19). The existing guidance documents agreed in recommending pre-hydration as the main preventive measure, but there was difference in recommended total volumes, composition, rate and duration of the infused solutions (19). There was no consensus on the use of sodium bicarbonate and none recommended N-acetylcysteine as solitary preventive measure (19). Recent guidance

documents recommend avoiding hypertonic contrast media, but did not recommend preference of iso-osmolar over low-osmolar contrast media (19). During IVU successful examination is dependent upon adequate renal capacity to concentrate urine, the poor concentration capacity of an impaired kidney limits the possibility to delineate the collecting system. A number of different conditions such as renal dysfunction, obstruction, congenital anomalies, fistula, stones and tumors may be detected. IVU is the appropriate first study in cases of extraurethral incontinence. When ectopic ureter is suspected (although this condition can also be responsible for urethral incontinence), delayed films and tomography are important because the renal unit or moiety associated with an ectopic ureter is often poorly functioning. In fact, IVU is sometimes unable to detect a small, malfunctioning moiety associated with a duplication and ectopic ureter or a poorly functioning or abnormally located kidney with a single ectopic system (20-22). In such cases where the diagnosis of ectopia is still suspected after IVU, another imaging modality such as CT, MRI or isotope scanning should be considered (23- 25). IVU is the appropriate first imaging study when uretero-vaginal fistula is suspected, usually after pelvic surgery. Typically, one sees ureteropyelocaliectasis proximal to the level of the fistula. This finding has been reported in 84-92% of cases (26, 27). Sometimes extravasation can be seen. Confirmation of the presence of the fistula, its size and exact location is often obtained with retrograde ureteropyelography.

1.2.3 Computerised Tomography *(CT scan)*

High quality information of the UUT anatomy can be obtained using multidetector helical CT scans and 3D reconstruction software. Differently from IVU which only acquires images in the anteroposterior or oblique CT acquires images in the axial plane. Pictures can then be reconstructed in 2D along any plane or in 3D when- ever required. CT scan can be used irrespective of renal function when no iodinated contrast medium is used. Whenever hydronephrosis is present, urine can be used to delineate the collecting system reducing the need for contrast agents. In general, intravenous contrast medium is required to highlight specific anatomic characteristics. CT scan is often used after the first line evaluation with USS and it has replaced IVU almost entirely. Several authors have reported the use of CT scan to detect ectopic ureter, in cases where the diagnosis is suspected, despite a normal IVU and ultrasound (28). In these cases the small size and poor function of the ectopic moiety make diagnosis difficult by IVU.

1.2.4 Magnetic Resonance Imaging *(MRI)*

MRI shares some of the advantages of CT over IVU in the evaluation of the UUT. Furthermore acquisition can be performed along any plane and pictures can then be presented in a 2D or 3D fashion. The paramagnetic contrast medium is free of allergic reaction risk although its use in the UUTremains dependent upon renal function and concerns about its nephrotoxicity have been recently raised (29). Low risk gadolinium contrast agents should be the choice, and dosage should be kept to a minimum, as higher doses have been linked to the development of nephrogenic systemic fibrosis (NSF)(30). While a pre-existing pro inflammatory state in the renal impaired is a high risk factor, liver insufficiency in itself is not a contraindication; however, patients may also have coexisting renal insufficiency and thus carry a risk of NSF (30). The development of the uro-MRI technique has gained an increasing role for the technology in the evaluation of hydronephrosis and urinary tract anomalies as an alternative to IVU. The use of MRI in the diagnosis of ectopic ureter has recently been described (31-35).

1.2.5 Isotopes

Isotopes are used primarily to examine morphological and functional characteristics of the upper urinary tract. Isotope scanning can be used to identify the location of a small kidney which is otherwise difficult to image with radiological techniques. Renography is used to examine the differential function of the two kidneys, to identify disorders of urine transit and to quantify obstruction of the upper urinary tract. There are many physiological factors and technical pitfalls that can influence the outcome including the choice of radio-nucleotide, timing of diuretic injection, state of hydration and diuresis, fullness or back pressure from the bladder, variable renal function and compliance of the collecting system (36, 37). Diuresis renography with bladder drainage is recommended when obstructive uropathy is suspected (38). Renal scintigraphy may be useful in the evaluation of ectopic ureters associated with hypoplastic kidneys (39). Detection rates of dysplastic kidney in single system ectopic ureter were 95.5% on DMSA, 95.5% on CT scan, 50% on USS, and 50% on MRI (40). DMSA would be a preferred option in this setting, because of its high detection rate and not requiring contrast medium.

1.2.6 Conclusions

Imaging of the UUT is rarely required in UI unless the condition originates from a malformation, a traumatic or an iatrogenic problem of the UUT. More rarely a condition of the lower urinary tract may endanger renal function, the preservation of which is required to guarantee a normal life expectancy in patients with UI.

1.2.7 Consensus Statement

- Imaging of the UUT is NOT indicated in the evaluation of non-neurogenic stress, urgency or mixed UI. (**Level of Evidence 3, Grade of Recommendation C**)
- Imaging of the UUT is indicated in cases of:
    - neurogenic UI with high risk of renal damage (due to high storage and/or voidingdetrusor pressure, e.g. myelodysplasia, spinal cord

injury) (**Level of Evidence 3, Grade of Recommendation C**)

- chronic retention with UI (**Level of Evidence 3, Grade of Recommendation C**)
- severe uterine prolapse, vault prolapse, or anterior vaginal wall prolapse, especially when surgical intervention is not indicated or delayed (**Level of Evidence 3, Grade of Recommendation C**)
- suspicion of extra-urethral UI by upper tract anomaly (**Level of Evidence 3, Grade of Recommendation C**)

- The choice of the imaging techniques and their sequence depend on the clinical question and their availability. The least invasive techniques should be preferred and should precede the more invasive, also taking into consideration cost effectiveness. (**Level of Evidence 3, Grade of Recommendation C**)

1.2.8 Suggested Research Areas

Prevalence of upper tract deterioration in various UI populations

- Natural history of upper tract changes
- Relation between upper tract dilation imaging, renal damage and bladder function

2. IMAGING OF THE LOWER URINARY TRACT

The use of imaging of the LUT in patients with UI dates back 40 years more than that e.g. Jeffcoate 1950's, particularly in female patients. The techniques have changed, over the decades from static to dynamic imaging, from qualitative to quantitative information. Although some of the techniques are now more than 50 years old their clinical value remains at best, unclear.

2.1. X-Ray Imaging

Voiding cystourethrogram (VCUG) was the mainstay of x-ray imaging of the LUT but it has been replaced almost entirely by USS because of its ease of use, low cost and availability. While CT has not gained acceptance because of the exposure of ionising radiation, MRI took the lead as the most promising imaging modality because it offered a comprehensive view of the pelvis and enabled visualisation of the position of visceral organs in relation to bony reference points. 3- and 4D USS recently offered volume acquisition with limitations in the depth of ultrasound wave penetration and the volume that can be imaged. Progressive technical developments in imaging technology and techniques have made this research area particularly interesting.

In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction separating the bladder neck from benign prostatic obstruction although it may play a role in the management of post-prostatectomy incontinence (1). In children the diagnosis and classification of reflux and diagnosis of posterior urethral valves have been the primary goals (2). The severity of the vesicoureteric reflux on one side determines the development of contralateral reflux and indicates a poorer resolution rate for reflux (3).

Positive-pressure urethrography has been used for the diagnosis of female urethral diverticula, it was shown to be more sensitive than voiding cystourethrography (4-6) although MRI is the gold standard for the diagnosis of diverticula and planning surgical repair (7, 8).

The rationale for imaging studies of the lower urinary tract in this field derives from the hypothesis that stress UI is caused by urethral hypermobility. This was the theoretical basis of the classification of UI published by Green in 1968 and then modified by Blaivas and Olsson in 1998 (9, 10). Investigation into cohorts of continent and incontinent patients failed to provide evidence to support the hypothesis and imaging techniques aiming at measuring bladder neck displacement during straining have been abandoned. The same applies to outcome research in urinary incontinence where surgery that limits bladder neck displacement does not necessarily lead to cure of the condition. A renewed interest derived from the availability of USS which took imaging out of the radiology suites and moved it into the urological and gynaecological outpatient clinics opening new opportunities for clinical research in this field. The possibility of imaging what was usually perceived during physical examination such as bladder neck mobility or POP increased the usefulness of USS. Research in the field of MRI first assessed the possibility of fast dynamic acquisition to image the displacement of visceral organs during effort to better quantify POP and then the morphological imaging of the pelvic organs muscular support to investigate the physiopathology of genital prolapse.

2.1.1 Female Cystourethrography

X-ray imaging of the urinary bladder and urethra has been used to assess the female urinary tract in women suffering UI to evaluate urethral/bladder neck hypermobility and to assess associated conditions such as urethral obstruction, vesico-urethral reflux, diverticula, fistulae, stones and tumours. In males the purpose of voiding cystourethrography has been mainly to locate infravesical obstruction (1, 11).

The diagnosis and classification of reflux and diagnosis of posterior urethral valves in children have been the primary goals (2). In a study comparing cystourethrography with direct radionuclide voiding cystography and voiding urosonography with contrast

medium were compared. Voiding sonography and direct radionuclide voiding cystography were shown to be the most sensitive (12).

2.1.1.1 Background

History and methodology of cystourethrography in females had been reviewed by Olesen (6). The technique is now over 70 years old. Voiding cystourethrography with lateral projection was first done by Mikulicz-Radecki in 1931 (13). The use of a metallic bead chain to identify the urethra was introduced by Stevens and Smith in 1937, and in 1956 Ardran, Simmons and Stewart reported on a cinematographic technique with contrast media also in the vagina and rectum (14, 15). In an attempt to combine qualitative and quantitative information regarding the function of the lower urinary tract, the combined used of fluoroscopy and pressure-flow recordings was proposed during the nineteen sixties and seventies (16-20).

2.1.1.2 Methodology (projection, positioning and exposures)

Bladder neck displacement is best viewed and quantified in true lateral projection although image quality is sometimes poor because of the increased body mass and the overlap of bony structures with the bladder neck area. Consequently, oblique projections are sometimes used notwithstanding the lack of quantitative information. Achieving a quasi-physiological voiding in a radiology suite is difficult because of the inevitable impact of the environment. The use of a sitting position is recommended for micturition studies as voiding while standing or lying will increase the embarrassment and therefore many impair the quality of the examination (13). Especially in patients with large body mass index, imaging of female urethra in a true lateral projection is difficult, it necessitates high radiation doses as the central x-ray beam must penetrate the trocanteric regions and further because the urethrovesical junction is sometimes overshadowed by the lateral parts of the bladder. A significant improvement in this area has been brought about by digital imaging which allows the subtraction of the bony structures. The position and mobility of the urethrovesical junction as well as urine leakage are supposed to be influenced by the filling volume as has been demonstrated on ultrasonography and leak point pressure measurements (21, 22). However, in VCUG the bladder is filled to capacity. Addition of a urethral bead chain or catheter and vaginal contrast to improve the visualisation of the urethra, bladder neck and trigone has been abandoned. Contrast in the rectum is not necessary for urinary incontinence purposes. Exposures at rest should be supplemented with provocative manoeuvres to test bladder neck mobility by contracting and relaxing the pelvic floor (e.g. coughing, straining, and squeezing). Whenever possible, pictures while the patient is voiding should be obtained. It is important to consider that coughing and straining result in a different effect on the pelvic floor. Straining might be associated with relaxation or contraction of the pelvic floor, and the imaging can change accordingly.

During coughing there is a reflex contraction of the pelvic floor, but coughs are of a short duration and difficult to capture on spot films. Bladder suspension defects were diagnosed at rest in 49% of 420 examinations, while coughing and micturition disclosed a further number of 20% and 4% respectively (13). Squeezing can demonstrate pelvic floor awareness and contraction (23).

2.1.1.3 Combined i6maging and urodynamics

Videourodynamics has been regarded by some as the “gold standard” in the evaluation of LUTD (23). Reproducibility of the combined examination has not been assessed and further the radiation dose has to be considered (15,20,24-26). One study has attempted to compare videourodynamics with saline cystometry (23). Independent observers carried out the two procedures with 75 women having the saline cystometry first and a further 75 women had videourodynamics first. The degree of bladder descent noted on screening was greater than on clinical examination. Nineteen women had trabeculation and a further 11 women had bladder or urethral diverticula, urethral stenosis and vesicoureteric reflux (1,11,14). Only seven of the eleven women could have been predicted by a selective imaging policy based on history alone which would image 43% of the 150 women. This suggests that a selective policy of screening will unnecessarily expose patients to radiation while not using the optimal technique for investigation for all patients who need the test. Nevertheless simultaneous videomonitoring along with tracings of pressure and urine flow rate are important to ensure that the exposures are made at appropriate moments so that the radiographs can be representative of the various functional states (13, 18, 27, 28).

Patients with Parkinson’s disease and multiple system atrophy are best evaluated by videourodynamics with sphincter motor unit potential analyses to identify the characteristic features of these conditions including: external sphincter denervation, neurogenic sphincter motor unit potentials, open bladder neck at rest and detrusor-external sphincter dyssinergia (29). Neurogenic patients show severe bladder trabeculation with diverticula and pseudodiverticula, pelviureteric reflux, widening bladder neck and proximal urethra, and narrowing at the level of the membranous urethra can suggest, the presence of neurogenic dysfunction of the lower urinary tract (occult spinal dysraphism, non-neurogenic neurogenic bladder (also known as the Hinman syndrome)) even in the absence of neurogenic symptoms and signs (30-32). Urodynamic parameters in children do not discriminate between those with or without vesicoureteral reflux thus videourodynamics has been considered essential. Additionally children with non-neurogenic voiding dysfunction are found to have a number of

abnormalities with videourodynamics (33,34). Indications for videourodynamics include previous continence and vaginal surgery, neurological disorders and suspicion of urethral diverticula.

2.1.1.4 Normal and defective bladder support

The whole issue about the clinical value of VCUG is about the pathophysiology of defective bladder support in the pathophysiology of SUI in female patients and the relation between the surgical correction of such a defect and cure. The concept of urethral hypermobility was central to the classification of SUI and the concept that impaired transmission of abdominal pressure to female urethra could be responsible for the observed leakage. Little remains regarding the concept of urethral hypermobility in a modern view of female SUI and this contributed to the decreasing use of VCUG in the evaluation of a standard female patient.

The normal resting bladder has a smooth surface although bladder trabeculation is often seen in elderly women and not necessarily related to any pathological condition. The internal urethral orifice is located just above a horizontal line through the lowermost part of the symphysis in a coronal projection. The urethra is straight and runs anteriorly and caudally toward the external meatus.

On coughing and straining, relaxation of the pelvic floor results in downward movement of the bladder neck, which can be associated with a backward movement of the bladder neck resulting in a change in urethral axis. Squeezing (and sometimes also straining) results in contraction of the pelvic floor muscle with a cranial movement of the bladder neck. During voiding the bladder base is usually lowered about 1 cm, the angle between the urethra and the trigone is straightened, making a funnelled appearance of the proximal urethra and the bladder base, the bladder contour is rounded and a fine sawtooth irregularity of the mucosa becomes visible above the trigone. Angles and distances between the urethra, bladder base and symphysis pubis have been assessed radiologically. The following parameters have been assessed for reliability:

1. The posterior urethrovesical angle (PUV) is defined by lines along the posterior urethra and the trigone (35). Cut off values were usually 115° or more (36, 37);

2. The urethral inclination is between the proximal urethral axis and the vertical plane, which is a plane outside the patient and, therefore, the angle also varies with pelvic inclination. In Green type I and type II descent the angle is less or more than 45° respectively (37);

3. The urethropelvic (UP) angle is measured during voiding as the anterior angle between a line through the middle of the internal urethral orifice and the urethral knee and a line through the posterior surface of the symphysis through the lowermost part of the obturator foramen closest to the film. In normal subjects the mean UP is about 95° and the cut off point for bladder descent are values below 70° (13);

4. Symphysis orifice (SO) distance is measured at rest as the distance on a horizontal line from the symphysis to the internal urethral orifice. Normal values are 31 ± 6 mm (mean ± SD) and values less than 20 mm are the cut off points for descent (13);

5. The urethral axis at rest (UAR) and during straining (UAS)

Funnelling of the proximal urethra and flatness of the bladder base (both anterior and posterior to the internal urethral orifice) and the most dependent portion of the bladder base (the urethrovesical junction or a point posterior to that) are important qualitative parameters estimated on straining films (36).

Anterior bladder suspension defects or bladder base insufficiency (BBI) is defined as SO < 20 mm with a normally positioned vagina at rest, during coughing or micturition and/or funnelling of the bladder base at rest or with coughing. BBI can be graded 1-3, which corresponds to Green's type I descent (13, 38). The supportive defect is supposed to be in the fascial and ligamentous system and their abnormal detachments (eg., paravaginal defects).

Posterior bladder suspension defects are defined as a posterior-inferior bladder displacement and a UP of less than 70° (13). It corresponds to Green's type II (39). Sometimes only the trigone and posterior part of the bladder is involved. The supportive defect is supposed to be in the muscular pelvic floor, that is, the pubo-vesical part of the pubococcygeus muscle or in paravaginal detachment.

Interestingly, when UAR and UAS were examined in a group of 76 continent women and correlated with age, a perfect linear regression was noted between UAR and age (R^2= 0.28). Patients with stress urinary incontinence were found to have an average UAR value of 25° with a mean UAS of 43° leading to a threshold value of hypermobility of about 20°. When standing cystourethrograms were repeated 3 to 6 months after surgery for SUI, UAR and UAS values were found to be close to normal suggesting a relation between the correction of the defective bladder support and cure (39). A more structured definition of cystocele (ranked by height in centimetres) was also obtained, adding to the emerging data that the reliability of the pelvic organ prolapse quantification (POP-Q) system increases when measurements are performed in a more upright position (39).

2.1.1.5 Reproducibility

The observer variation has been evaluated in four university uro-gynecological units (Table 1) (23, 36, 40, 41). The inter-observer agreement was 43-79%

and the intra-observer agreement was 53-99%. These figures are in the same range as has been found for other diagnostic tests (42).

2.1.1.6 Accuracy for the diagnosis of SUI and post-operative results

Evaluation of accuracy is the mainstay in the evaluation of a diagnostic technique. The sensitivity and specificity of a diagnostic technique depend on intrinsic factors such as reproducibility (as measured by intraobserver and interobserver variation) and extrinsic factors such as the characteristic of the patient cohort used to assess accuracy.

The accuracy of the previously mentioned radiological criteria have been measured by comparing imaging data with the 'so called' index-test which in this case was a clinical diagnosis of urodynamic stress incontinence and expressed as specificity and sensitivity or as predictive values. Unfortunately, the diagnosis of SUI is controversial and might be based on subjective criteria, urodynamic tests, or measurement of leakage. Even radiological criteria have been included in the diagnosis.

Reproducibility (e.g. test-re-test agreement) has not been measured, but intra- and inter-observer variation has been calculated and adjusted for expected chance agreement (kappa coefficient). The predictive values and the kappa coefficient are supposed to depend on the prevalence, and therefore, comparison between different materials are difficult (42).

No consensus has been reached in the peer-review literature as to the lack of discriminant value of VCUG between SUI and continence, the majority of published papers are consistently negative although new promising data have been published (37, 39, 43-45)

Table 1: Inter- and intra-observer variation (agreement) on cystourethrography in females with urinary incontinence.

Type of examination, patients and observers	Inter-observer variation	Intra-observer variation
Bead-chain [1] stress & urgency incontinence n°92 3 observers on 5 landmarks	45.8-80.7 %	
VCCU [2] stress incontinence n° 52 1 observer on type of descent	79% 95% c.l. 65-89	
VCCU [3] stress incontinence n° 29 2 observers on type of descent	70% 95% c.l. 75-89	53% 95% c.l. 27-78
VCCU [4] n° 93 stress & urgency incontinence 6 observers on type of descent	43-60% kappa 20-39%	72-99% kappa 57-98%
VCUG [5] Stress incontinence n° 11 2 observers on urethral angle shift from rest to straining	r = 0.83 (p=0.001) for UAR r = 0.82 (p=0.002) for UAS	

1: static bead-chain cystourethrography with straining (36). The 5 landmarks were the posterior urethrovesical angle, urethral inclination, funnelling of the proximal urethra, flatness of the bladder base and most dependent position of the bladder base;

2: voiding colpo-cystourethrography (VCCU) at rest and with coughing, straining, micturition and squeezing; one observer against original diagnosis (that is, normal appearance or anterior, posterior or combined suspension defects) made by a few senior radiologists (22);

3: voiding colpo-cystourethrography at rest and with coughing, straining, squeezing and micturition. Possible diagnoses were: normal appearance or anterior, posterior or combined descent respectively (41).

4: voiding colpo-cystourethrography at rest, coughing, with holding and voiding. Possible diagnoses were: normal appearance and anterior or posterior descent respectively (40);

5: standing voiding cystourethrography, urethral angle was measured at rest (UAR) and during straining (UAS) (39).

The specificity of 5 radiological parameters on static bead chain VCUG was 44-76% and the sensitivity 53-100% (45, 46). Neither was the degree of SUI correlated with the type or degree of suspension defects (23, 40, 47). The positive and negative predictive values for a bladder suspension defect were 0.70 (95% C.I.: 0.62-0.78) and 0.52 (95% C.I. 0.41-0.63) respectively on voiding colpo-cystourethrography (38, 48).

In a later publication on 159 women, positive and negative predictive values of 0.56 and 0.74 were obtained (45). Evaluation of the urethral angle at rest and during stress in controls and in patients with SUI and various grades of anterior vaginal prolapse show a significant relationship between UAR and aging (from 2.4° ± 14.9° in the third decade to 29° ± 9.2° in the 9th decade; r^2= 0.28). In patients with SUI, UAR and UAS decreased from 25.7° ± 13.6 ° and 42.6° ± 15.9° to 16.6° ± 14.7° and 23.8° ± 17.5°, respectively; the observed changes were found to be statistically significant. A similarly significant difference was found in patients with moderate to grade 3 cystocele and urethral hypermobility (at least 5 cm descent of the bladder base below the inferior ramus of the pubic symphysis on the lateral view of a standing VCUG): UAR and UAS decreased from 48.1° ± 16.5 ° and 64.4° ± 16.8° to 22.3° ± 26.9° and 29.8° ± 22.8°, respectively.

Comparison of a randomly selected control cohort (aged-matched) with patients suffering SUI showed a significant difference of UAR and UAS at diagnosis while similar values were found after surgery. This was similar to patients with grade 3 cystocele in whom both UAR and UAS were significantly different from controls at baseline while showed similar values in the postoperative follow-up.

Measurement of the cystocele height obtained as the distance between the inferior border of the pubic symphysis and the inferior edge of the cystocele in controls and patients with mild and severe cystocele showed a significant difference between the two cohorts (16.63 ± 10.9 versus 27.4 ± 12.3 mm versus 73.4 ± 15.6 mm, respectively). Following formal cystocele repair, a significant change of cystocele height values was found in patient with mild and severe cystocele (from 27.4 ± 12.3 mm to 13.9 ± 18.0 mm and from 73.4 ± 15.6 mm to 25.4 ± 24.6 mm, respectively ($p<0.001$).

These are the first data supporting the use of standing VCUG as an outcome measured, previous peer-review papers suggested the inability of its technique to distinguish postoperative failures from success (13, 23, 42, 44, 46, 49-52).

2.1.1.7 Comparison of cystourethrography and ultrasonography

The development of USS techniques for the evaluation of the lower urinary tract raised the question of the relationship between X-ray and USS imaging. Static bead chain cystourethrography has been compared with transrectal and perineal USS and voiding colpo-cystourethrography has been compared with perineal USS (46, 47, 53, 54). The findings correlated well regarding bladder neck position and mobility, PUV, urethral inclination, SO distance and rotation angle.

Specificity, sensitivity and interobserver agreement were also comparable for the two methods. All the authors seem to prefer the sonographic modality because imaging can be performed at the same time as the physical examination. This has also been the case in men with neuromuscular dysfunction (11). Simple and extensive funnelling is more easily imaged in upright patients during cystourethrography than in the supine position frequently used for ultrasound studies (30).

2.1.1.8 Comparison of cystourethrography and MRI

The introduction of MRI in the assessment of the LUT required adequate comparison of this technique with standard X-ray imaging. The comparison of cystourethrography and colpocystourethrography with dynamic MRI showed comparable data on bladder neck position and cystocele extension (55, 56). Although there is an obvious concern about the fact that dynamic MRI imaging is usually performed with the patient lying in a dorsal lithotomy position, comparison of standing and lying colpocystourethrography did not show any significant difference (56).

2.1.1.9 Conclusions

VCUG does not have a major role in the evaluation of the standard female patient with UI confirmatory results on the clinical utility of measuring urethral angle and cystocele height in patients with UI and POP who are scheduled for surgery still missing. Defective bladder support can be diagnosed on VCUG with a reliability comparable with other diagnostic tests.

Dependent on local facilities the method might be considered if the choice of a surgical procedure is based on type and degree of supporting tissue deficiencies and possibly if new procedures are evaluated for the ability to restore this deficiency.

2.1.1.10 Consensus statement

Cystourethrography is NOT indicated in primary uncomplicated stress, urgency or mixed female urinary incontinence **(*Level of Evidence 3, Grade of Recommendation C*)**.

Cystourethrography may be a reasonable option in the preoperative evaluation of complicated or recurrent female urinary incontinence **(*Level of Evidence 3, Grade of Recommendation C*)**.

Variation of VCUG parameters in patients with SUI +/- ISD and prognostic value for surgical repair.

VCUG parameters in re-do surgery for SUI compared with controls

2.2. Ultrasonography

Ultrasonography has been used in the evaluation of urinary incontinence as early as 1980 (1). Over the past three decades the quality of the ultrasound image and its processing has improved beyond what could have been imagined during the 70's. Various

new developments, such as the use of contrast medium, colour Doppler, 360 degree transducers and three- and four dimensional imaging have been introduced and have led to the more widespread use of ultrasonography in the evaluation of the lower urinary tract and pelvic floor disorders.

A number of studies have reported good correlations between ultrasonography and x-ray in the evaluation of urinary incontinence (2-11). In particular, the position of the bladder neck at rest and during Valsalva (10, 12) manoeuvre has frequently been compared, and all authors agree on a good correlation. Some authors even found better accuracy for ultrasound (5), especially in obese women (2). Ultrasonography is cheaper than X-ray imaging, it is often preferred by physicians because the imaging studies can be performed in their own office as part of the physical examination and it is also more acceptable to patients because of the lack of for radiation exposure. However, ultrasound itself produces problems by needing the probe to be in direct contact with the patient even during dynamic manoeuvres and the resolution is dependent on the frequency of the probe used. The higher the ultrasound frequency, the better the resolution but there is reduced penetration into the tissues.

2.2.1 Types of Ultrasonography

Different imaging approaches have been used, such as abdominal, transvaginal, transrectal, perineal and transurethral. Synonyms for the perineal approach are transperineal, introital, labial or translabial access, all use a similar method and there does not appear to be a substantive difference between these terms, a common agreed term needs to be decided upon.

Abdominal ultrasonography is generally not considered to be helpful in pelvic floor and urethral imaging because of the acoustic shadow caused by the pubic bones particularly in the obese patient (1). All approaches in ultrasound have a problem of distorting the tissue being imaged due to compression. With vaginal ultrasonography this risk is probably highest (13), although this has also been denied (14). Most recent studies report on perineal ultrasonography that allows the visualisation of all three compartments in one image but again compression of the urethra may occur and imaging is impaired with vaginal prolapse or gas in the rectum.

The development of three-dimensional ultrasonographic systems has brought increased accuracy to measuring volumes of irregular structures as well as reconstructed images from novel directions and allowing pelvic floor imaging. Three-dimensional ultrasonography was first described for the female urethra in 1999 (15); the three-dimensional image can either be evaluated as a separate entity on the screen, or in combination with each of the two-dimensional planes from which it is derived (**Figure 1**). These three two dimensional planes are at orthogonal to each other being the sagittal, coronal and axial planes. Three-dimensional images are built up as a rendered image of a self defined region of interest, major advantages over 2D imaging include the possibility of reviewing the acquired images from any investigator and the ability to analyse the acquired volume through any plane (similar to CT scans or MRI) (**Figure 2**). This means that the levator ani muscle can be easily visualised. However interest has focused on the absence of the pelvic floor being imaged and a defect being implied.

Ultrasound produces images by its waves being reflected by a tissue. These reflective surfaces produce images of great clarity and resolution which are independent of the ultrasonic frequency. However once the tissue is perpendicular to the direction of travel of the ultrasound waves axial resolution is effective, limiting the accuracy and the ability for tissues to be imaged. This highlights the importance of testing all ultrasound imaging modalities against a gold standard such as cadaveric dissectionor comparing then toanother medium such as MRI or CT. Four-dimensional imaging involves a volume of tissue being continuously scanned, thusinevitably involving time delay;albeit not truly “real-time”, it incorporates the enormous improvement in speed of three-dimensional systems over the last few years and it makes three-dimensional assessment of the dynamic relation of the pelvic organs on Valsalva manoeuvre and pelvic floor contraction possible.

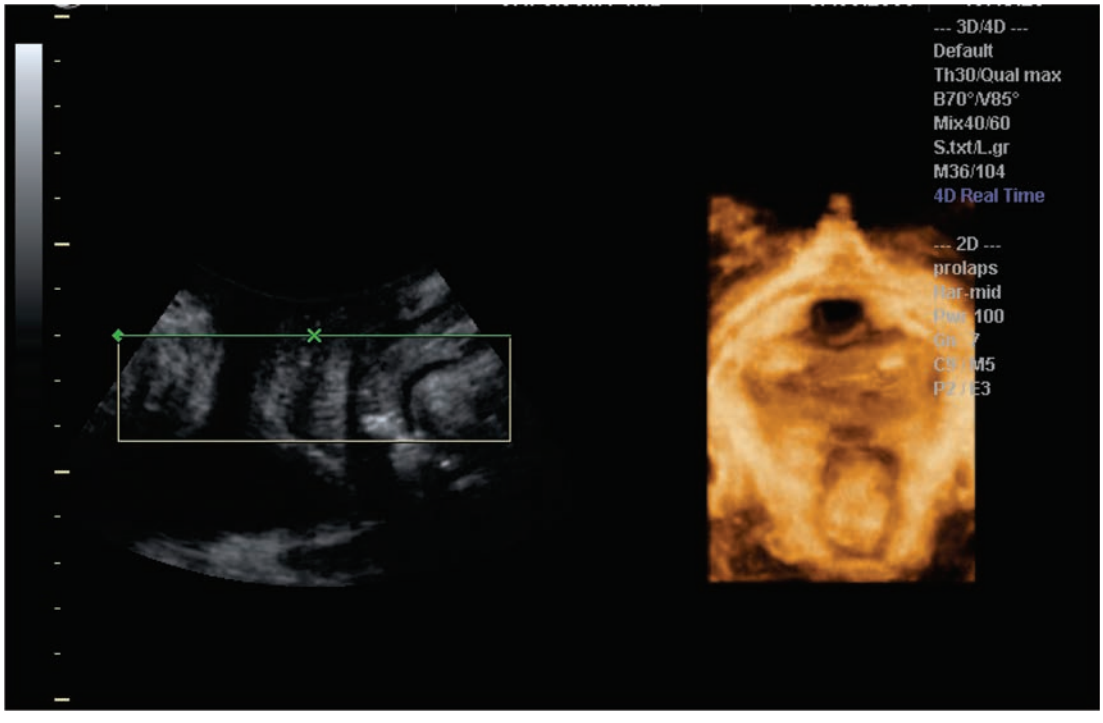

Figure 1: Perineal midsagittal two-dimensional view and three-dimensional rendered image.Normal anatomy.

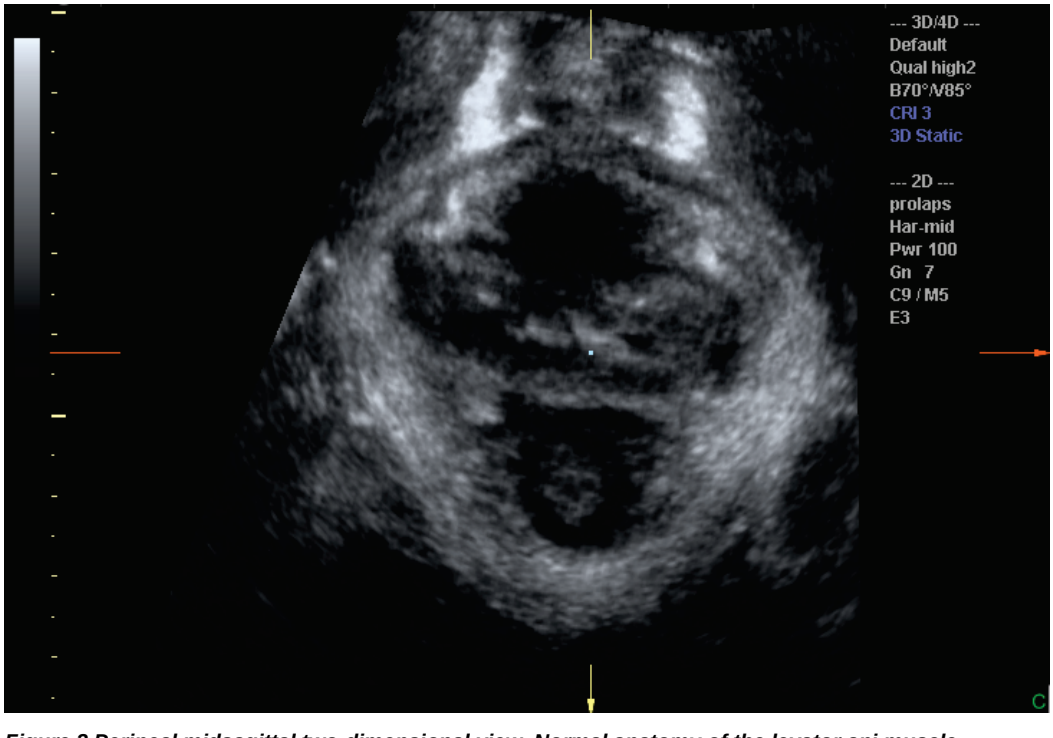

Figure 2 Perineal midsagittal two-dimensional view. Normal anatomy of the levator ani muscle.

2.2.2 Standardisation

No consensus has been reached as to the standardisation of image orientation. Some prefer orientation with cranial structures above (**Figure 3a**) (15) whereas others prefer presentation of the cranial parts below (**Figure 3b**) (16-17). All authors agree that the symphysis pubis, and its inferior border in particular, is a well recognisable and fixed reference point. This point can be used in the evaluation of the various aspects of relevant structures at rest and during dynamic imaging. In general, ultrasonographic studies are performed in the supine position (**Figure 4**). Small differences between the supine and standing position of the patient have been documented, although these differences disappeared during a Valsalva manoeuvre (18). Only a few studies have been performed in the standing position (19). There is no clear consensus on the amount of bladder filling, some authors prefer significant bladder filling, others prefer a nearly empty bladder because an empty bladder seems to descend more on Valsalva manoeuvre compared with a full bladder (19,20). Attempts to standardise Valsalva manoeuvre, ideally with intra-abdominal pressure measurements, has not been widely accepted (14,21). In one study (19), a peak flow meter has been used, where women were asked to "huff" maximally and to reach the same force during a number of "huffs". It has been shown that the mobility of the bladder neck differs between coughing and Valsalva manoeuvre (22). Co-activation of the pelvic floor muscles during Valsalva manoeuvre has been documented and is one of the reasons for the lack of standardisation (22, 23).

2.2.3 The Urethra and Bladder Neck

When collagen fibres and muscle fibres are located parallel to the ultrasound beam, the structure becomes hypoechoic. These same structures will become hyperechoic, however, when the fibres are located perpendicular to the beam. Ultrasonography may result in variable images of the urethra, since the echogeneity of the structures depends on the position of the transducer in relation to the urethra. This may produce confusing images, especially in the dynamic process of pelvic floor contraction and Valsalva manoeuvre. In the midsagittal plane on perineal ultrasonography, and with normal anatomical position of the urethra at rest, the internal sphincter and inner urothelial layer of the urethra will appear hypoechoic (Figure 1), thus making these structures indistinguishable on ultrasonography. In the midsagittal plane and with normal anatomical position of the urethra at rest, the striated external sphincter or rhabdosphincter will appear hyperechoic, and can hardly be distinguished from the surrounding structures. It will, however, be easily visible as a hyperechoic circular structure in the axial plane as seen on three-dimensional ultrasonography (24,25). The rhabdosphincter has been found to be thinner dorsally (15), and both ventrally and dorsally (26) by various authors and more difficult to distinguish from the internal sphincter ventrally and dorsally compared with laterally (27). These differences may be due to the approach used to image the structures as well as types of probes applied but this has not been addressed in any study to date.

With the use of ultrasonography, thickness and length of the urethral sphincter muscle can be measured and urethral volume calculated (17,27-28).

Figure 4 Perineal ultrasound examination in the supine position.

Intra-urethral ultrasonography has been used for this purpose although complete imaging of the lateral parts of the sphincter are difficult due to the higher frequencies emitted by these probes (29), others have used two- or three-dimensional ultrasonography of the urethra (15, 24,26,30).

Comparison of transvaginal and transrectal approach showed a lower degree of urethral compression with the latter approach (26,31). Ultrasound measurement of the female urethra has been found to be reproducible (15, 24,32). Sphincter volume may differ significantly when 2D or 3D imaging is used (24). Urethral volumes, measured by 3D ultrasonography, were positively correlated with the actual volumes in cadavers (30,32). A significant and positive correlation between rhabdosphincter volumes and symptoms and signs of urinary incontinence has been reported (15); correlation with the urethral pressure profile (UPP) meausres has alsobeen found (25,27,28,30) but these data could not be reproduced (33). Ultrasonography imaging during micturition has been explored with the aid of a remote control systems (34). The use of intra-urethral ultrasonography with rotating probes (360°) has been proposed by various authors although no advantages over perineal US could be identified and incomplete imaging appears to be a problem due to the high ultrasound frequency emitted (29,35-38).

The advantage of preoperative and intraoperative three-dimensional ultrasound scanning in women with urethral diverticula has been outlined by Yang et al. (39-40).

2.2.4 Bladder Neck

The bladder neck and proximal urethra are easily visible on all types of ultrasonography without the need for catheterisation (Figure 1). Measurements are usually taken at rest, during straining (Valsalva manoeuvre), and sometimes during a cough and squeeze. The position and movements are measured in relation to the lower margin of the symphysis pubis. The difference between rest and strain is referred to as the bladder neck descent (the distance between the bladder neck and a horizontal line through the lower end of the symphysis pubis) (**Figure 5**). On Valsalva manoeuvre the bladder neck rotates in a posterior and inferior direction away from the symphysis pubis. The axis of the urethra in relation to a vertical or horizontal line can be measured in degrees and provide the degrees of urethral rotation or bladder neck mobility. Other parameters are the posterior urethrovesical angle and the anterior urethrovesical angle. A number of studies have validated the use of ultrasonography in the assessment of the position and mobility of the bladder neck and proximal urethra. Good results for this validity testing have been reported although the clinical value of such measurements is still elusive (4, 14, 41-43). Normal values of bladder neck mobility have not been fully defined, since there is a great range in mobility even in young nulliparous women. In one study amongst nulliparous continent women of approximately 20 years of age, the bladder neck descent varied between 1mm and 40mm (44).

Others (41) found an average descent of 15 mm on Valsalva manoeuvre and 8 mm on a cough. Brandt et al. have found an average bladder neck descent ofonly 5 mm in 16 year old girls (45). More recently Naranjo-Ortiz et al proposed 25mm of bladder neck descent as cut off for “normality” as further descent was associated with SUI and USUI (46).

Racial differences have been demonstrated, with white women having greater bladder neck mobility compared with black women (47). Genetic determination of bladder neck mobility has been suggested (48). Numerous studies have found greater bladder neckmobility in parous compared with nulliparous women (14, 33, 49-51). Bladder neck hypermobility, however defined, is considered to be related to stress urinary incontinence (17,33,46). A large number of studies have correlated ultrasonographic findings with urodynamic parameters (46, 51-60). Specificity and sensitivity of ultrasonography for the diagnosis of stress incontinence were 83 and 68% in one study (54) and 92 and 96% in another study (61). Other studies have demonstrated that ultrasonographic findings of bladder neck descent and rotation of the retro-vesical angle increase the odds for SUI by 2.5, however they concluded that ultrasonography’s low a diagnostic value does not allow it to replace urodynamics (62).In one study in which ultrasound-measured movement of the bladder neck on coughing and Valsalva was used as a marker inpatients undergoing pelvic floor exercises, response to treatment was not associated with changes to the bladder neck mobility (63) underlining this is probably an associated phenomenon and not the cause for stress urinary incontinence.

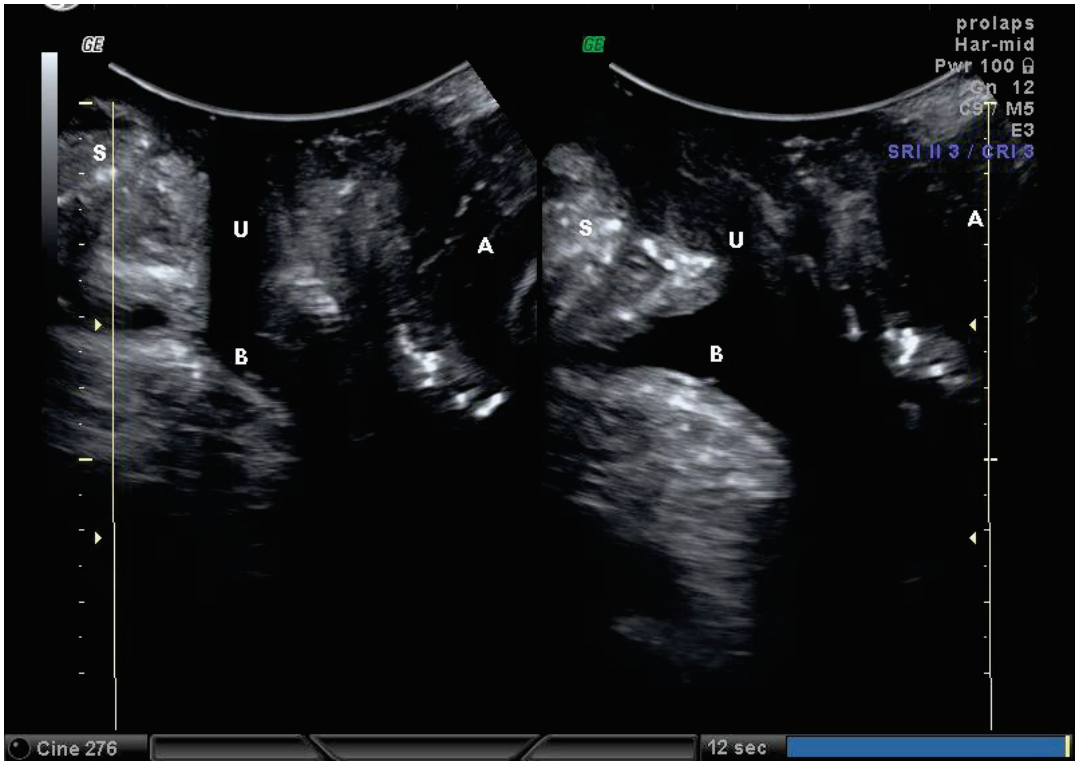

Figure 5 Perineal midsagittal two-dimensional view at rest and on Valsalva manoeuvre. Bladder neck descent. (S= symphysis pubis; U= urethra; B= bladder; A= anal canal.)

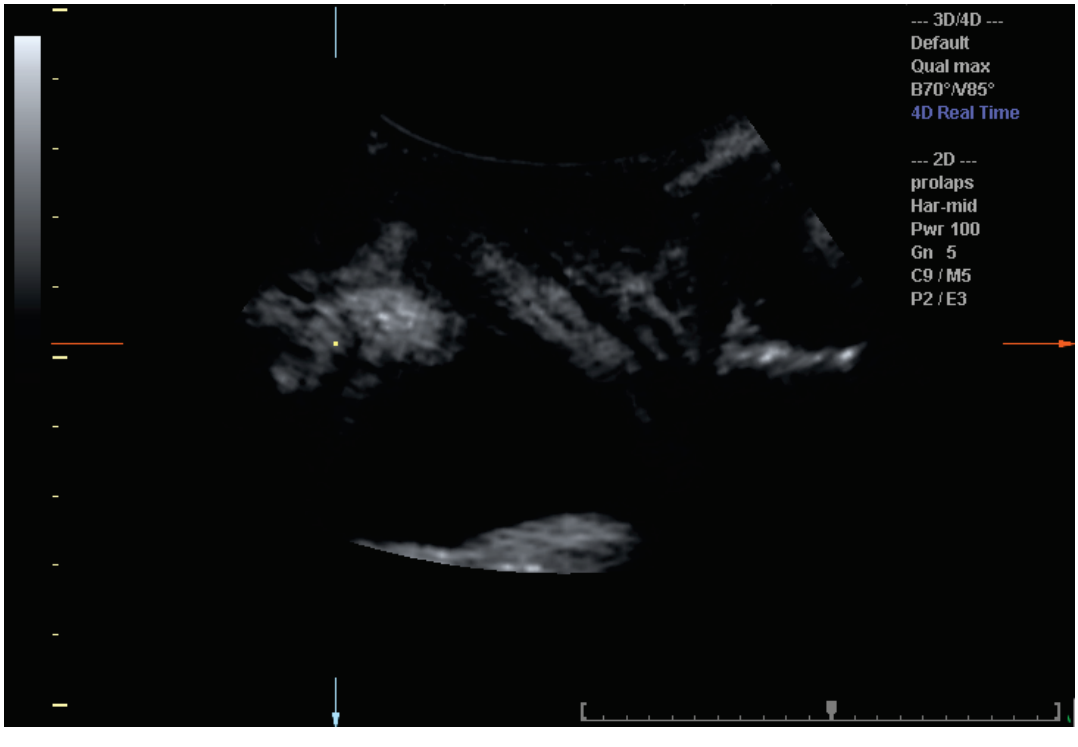

Figure 6 Perineal midsagittal two-dimensional view. Urethral funnelling.

Other researchers have contradicted these data by demonstrating that women with SUI who conducted physiotherapist-guided pelvic floor exercises showedreduced bladder neck mobility during coughing and increased cross-sectional area of their urethra as compared to before the training (64).

Further data from a RCT in primigravidae suggested that PFMT can play a preventative role in reducing the risk for SUI despite not conveying a significant change in bladder neck descent (65).

One research group has specifically investigated simultaneous perineal ultrasonography and urethrometry. They demonstrated that the variations in urethral pressure were caused by the activity of the urethral sphincter as well the pelvic floor muscles (66). The contractions from the urethral sphincter during acute stress events such as coughing are thought to be due to fast contractions. Some studies have used ultrasonography to optimise patient management, but despite the abundant literature on the use of ultrasonography in the investigation of women with urinary incontinence, disappointedly, a clinical advantage in terms of patient outcome has not been reported until now (67,68).

Urethral funnelling can be observed on ultrasonography (**Figure 6**) particularly with the use of contrast agents. It is a typical finding in women with stress urinary incontinence but can be seen in asymptomatic women as well (69-71). In a study on stress incontinent women, funnelling was found to be present in nearly all women (70,72). Urinary incontinence can be demonstrated by the use of colour Doppler of the urethra (73-74). Colour Doppler has, furthermore, been used to visualise the periurethral vasculature in nulliparous women (75) and differences have been described between continent and incontinent women (76-77) and before and after oestrogen supplementation in postmenopausal women. More recent data with the use of high frequency endovaginal ultrasonography have highlighted differences in urethral vascularity amongst continent women with parity (78). Doppler velocimetry has recently been used in a study on the vascularisation of the levator ani musculature and a correlation has been found between the absence of an end-diastolic flow and the presence of stress urinary incontinence (79). The blood flow around the urethra and bladder has been studied with Doppler before and after insertion of tension free vaginal tape and the transobturator tape. The blood flow decreases only after insertion of the tensional free vaginal tape whereas the blood flow was unchanged after insertion of the transobturator tape which may relate to the direction of urethral compression (80). More recent data showed no difference in urethral vascular indices measured by endovaginal ultrasound between women with SUI who were managed surgically or conservatively (81).

2.2.5 Determination of the Post Void Residual Urine and Bladder Wall Thickness

Ultrasonography is the gold standard technique for measuring bladder volume and post-void residual urine (82-86). Ultrasonographic data have been compared with residual volumes obtained by in and out catheterisation under ultrasound control and were found satisfactory. Although there is no universally accepted definition of high urine residual volume, there is consensus on the need for a short interval between voiding and post-void residual (PVR) measurement and the preference of ultrasound bladder volume measurement over urethral catheterization (87). However, Khan et al. have challenged the methodology of some studies and found deficiencies in all reports on the topic (88). A simple formula often used is (Height * Width* Depth cm) * 0.7= Volume (ml) in which the factor 0.7 is the correction for the non-spherical shape of the bladder. Automated ultrasound systems for measuring bladder volume and post-void residual have been developed and found to be more accurate than standard ultrasound measurements, furthermore they can be used by health care providers with no training in ultrasound imaging (89). However, measurement of bladder volume can easily and accurately be facilitated by use of cheap, standard 2D ultrasound machines, irrespective of the calculation formula used, even in women with severe pelvic organ prolapse (90). Automated bladder scanners are widely used and are, in general, experienced as reliable enough for clinical use, however, in the case of ascites (91) or an ovarian cyst (92) for example, the estimated urinary volumes can be incorrect, and in post partum women.

Recently the normal values for the post void residual urinary volumes in asymptomatic women have been presented; in 60 year-old women, the median residual volume was 19 ml, and 95% of women had a post void residual volume of less than 100 ml (83). The ICS Urodynamics Committee has recently published its Good Urodynamic Practice recommendations regarding PVR measurement suggesting that for clinical practice a PVR <30 ml can be considered insignificant, while residual volumes persistently >50 ml could be regarded as important. They also suggested that large PVR (>200–300 ml) often indicates LUTD, acknowledging however that no level of residual urine, of itself, mandates invasive therapy and no PVR threshold is yet established for decision-making (87).

Ultrasound measurement of bladder wall thickness (BWT) and ultrasound estimated bladder weight (UEBW). Ultrasound measurement of BWT was first proposed as a non-invasive method for diagnosing infravesical obstruction in children (93). More recently, BWT has been used to predict the outcome of children with primary nocturnal enuresis (93-95). BWT has also been proposed as a risk factor for upper urinary tract deterioration in children with myelodysplasia (96). Measurement of BWT was also proposed to diagnose bladder dysfunction (detrusor overactivity

and detrusor hypocontractility versus normal detrusor function) in children with urinary tract infections (97-98). Additional parameters such as the bladder wall thickness index (length x width x depth of the bladder at full bladder/average BWT) were proposed and a nomogram for the paediatric population provided (99).

In the adult population, higher BWT values have been measured in men than in women. Thickness may certainly differ depending the measurement technique; values of 3.3 +/- 1.1 mm and 3.0 +/- 1.0 mm, respectively were reported by Hackenberg and co-workers (100). Oelke confirmed a significant difference between male and female detrusor thickness (1.4 versus 1.2 mm, respectively) (101). A small increase of detrusor hypertrophy with age has been reported in both genders (99). In men, measurement of bladder wall thickness proved to be the most sensitive parameter (outperforming uroflowmetry) to diagnose BOO in patients suffering LUTS (102-103). These findings were corroborated by the results of more recent ultrasonographic studies by use of automated bladder scanners (104).

Transvaginal ultrasound was first proposed in 1994 for the measurement of BWT in women with bladder volume of less than 20 ml. A significant difference was shown in patients with DO and USI (6.7 +/- 0.6 versus 3.5 +/- 0.6 mm, respectively). Low intraobserver and interobserver variability were measured: 0.02 mm in both with a 95% confidence interval of -0.22 to 0.18 and -0.32 to 0.35 mm, respectively (105). In 1996, Khullar and co-workers showed how ultrasound measurement of BWT is a sensitive method for diagnosing DO in symptomatic women without bladder outlet obstruction with 94% of women with BWT greater than 5 mm having involuntary detrusor contractions on videocystourethrography or ambulatory urodynamics (106). In 2002, the same group showed no overlap in the 95% confidence intervals of BWT between patients with DO and USI in women with storage symptoms, confirming the potential of this parameter for diagnosing DO (107). More recent data on the diagnostic value of transvaginal ultrasound in patients with overactive bladder symptoms confirmed a sensitivity of 90 % and specificity of 78 % for predicting OAB, when a cut off value of 4.78 mm was used (AUC = 0.905) (108). Conversely, a large UK-based cross-sectional test accuracy study found no evidence that BWT had any relationship with DO, regardless of the cut-off point, nor any relationship to symptoms as measured by the ICIQ-OAB; the authors concluded that despite patients' wide acceptability of the method BWT measurement was not sufficiently reliable or reproducible to predict DO (109).

In 2003, a study on ultrasound cystourethrography in women confirmed a significant association between age and intravesical pressure at maximum flow with BWT (110). Researchers have also demonstrated reduction in BWT following urethrolysis in women with bladder outlet obstruction resulting form anti-incontinence surgery (111). Methodological and technical issues in the ultrasound measurement of bladder wall thickness and weight remain open and constitute a major limitation for a more widespread use of these parameters. In 2005 Chalana and co-workers published an early report on automatic measurement of the ultrasound estimated bladder weight from three-dimensional ultrasound. An average value of 42 +/- 6 g was measured in healthy male subjects. A standard deviation of 4 g was seen among measurements performed in the same subject at different bladder volumes (200 to 400 ml) (112). Normative values for UEBW and BWT in healthy female volunteers were calculated by another group by use of an automated bladder scan device showing mean values of 32.23g (SD +/- 4.9) and 1.62 (SD +/- 0.34), respectively (113). Further research in this area is certainly needed and further improvement in the accuracy of automated systems is eagerly awaited.

Although data published in the peer review literature on this subject are quite consistent, two discordant papers were recently published from Australia. Blatt and co-worker showed uniform values of BWT measured using an abdominal approach among men and women with non-neurogenic voiding dysfunction suggesting this parameter cannot be used to diagnose storage or voiding dysfunction; this may reflect the thinning of the bladder wall with increasing bladder volume (114-116). A retrospective study on women undergoing translabial ultrasonography suggests a significant association between BWT and DO although a low diagnostic accuracy was shown for the diagnosis of DO (117), which could be due to translabial ultrasound being a less reliable technique (118).

The association between detrusor hypertrophy and bladder dysfunction (DO and BOO) is a well established fact in Urology. Ultrasound measurement of BWT and UEBW is an interesting alternative approach that may avoid invasive urodynamics in some patients. (119). As, previously mentioned, The reduction in bladder wall thickness has been found after the relief of bladder outlet obstruction (111). The development of automated ultrasound systems for measuring UEBW is instrumental to foster further research in this area, particularly in the management of patients with LUTS (120) and in the evaluation of bladder response to pharmacological treatment (119).

2.2.6 Pelvic Floor Muscles

Ultrasonography can be used to assess pelvic floor muscles and their function. Contraction of the pelvic floor results in displacement of pelvic structures that can easily be imaged on ultrasound (**Figure 7**) such as the cranial lift of the urethra in relation to the symphysis pubis during a maximal squeeze (18, 122) but also the dimensions of the genital hiatus or the posterior ano-rectal angle can serve this purpose (123). Comparison with traditional measurements of pelvic floor muscle strength has been performed (122), and good correlations with palpation and perineometry have been found (124-125). Ultrasonography has

been used to evaluate the effects of pelvic floor muscle training. A higher resting position of the bladder neck and a reduction in the rotational excursion of the urethra during Valsalva manoeuvre have been found with pelvic floor training (126). Another research group has reported that the thickness of pelvic floor muscles increased after training (127). A number of studies have assessed healthy female volunteers to establish normal values (47,127), and one study has specifically compared elite athletes with normal volunteers (128). Measurements of the levator ani muscle, with the use of two-dimensional imaging, has been recently described, and although direct comparisons to three dimensional ultrasonography are lacking, the acquired data were comparable (129). However, one study has compared three-dimensional ultrasound of the levator ani hiatus at rest and during contraction in a number of different groups of women with prolapse, urodynamic stress incontinence and asymptomatic women suggesting that these measurements are not sensitive enough to discriminate between different groups (130).

Almost half of women are unable to perform an optimal contraction of the pelvic floor muscles. Ultrasonography can be used in pelvic floor training to provide women with a visual feedback of their exercise (18,131). In one study, 57% of the women who were not able to perform a proper pelvic floor contraction, were able to do so with the help of visual biofeedback of ultrasonography to observe bladder neck movement (18). This does not appear to produce better outcomes of changes with pelvic floor physiotherapy (132). Another prospective study in women receiving physiotherapist-guided PFMT due to pelvic floor dysfunction, however, did demonstrate that the vast majority of patients would improve muscle contractility after the programme; amongst the non responders ("non-contractors") almost 67% were found to have levator ani defects on transperineal ultrasound (133). The contraction of the pelvic floor muscle just before and during a cough, "the knack", can also be visualised (134). It has been demonstrated that the knack can significantly reduce urethral mobility during a cough.

Direct measurement of the pelvic floor muscles is possible with the use of two and three-dimensional perineal ultrasonography. An alternative technique makes use of a 360 degree rectal probe intravaginally (**Figure 8**) (129). Most studies, however, have used three-dimensional perineal ultrasonography for this purpose (19, 123, 128, 135-136). The thickness of the pelvic floor muscles as well as the hiatal area can be measured. Hiatal dimensions and pelvic floor muscle thickness have been extensively validated and have good test retest and inter observer characteristics (19). There is a learning curve to measurement of the levator ani hiatus needing over ten sets of scans to perform the measurement. However, measurements of the pubic arch were not accurate suggesting that measurements of levator avulsion may require more training (137).

The pelvic floor muscles were thinner in women with pelvic organ prolapse (17, 129, 138) and with urinary incontinence (139), whereas their genital hiatus was larger (140); interestingly this finding does not produce a significantly reduced maximal voluntary contraction even with pubovisceral muscle defects (141). Well trained women have thicker pelvic floor muscles compared with controls (128), and Chinese women had thinner muscles compared with Caucasian women (136). In nulliparous Chinese women, the anterior/posterior hiatal diameter was significantly increased in women with a higher body mass index (136).

Very recent studies looked at the uselfuness of real time trans-abdominal ultrasound scan (TAUS) in assessing pelvic floor muscle strength before and after a structured PFMT; a RCT in 140 incontinent women demonstrated that TAUS was accurate in detecting even minor differences in pelvic floor muscle strength between the PFMT and non-intervention groups and this correlated very well with assessment by digital palpation (142). By using this imaging modality as biofeedback, another research group from Japan established that women with postpartum SUI were less successful in achieving good pelvic floor muscle strength following an intensive PFMT in comparison to their continent counterprts, despite no morphological differences in the LAM between the groups before and after intervention (143).

Pelvic floor biomechanics were investigated with ultrasound using the position of the bladder neck in combination with continuous vaginal pressure measurements (144-145). A novel biosensor was used to measure the force as well as the displacement of the pelvic floor during contraction (146). Another research group has inserted a water filled plastic bag to study the shape of the vagina during contraction (147)). Others (148) have assessed elasticity by means of the correlation of the dynamic dimensions of the hiatal circumferences and direct palpation of the muscles. Real time biomechanics of the pelvic floor have been compared between women with and without pelvic organ prolapse with the use of translabial 3D ultrasound and standardised Valsalva effort; significant pelvic organ prolapse was associated with a less compliant levator ani muscle close to its origin from the pubic ramus (median maximum strain 26% vs 32%, respectively, P=0.03) (149).

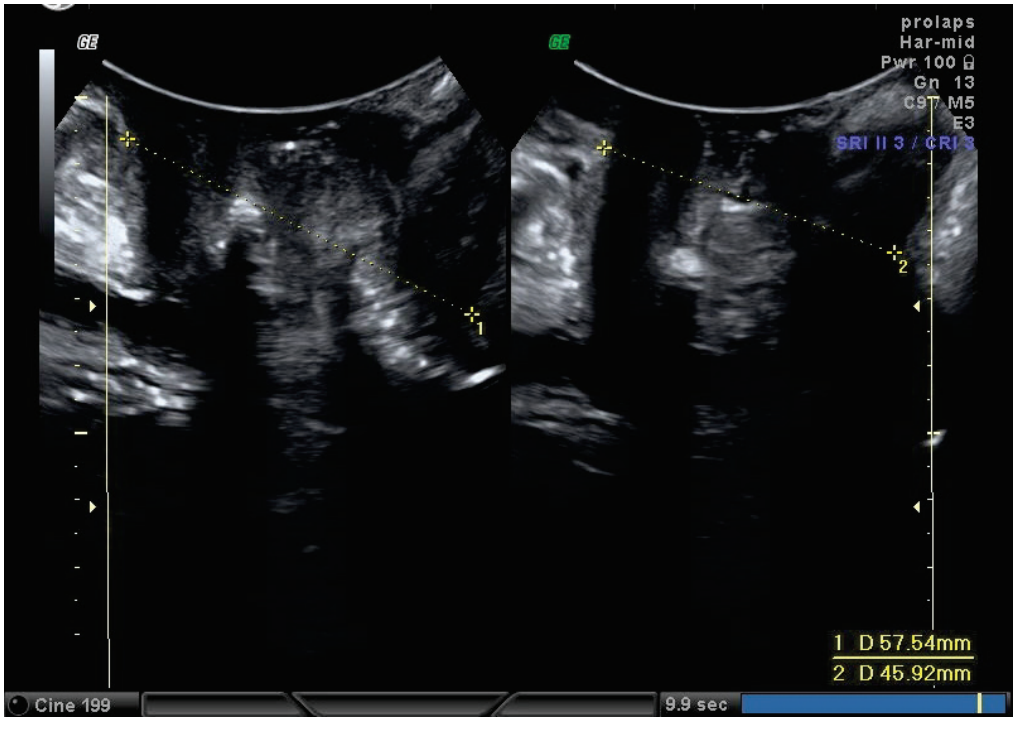

Figure 7 Perineal midsagittal two-dimensional view at rest and on contraction. Levator contraction with ventro-cranial displacement of the urethra.Measurement of minimal dimension of genital hiatus (from symphysis pubis to levator ani muscle)

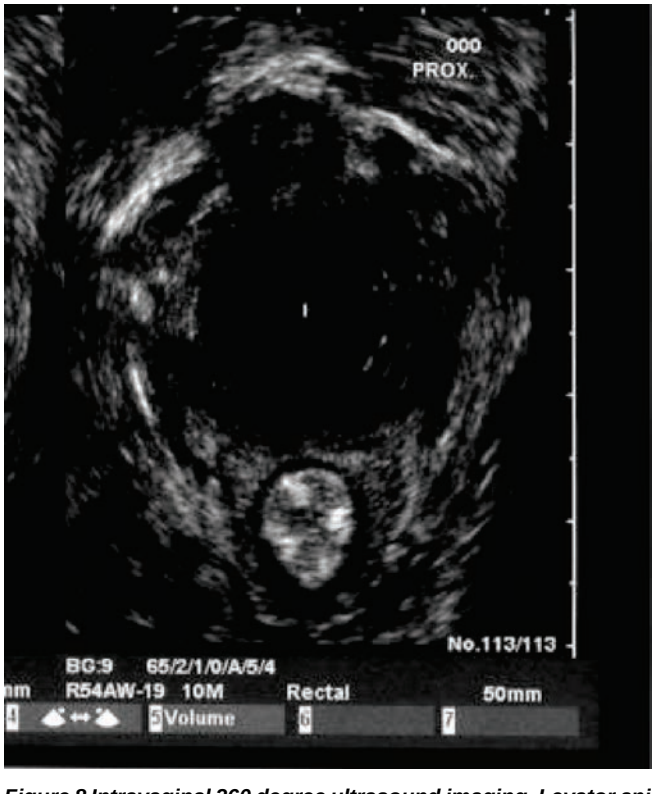

Figure 8 Intravaginal 360 degree ultrasound imaging. Levator ani muscle, urethra and anal sphincter complex.

2.2.6.1 Levator Trauma

Using three dimensional transperineal ultrasound avulsion of the levator ani muscle from the symphysis pubis has been described in up to 36% of parous women (150). The integrity of the attachment of the pelvic floor muscle to the symphysis pubis can be visualised **(Figure 2 and 9a)**.

A systematic review of diagnosing pubovisceral avulsions on ultrasound and MRI has been published which showed an association with pelvic organ prolapse and recurrence after surgery. However there was no association between pubovisceral avulsions and urinary symptoms or anorectal dysfunction (151). A recent prospective comparison study in primiparous women found that obstetricanal sphincter injuries (OASIS) do not constitute a risk factor for LAM avulsion (152). This is similar to results from MRI studies, where it has been shown that the risk of pelvic organ prolapse further increases when the levator injury goes together with vaginal architectural distortion (153-154).

Although these defects have recently been identified during labour, it is not known whether there is any reasonable (preventive) treatment for these women (155-156). There is an increase of the occurrence of levator muscle trauma with maternal age at first delivery (157). There was a strong correlation between the presence of levator muscle avulsion and poorer muscle strength (158). It has, however, been shown that the correlation between the clinical assessment (palpation of the muscle) and three-dimensional ultrasonographic assessment of muscular defects was only poor (159), as well as the inter-observer repeatability of the palpation of defects (160). A quantification method for levator muscle defects on ultrasonography (tomographic ultrasound imaging) **(Figure 9a and 9b)** has been described (135). Another parameter, which has been found to be related to the severity of pelvic organ prolapse, was the size of the inner circumference at minimal hiatal dimension of the levator ani muscle on Valsalva manoeuvre (129, 135,155). The area of the levator hiatus on Valsalva manoeuvre ranges from 6 to 36 cm2 in nulliparous women, with an outlier of almost 50 cm^2 in a young nulliparous athlete (128, 140). An area of more than 30 cm^2, 35 cm^2 and 40 cm^2 on Valsalva manoeuvre has been described as mild, moderate and severe ballooning of the genital hiatus respectively (**Figure 10**) (161). The assessment of the levator hiatus has been shown to be a reproducible measurement (19, 150), whereas the reproducibility was less for muscle diameter measurements (19, 123, 140). Despite the recommendations for adherence to universal protocols in depicting LAM defects, significant variation in the reported prevalence of LAM defects exists in literature; transperineal ultrasonography 13–36%, needle electromyography 30% and MRI 20% (162). Hence direct comparison between similar studies, which would allow for drawing meaningful conclusions is difficult due to variable patient selection, differences in demographics and most importantly lack of consistency in the definition and classification of LAM injuries. A very recent cadaveric study has questioned the validity of pelvic floor ultrasound in depicting true levator muscle avulsions; whilst 3D introital ultrasound detected complete “avulsion” in 36.7% of the cadavers no detachment of the levator ani muscle from the pelvic side wall was identified in any of the cadaveric dissections with a 0% incidence on both left and right sides. No avulsion was found either upon dissecting an additional thirty-nine cadavers at multiple international centres, raising the hypothesis that what appears to be an “avulsed’ LAM on scan most likely represents an imaging artefact due to the inability of the ultrasound to resolve the smaller insertion sites (163).

Comparisons of the hiatal diameters and hiatal area as measured by three-dimensional ultrasonography and MRI revealed good correlations, especially for the measurements at rest. The correlation for hiatal diameter at Valsalva manoeuvre was lower, which is most likely due to the difficulty to reach the correct plane of the levator ani muscle on MRI (164). However, at rest using MRI to alter the angle of acquisition plane has been shown to change the area of the levator hiatus by 10% (165). This has been supported by subsequent papers showing a good inter and intra-observer relationship when measuring the levator hiatus with ultrasound and MRI (166) and even with interdisciplinary readers (167) though the latter group did find only fair agreement when measuring the anorectal angle with ultrasound. The width of the levator ani hiatus on 3D transperineal ultrasound has been found to wider in black women than white women and the urethral sphincter volumes were significantly larger in black women than white women (168).

The presence and clinical relevance of paravaginal defects represent a controversial issue amongst urogynaecologists, and there is a lack of scientific proof for the concept. In a study by Reisinger et al., an echogenic layer in the lower anterior vagina, which was thought to be a part of the endopelvic fascia, could be identified reproducibly in nulliparous and parous women by transrectal three-dimensional ultrasonography (169). According to more recent insights, however, previously described paravaginal defects with loss of the H-shape of the vagina in the axial plane on three-dimensional ultrasonography (158, 170-171) could represent the detachment of the levator ani muscle from the symphysis pubis (172). In a study comparing ultrasound and MRI to assess levator avulsion there was only a moderate correlation with ultrasound showing a higher number of complete avulsions and MRI showing a higher number of partial avulsions (173).

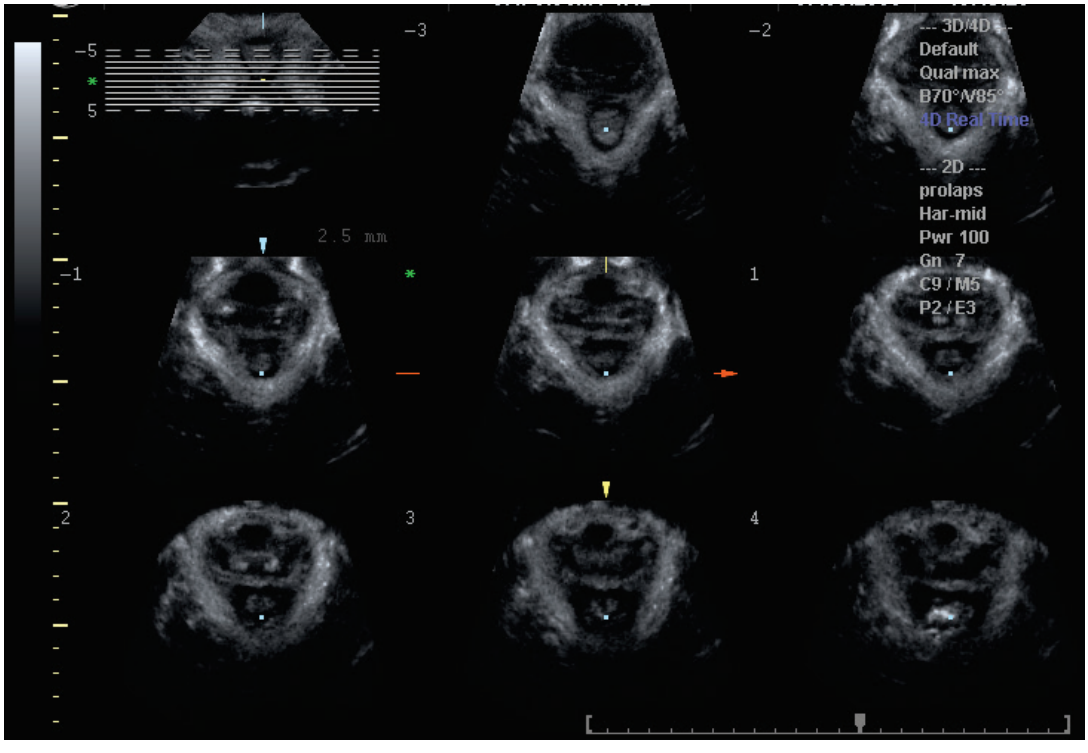

Figure 9a Tomographic ultrasound imaging in oblique axial plane. Normal attachment of the levator ani muscle.

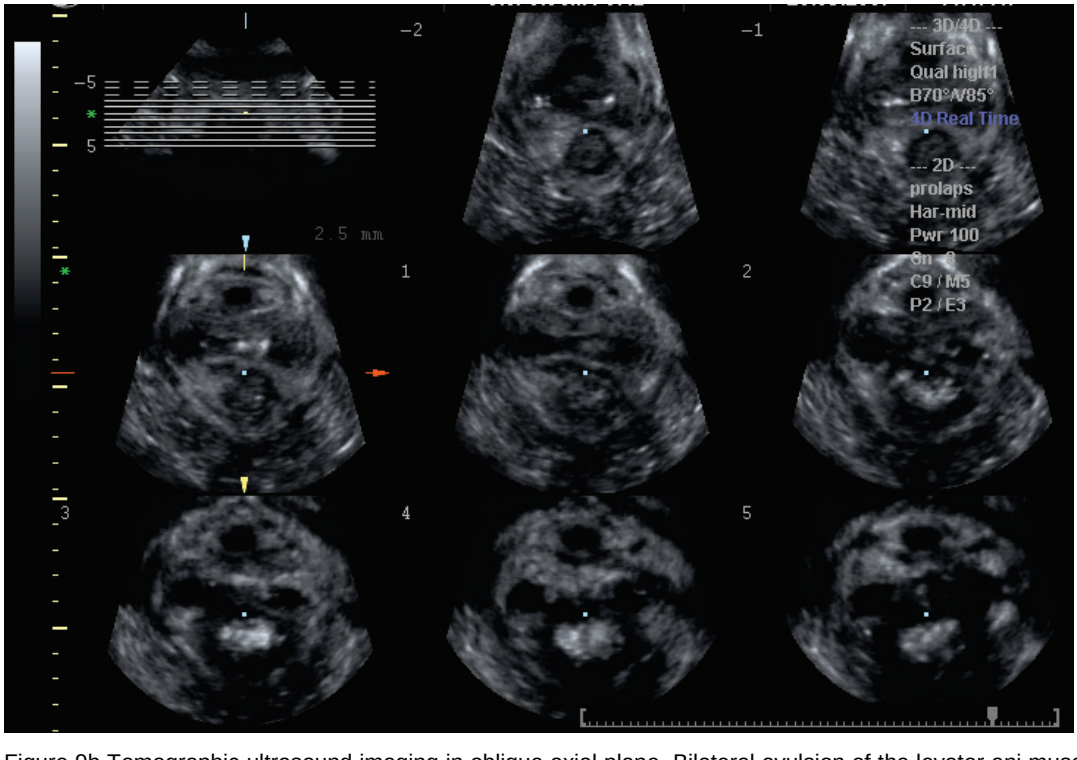

Figure 9b Tomographic ultrasound imaging in oblique axial plane. Bilateral avulsion of the levator ani muscle from the symphysis pubis.

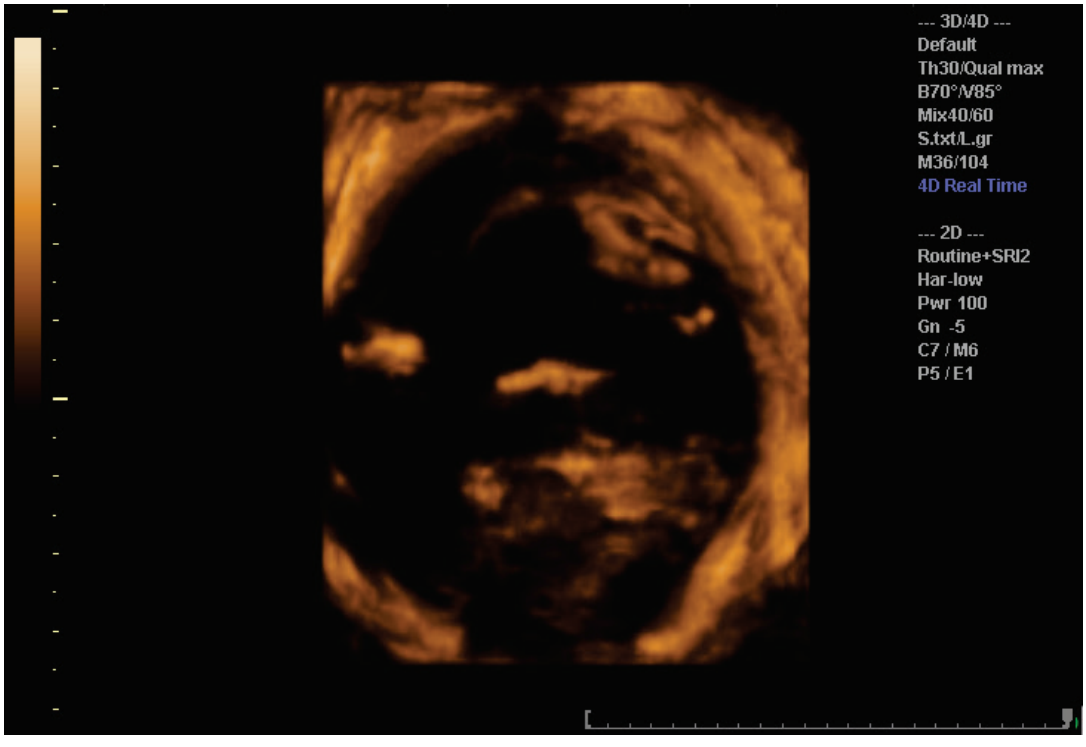

Figure 10 Perineal three-dimensional rendered image. Ballooning of the genital hiatus.

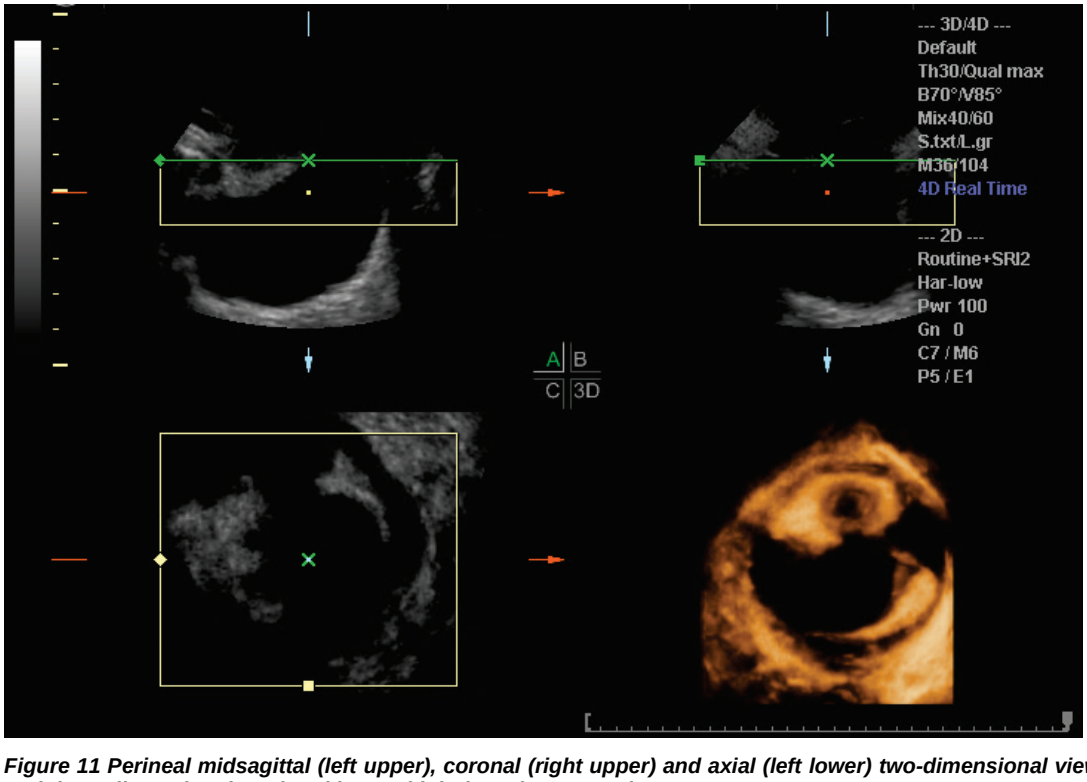

Figure 11 Perineal midsagittal (left upper), coronal (right upper) and axial (left lower) two-dimensional view and three-dimensional rendered image (right lower) . Cystocele.

Vergeldt TF et al confirmed the difference in LAM defects classification between MRI and perineal ultrasound, showing higher grades of LAM damage on US compared with MRI despite the very good agreement in depicting such defects with both imaging modalities (174).In an attempt to increase validity of the levator avulsion diagnosis, a minimum criteria have been set (175), but even with these more stringent rules two out of three normal women were considered false positives, where they were thought to have full avulsions. It is important to note that MRI studies tend to image thinning or aplasia rather than avulsion perhaps indicating that transperineal ultrasound may not have the resolution to visualise very thin levator ani muscles (176). This finding was corroborated in a very recent comparison study by Notten et al, which showed 78% sensitivity and 86% specificity in detecting major levator ani defects with translabial three-dimensional ultrasonography compared with MRI (177).

2.2.7 Pelvic Organ Prolapse

In cases of mild and moderate pelvic organ prolapse, perineal ultrasonography can be used, for the investigation of the prolapse. Ultrasonography should, however, only be used in addition to the patient's history and clinical examination. In cases of severe pelvic organ prolapse, ultrasonographic assessment is not possible due to transducer dislocation by the prolapse. The ultrasonographic imaging of the anterior compartment (i.e. bladder, bladder neck and urethra) is the easiest to perform and the majority of scientific studies deal with this compartment (**Figure 11**).

Correlations with clinical examination (154, 155) are also highest for this compartment. Reproducibility of ultrasonographic imaging of prolapse in the anterior compartment were shown to be good (155). This reproducibility has not been studied for the other two compartments until now.

In two studies amongst 83 and 117 women with the uterus in situ, the uterus could be visualized on perineal ultrasonography in 82% and 97% of cases, respectively (**Figure 12**) (155, 156).

A number of studies have focused on the posterior compartment (157-165). The distinction between enterocele (**Figure 13**) and rectocele (**Figure 14**) is known to be difficult on clinical assessment. In these cases, two-dimensional ultrasonographic imaging in the midsagittal plane can be helpful. The ultrasonographic visualisation of an enterocele has been confirmed with defaecography as well as intraoperative findings (157). It has not been shown, until now, however, whether this extra ultrasonographic investigation leads to superior clinical outcomes of prolapse surgery. Interestingly anterior compartment prolapse is related to levator ani area whereas posterior compartment prolapse is not as well as prolapse symptoms not being associated with levator ani hiatus area (166).

In a study on ultrasonography of the posterior compartment a differentiation between true rectocele, enterocele and perineal hypermobility has been made (160). Intussusception can also be visualised on ultrasonography (167). Perineal hypermobility and an enterocele was seen as descent of the rectovaginal septum or abdominal contents on Valsalva manoeuvre respectively, below a horizontal line through the inferior margin of the sympysis pubis (see below for more information on these measurements). Ultrasonographic staging was significantly correlated with clinical staging and the presence of symptoms of obstructed defaecation (15, 161). In one third of the patients with clinically diagnosed rectocele, however, no ultrasonographic abnormality could be found. As far as interrater reliability was concerned, two expert ultrasonographists have reached moderate to good interrater reliability for the detection of a rectovaginal septum defect, descent of rectal ampulla, and the depth and width of a rectocele (160). In one study, rectocele and perineal hypermobility were present in nulliparous women in 12 and 13% respectively the significance of these findings has not yet been determined (162). The posterior anorectal angle, which is the angle between the anal canal and the posterior rectal wall can be measured at rest and under dynamic circumstances such as straining and squeezing. A number of studies have compared these findings with defaecography and found a generally good correlation (164, 165, 168) but one study found poor inter-rater reliability (146).

2.2.7.1 Quantitative Assessment of Pelvic Organ Prolapse

In the quantitative assessment of prolapse in the various compartments, a reference line, such as the hymen in POP-Q is needed. For ultrasonography, a horizontal line drawn from the inferior margin of the symphysis pubis is the most widely used reference line for this purpose (Figure 3a). A disadvantage of this line is that there is only one fixed point through which the reference line can be drawn and the horizontal line may change with the rotation of a handheld transducer.

The effect of rotation is obviously increased with increasing distance from the fixed point, and consequently there is greatest error in the posterior compartment (179). Although this problem has been overcome in research settings with the use of motion tracking systems, at the moment this is not a realistic option for routine use in clinical practice (195). For quantitative assessment of rectoceles, the depths of the rectocele as measured in relation to a line through the anterior anal canal, may be more useful as compared with the descent in relation to the horizontal reference line (196).

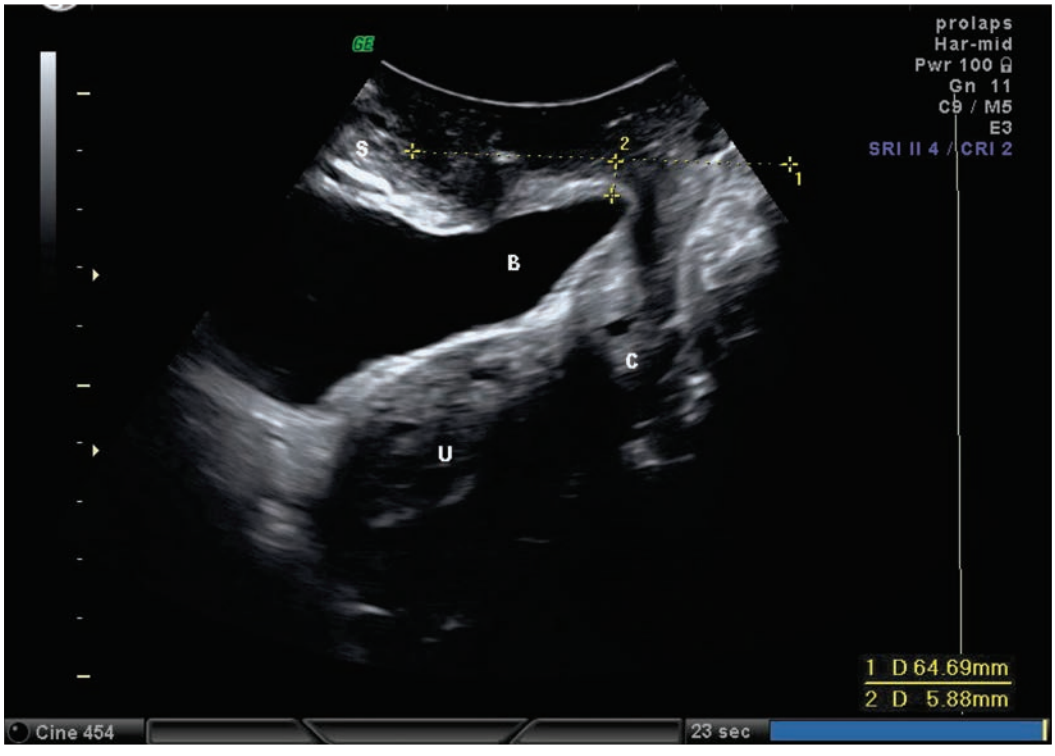

Figure 12 Perineal midsagittal two-dimensional view. Cystocele and descending uterus. (S= symphysis pubis; B= bladder; U= Uterus; C= cervix.)

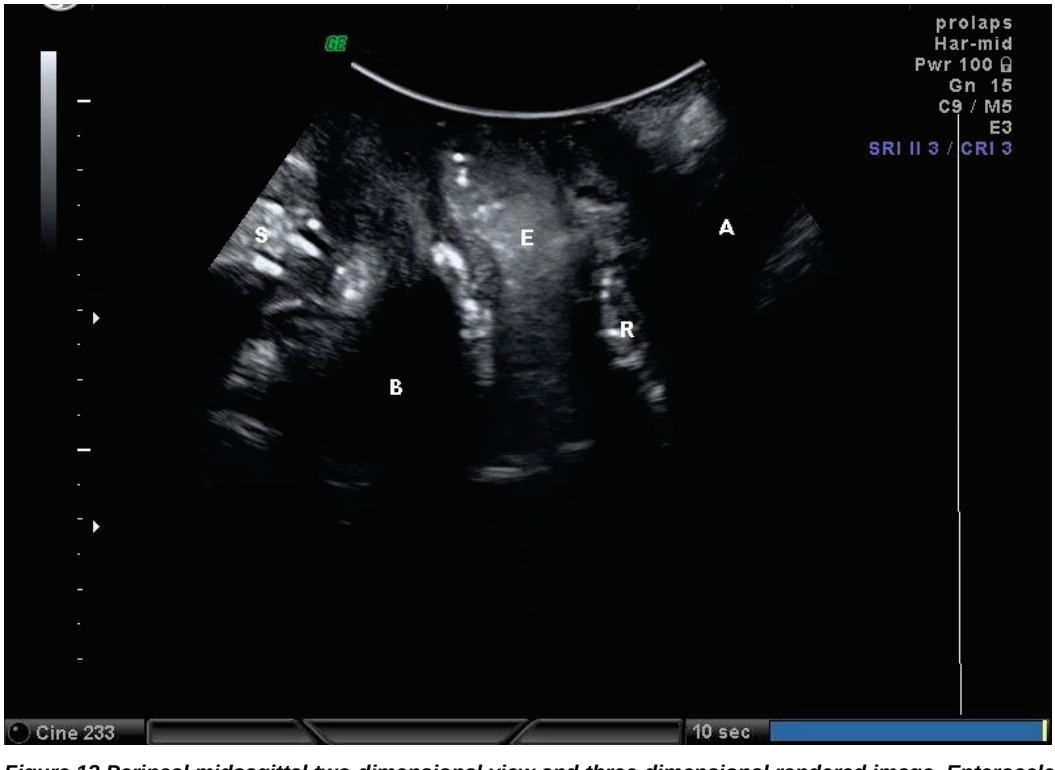

Figure 13 Perineal midsagittal two-dimensional view and three-dimensional rendered image. Enterocele. (S= symphysis pubis; B= bladder; E= enterocele; R= rectum; A= anal canal.)

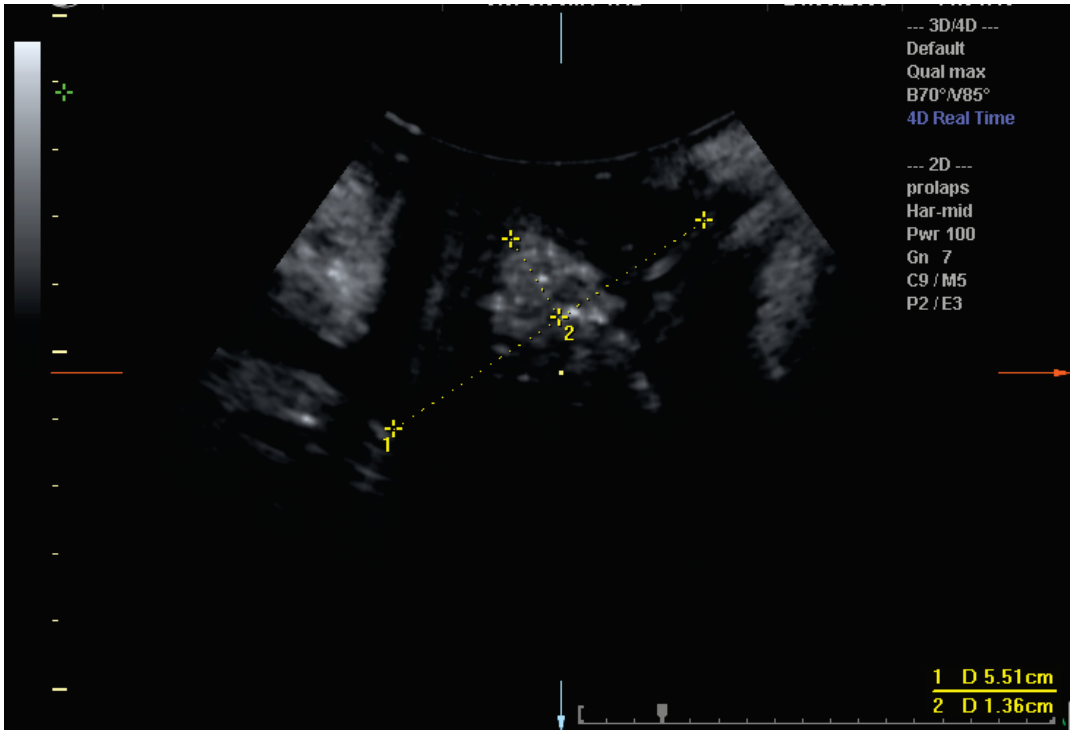

Figure 14 Perineal midsagittal two-dimensional view. Measurement of the depth of the rectocele, perpendicular to a straight line through the anterior border of the anal sphincter complex, i.e. 14 mm.

More recently, Hennemann J et al proposed a new reference line for pelvic floor biometry, which passes between two fixed points on the syphysis pubis and should improve efforts for standardisation of ultrasound measurements of anatomical indices since it has excellent reproducibility, allows for visualisation of markers in all three vaginal compartments and avoids angle errors due to probe movement (197).

Since pelvic organ prolapse can be visualised well with the use of ultrasonography, it raises the question whether this assessment modality is superior to others, such as clinical examination. In a recent study on the relationship between prolapse symptoms and the most dependent point of the prolapse on POP-Q and on ultrasonographic assessment, POP-Q performed better in the prediction of prolapse symptoms with increasing stages of prolapse (196). This finding has been replicated in all compartment underlining the superiority of clinical assessment over ultrasound (180). In a previous study, where only women with a single compartment prolapse were studied, the area under the receiver operating curve was good at 0.86 and 0.82 for the anterior and posterior compartment respectively (198). In both studies the cut-off value for symptomatic prolapse averaged 15 mm below the horizontal reference line through the symphysis pubis. Larger anterior vaginal wall prolapses do have larger levator ani hiatuses and are more likely to have avulsions (69% compared with 35%) (199).

As far as dynamic MRI and X-ray defecography are concerned, there are only a few studies available as yet, on comparison with ultrasonography. For enterocele detection in women with obstructed defaecation, perineal ultrasonography has been compared with X-ray defaecography, but not with the clinical findings (190). In cases where an enterocele had been detected by either method, an enterocele was detected by both ultrasonography and X-ray in 71% of women. In this study, perineal ultrasonography showed more severe stages of enterocele compared with X-ray defaecography. In another recent study from a different research group, X-ray defaecography has been compared with perineal ultrasonography using a vaginal probe in women with impairment of the posterior pelvic floor. Good to excellent concordance has been found for the assessment of the anorectal angle, rectocele and intussusception. The authors claimed, however, that rectoceles with a depth less then 20 mm could not be detected on ultrasonography (185), which is discordant with most other publications (180-181) on the topic and as well as the authors' experience.

2.2.8 Ultrasonography in Relation to Pregnancy and Delivery

Vaginal delivery is commonly accepted as the major risk factor for the development of pelvic organ prolapse in later life. In nulligravid women, there is a wide variation in pelvic organ descent for all three compartments (146, 182, 200-202). In a study of 169 women who underwent ultrasonography during and after pregnancy, a significant increase in pelvic organ mobility (downwards displacement) was found in all

three compartments (203). The increase in mobility was significantly correlated with the length of second stage of labour and the mode of delivery. The greatest mobility was found in women who underwent an operative vaginal delivery, but no association was found with the gestation at delivery, length of the first stage of labour and birth weight, although birth weight reached borderline significance. In a similar study, focusing on the posterior compartment in 52 nulliparous pregnant women, 8 women developed de novo true rectoceles, and the descent of the rectovaginal septum increased with 22 mm for the entire group, which was statistically significant (204). On the other hand, in a study amongst 207 women, of whom half had a clinically diagnosed rectocele, no relationship was found with vaginal parity and only a weak correlation was found with age for a posterior vaginal wall prolapse as assessed with ultrasonography (186). This suggests that the effect of vaginal parity on pelvic organ descent, is most evident in the anterior and central compartments, and may have another pathophysiology compared with the posterior compartment (203).

Concerning bladder neck descent, it has been shown that the first delivery caused the most marked changes compared with the subsequent deliveries, with the most marked changes resulting from forceps delivery (205). This is supported by two different research groups, who have reported that an increased antenatal ultrasonographic bladder neck descent was associated with normal vaginal delivery (206-207). Furthermore, vaginal delivery was strongly associated with a larger and more distensible antenatal levator hiatus (206). The underlying reason remains hypothetical, but more antenatal laxity of the structures may allow for a smoother delivery. Women with increased bladder neck mobility also have an increased risk of de novo urinary incontinence post partum (21) but the risk can be halved by antenatal pelvic floor exercises (208). Avulsion of the levator ani muscle from the symphysis pubis, as outline above, is typically found in vaginally parous women only (Figure 9b) (150, 209-210). It has, furthermore, been shown that a higher maternal age at first vaginal delivery is strongly related to an increased risk of these avulsions (150, 210). Mode of delivery has a strong association with the incidence of levator ani injury such that vaginal delivery 15.4% are affected, 33.3% after ventouse delivery and 71.4% after a forceps delivery but there were no levator injuries detected in the Caesarean section group (211); similar findings have been reported by other groups (212-215). The timing of the levator ani damage appears to be as the head crowns (216). The levator ani hiatus has been reported as enlarging after vaginal delivery (217-218) and this enlargement being maintained for up to three years later (219) but other groups have not found it enlarged nine months after delivery compared with antenatal measurements. However, forceps delivery did lead to long term enlargement of the levator ani hiatus (220). The risk of levator ani avulsions increased with enlarged head circumference and prolonged second stage in labour (221).

In a large prospective cohort in nulliparous women, amongst which 15.1% suffered a LAM injury postnatally, the only independent risk factor after multivariate analysis of pelvic floor biometry was a smaller antenatal anteroposterior diameter of the levator hiatus (222). Other researchers have found that a combination of risk factors increase the odds for LAM avulsion injuries in primiparous women who delivered vaginally; women who had sustained a protracted labour, forceps delivery and OASIS had a 75% chance of suffering a complete or incomplete LAM avulsion (223). Fetal head circumference and length of first stage of labour have been suggested as additional risk factors for LAM injury, suggesting that the longer the pelvic floor is subjected to high stretch forces the more likely the occurence of minor or major LAM defects (224). Conversely, greater levator hiatal dimensions in the third trimester of pregnancy had a significant association with a shorter active second stage of labor and a spontaneous vaginal delivery (225).

Another interesting concept of the relationship between vaginal delivery and LAM injury is the early postnatal ultrasound imaging findings and the subsequent changes. van Delft Ket al observed that all LAM haematomas seen on 3D transvaginal ultrasound as early as 4 days postpartum went on to form complete avulsion injuries 3 months after delivery. Interestingly, further avulsions noted at 3-month scans were not originally seen during the early asseement and, moreover, muscle haematomas, which were further away from the attachment point to the pubic bone did not evolve into avulsions (226). When these women with avulsions where further followed up, however, 1 year after their deliveries, more than 60% of the injuries had resolved (227). Similar findings were reported by an earlier MRI study (228) and recent ultrasound studies demonstrating recovery of the hiatal biometry for a significant proportion of women within 1 year of delivery, although not necessarily to pre-pregnancy (pre-delivery) levels (229-230). Such results have been contradicted by other researchers who demonstrated persistence of sonographically depicted LAM defects, identified in the immediate postpartum period for months or years after delivery (231), again pointing out the huge variation and inconsistency in the classification of pelvic floor injuries and lack of standardisation in reporting those.

2.2.9 Pelvic Floor Surgery

Ultrasonography has been used during anti incontinence surgery with the aim of obtaining optimal results from surgery, for example during Burch colposuspension (232-233). On an individual basis, the bladder neck was lifted between 1 mm and 10 mm. The authors have obtained excellent results with a 94% continence rate after 1 year, but unfortunately no control group was incorporated in the study. Levator ani avulsions have been found to be associated with

persistent vaginal prolapse even after attempted surgical repair (234). Lone and co-authors compared 2D transperineal ultrasound - assisted ad hoc by additional 3D endovaginal ultrasound - with clinical examination for pelvic floor disorders and found that TPUS enhanced the differential diagnosis in the anterior compartment by distinguishing vaginal cysts and urethral diverticulae from pelvic organ prolapse (235). Perhaps the pre-operative value of TPUS is even greater when it comes to defects in the posterior compartment; improvement in diagnosis of enterocele with multi-compartmental pelvic floor scan, missed on clinical examination was demonstrated by use of TPUS of the pelvic floor. Diagnosis of enterocele and intussusception was further enhanced following primary surgical correction of the prominent prolapse in any of the vaginal compartments (235).

2.2.9.1 Slings and Meshes

Monofilament meshes, for example polypropylene meshes, are easier to visualise on ultrasonography compared with multifilament meshes, such as IVS (236). Ultrasonography has been widely used to localise the exact position of tension free midurethral tapes (Figure 15) (206, 237-242). The tape is generally easily visible as an hyperechogenic structure under the urethra and is easy to recognise, which contrasts with the poor images of polypropylene on MRI (243). Exact midurethral position of the tape is not essential for proper function (244). Despite the fact that the tape was located in the midurethra in only two-third of cases, this had no relation to postoperative continence status (245). A more recent ultrasound study, however, has challenged these findings, demonstrating a higher recurrence stress incontinence rate in cases where the suburethral sling was placed at the bladder neck in comparison to placement of the tape at the proximal and middle urethra (241). During Valsalva manoeuvre, the tape moves in a semicircle movement around the inferior margin of the symphysis pubis (246). This results in a position closer to the symphysis, which consequently leads to a certain degree of mechanical compression during Valsalva manoeuvre. Another mechanism of action is kinking of the urethra around the tape (247). A number of studies have looked at transobturator tape and compared these with retropubic tapes (236, 242, 248-251). Two studies could not detect any differences between the two types of tape (236, 242, 251), whereas in the other two studies (248,250), subtle differences with no apparent clinical consequences were found.

Imaging both tension-free and transobturator tape procedures during straining show a reduction in the diameter of the hypoechoic urethral core and the diameter became significantly smaller only in the successful procedures (252) and a reduction in the symphysis pubis to tape distance led to continence (253). Other authors have suggested optimal positions of the tape being between the distal third and middle of the urethra with a tape-urethral distance of 2mm, greater than 3.9mm distance led to failure of the procedure. The tape to urethral distance can be reliably assessed using 4D ultrasound (254). Midurethral tapes impinging on the urethra has been reported as being associated with voiding difficulty and the “V” shape of the tape was the same regardless of the insertion method (ie TOT compared to TVT) (255). Tunitsky-Bitton et al. found that the RP sling angle was significantly more acute than the angles of the TOT and TVT-O slings on 3D pelvic floor ultrasound, however no difference was noted between the 2 transobturator slings (242). Tapes sited around the midurethra resulted in a reduction in flow rate compared with a distal tape position under the urethra which did not change flow rates (256) and this positional information has been used to determine the management of de novo symptoms after surgery (257). Muati and Shobeiri have proposed the use of 3D pelvic floor ultrasonography intraoperatively for releasing the mid-urethral part of a sling to overcome voiding dysfunction (258).

The bladder neck is displaced during insertion of a midurethral by using a rigid guide during insertion of a tension-free vaginal tape. Ultrasound has been used to determine that the bladder neck is moved by 1.4cm by this technique (259).

Recently, ultrasonographic localisation of polypropylene mesh as used in prolapse surgery has been described (**Figure 16 and 17**) (260). These meshes are usually easily visible on ultrasonography. It appears that the ultrasonographic appearance of the mesh is significantly shorter and narrower than the size at implantation within six weeks of the procedure (261). It is unclear whether this is due to shrinkage of the mesh or represents difficulties in visualising the full extent of the implanted mesh. The failure of mesh to support vaginal prolapse was associated with mesh shrinkage (262-263).

The differentiation between recurrent herniation and the detachment of the mesh arms from the pelvic sidewall for example, will aid in the better understanding of the mode of action of these meshes (264).

2.2.9.2 Bulking Agents / Injectables

Periurethral bulking agents/injectables, such as microparticulate silicone (Macroplastique), various gels (e.g. Durasphere, and collagen) can be visualised by imaging techniques. For MRI, an overview of appearances of periurethral bulking agents is already available (265).

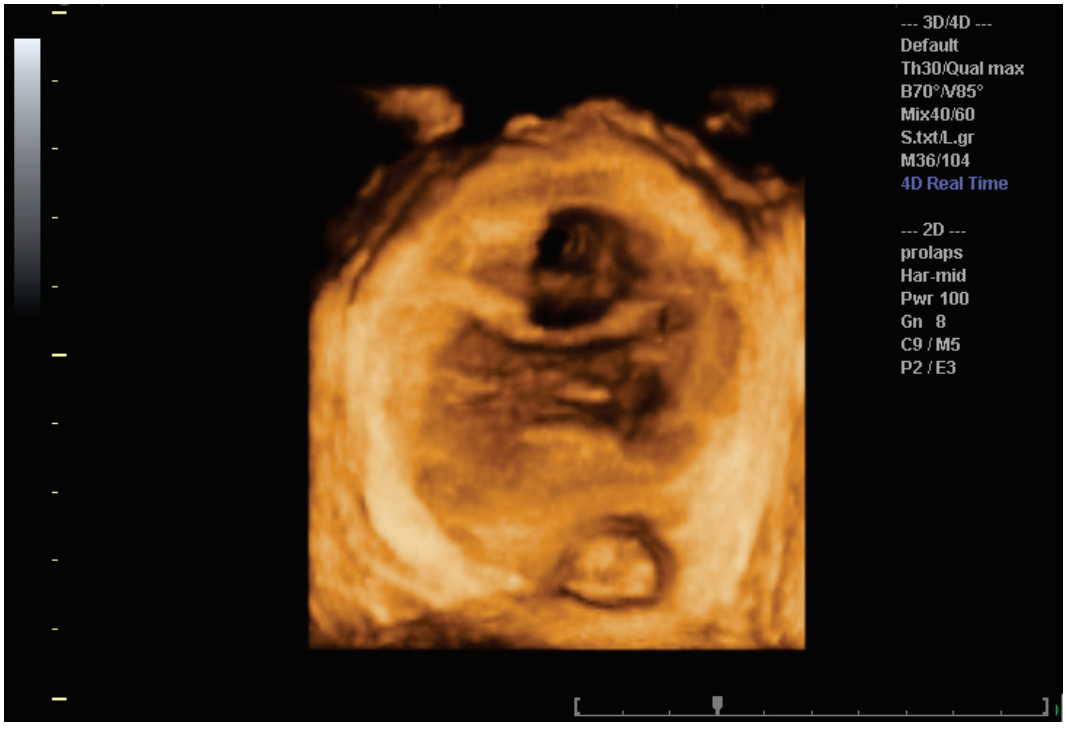

Figure 15 Perineal three-dimensional rendered image. Polypropylene mesh (TVT-O) after one-sided incision of the tape.

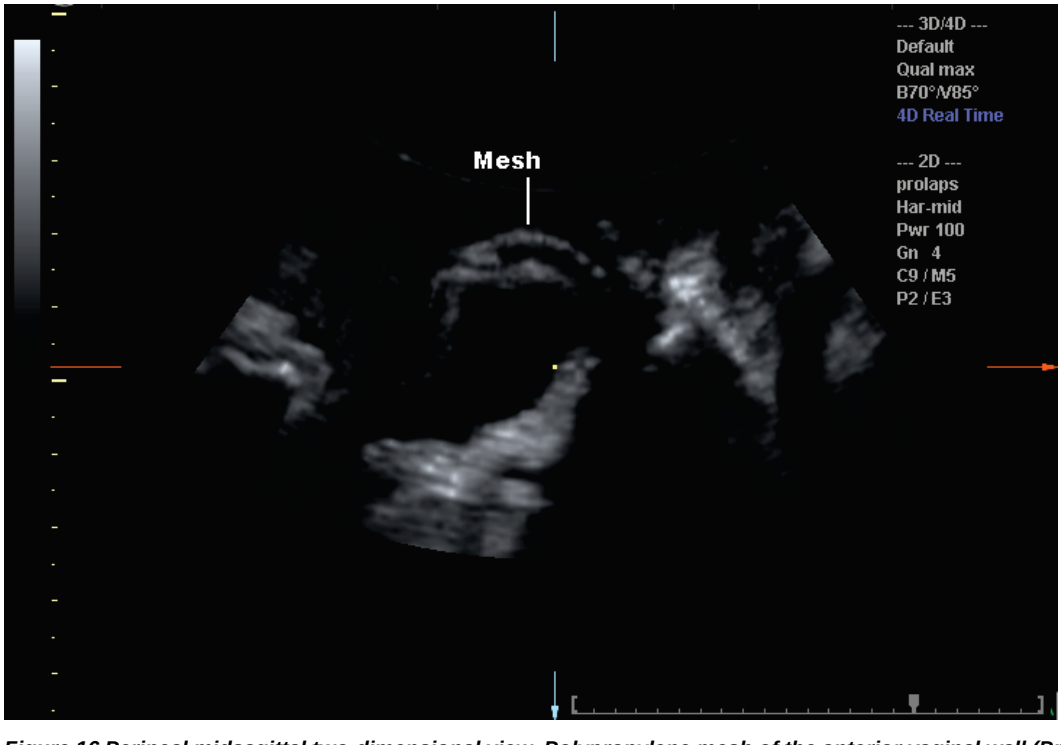

Figure 16 Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior vaginal wall (Prolift anterior).

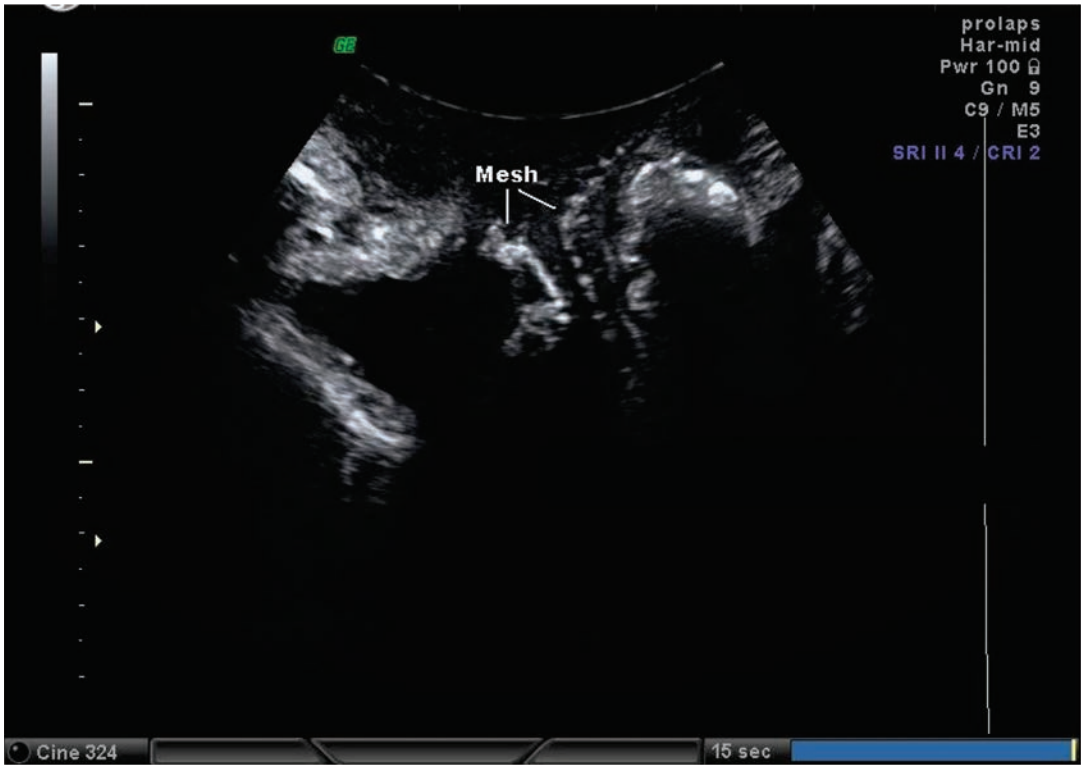

Figure 17 Perineal midsagittal two-dimensional view. Polypropylene mesh of the anterior and posterior vaginal wall (Prolift).

On ultrasonography, the injectables appear hypoechoic after injection, and become more hyperechoic over time due to dehydrogenation. Good intra-observer variability of repeated measurements of periurethral collagen volumes have been found (266).

The location in relation to the bladder neck and a circumferential distribution of collagen injectables around the urethra, as well as the height and volumes of the injected periurethral collagen bumps, were associated with the treatment success of periurethral bulking agents (266-268). Using an endovaginal probe Elia and Bergman found that optimal location of collagen implant was less than 7 mm from the bladder neck (268). It appears that optimal periurethral collagen location is a circumferential distribution around the urethra, while an asymmetric distribution is associated with a significantly smaller improvement in incontinence symptoms (267). A recent prospective study by Hegde et al confirmed these findings demonstrating that best short outcomes occur with a combination of circumferentially distributed and proximally located Macroplastique (269). Although the volume range was wide, a collagen volume of 2.8 cc on three dimensional ultrasonography has been assessed as optimum volume from a continence point of view. Poon et al. have published a decision tree, in which a combination of the patients´ symptoms after collagen injection and the configuration and volume of the periurethral collagen on three-dimensional ultrasonography, assist in the decision for further treatment of women with intrinsic sphincter deficiency (266). In this algorithm, women with asymmetric deposition and/or low collagen volumes were offered further treatment with injectables as this is associated with failure (270).

Ultrasonography has not only been used for follow-up, but also during placement of periurethral injections. Transurethral ultrasonography-guided injection of autologous stem cells has been used in women and men with stress urinary incontinence. The technique allowed precise injection of the myoblasts directly into the rhabdosphincter and was more effective in the resolution of incontinence compared with urethroscopic guided collagen injectables in the submucosa in a randomized controlled trial (271-272). The use of stem cells in the management of urinary incontinence is of great interest although the subject remains controversial and confirmatory studies are eagerly awaited.

2.2.10 Conclusions

Research in US imaging of the pelvic floor has flourished over the last decade although the clinical benefit of it remains uncertain. Standardisation of imaging techniques and terminology are eagerly awaited. Imaging of pelvic floor muscle in relation to POP isa promising area because of the possible insight into the pathophysiology of the condition and treatment outcome. Research suffers from a lack of coordination among different research groups and a more

structured approach to research on imaging of UI and POP is advisable

2.2.11 Consensus statement

- Ultrasound is not recommended in the primary evaluation of patients with urinary incontinence and/or pelvic organ prolapse (rectal prolapse is dealt with in a different section). **(Level of evidence 3, Grade of recommendation C)**
- Ultasound is an optional test in the evaluation of patients with complex or recurrent urinary incontinence and/or pelvic organ prolapse. **(Level of evidence 3, Grade of recommendation C)**
- Ultrasound is recommended for measuring post-void residual and assessing pelvic floor muscle training **(Level of evidence 2, Grade of recommendation B)**

2.2.12 Future research areas

- Standardisation of terminology of pelvic floor US imaging
- Internal and external validity of techniques of pelvic floor imaging
- Confirmatory studies to validate previously published evidence on imaging of UI and POP
- Accuracy of US diagnosis of levator ani injury
- Prognostic value of preoperative US imaging and outcome of POP surgery
- Health technology assessment of pelvic floor imaging in the management of UI and POP.

2.3. MRI (The evolving role of MRI in the assessment of the female pelvic floor).

2.3.1 Introduction

The role of magnetic resonance imaging (MRI) in evaluating pelvic floor disorders has been established in recent years and continues to evolve. This technique provides unparalleled images of pelvic floor muscles, connective tissue, and organs. In addition to the detailed static picture of the pelvic organ support system anatomy, MR can also reveal the downward movement of each pelvic compartment during increases in abdominal pressure. Advances in MR imaging, equipment and software have significantly improved image quality and now MRI provides ever more detailed pictures of anatomy and function. At present active investigation is ongoing to see how this imaging might result in a better understanding of these diseases and improve their diagnosis and management.

Although women might present with symptoms isolated to one of the pelvic compartments, they often have concomitant defects in other compartments or pelvic structures. In these women, imaging can provide information to extend what can be determined on physical examination (1). Furthermore, surgical failures could result from lack of a thorough preoperative evaluation of the female pelvis and inadequate diagnosis and staging of pelvic floor deformation and dysfunction (2). Accurate diagnosis of coexisting abnormalities is therefore essential in planning reconstructive and anti-incontinence procedures. Although most diagnoses of pelvic floor prolapse are made on detailed physical exam, the sensitivity and specificity of the pelvic exam in diagnosing various forms of pelvic floor prolapse is low(3)(4)(5) . Ultrasound and fluoroscopy have been used to improve diagnosis (6)(7) and the role of MRI in pelvic floor dysfunction is rapidly developing.A systematic review suggests that prolapse assessment on dynamic MR imaging may be useful in the posterior compartment, although clinical assessment and dynamic MR imaging seem interchangeable in the anterior and central compartment (8).

MRI provides detailed images of bladder neck and urethral mobility, rectocele, cystocele, enterocele and uterine prolapse, in a single non-invasive study without exposing the patient to ionizing radiation (9)(10)(11)(12)(13)(14)(15)(16)(17)(18). MRI also provides a multiplanar thorough evaluation of pelvic organs including the uterus, ovaries, ureters, kidneys, and levator muscles, as well as the urethra, that is unavailable by any other imaging modality (11)(13)(14)(15)(16)(17)(19)(20). MRI can identify ureteral obstruction, hydronephrosis, and uterine and ovarian pathology. In addition, MRI remains the study of choice for the evaluation of urethral diverticula.

The following measurements using MRI in urogynecology and female urology have been highlighted in the IUGA/ICS Joint Report on the Terminology for Female Pelvic Floor Dysfunction (21):

- Bladder neck and cervical descent/mobility:
    - Position of bladder neck and cervix at rest and on Valsalva.
    - Pubo-coccygeal line: A line extending from the inferior border of the pubic symphysis to the last joint of the coccyx. Bladder neck or cervical descent >2 cm below this line with straining indicates weakness of the pelvic floor. If alternative landmarks are used in scientific papers they should be clearly described.
- Intercurrent pelvic pathology: For example, fibroids, ovarian pathology.
- Uterine version: Anteverted or retroverted; flexion at the isthmus.
- Bladder abnormalities: For example, tumor; foreign body.
- Urethral abnormality: For example, diverticulum.

- Postoperative findings: For example, bladder neck mobility.
- Pelvic floor measurements/levator defects: Assessment of the configuration of pelvic floor muscles, in particular, the levator ani.
- Descent of pelvic organs.

2.3.2 Technique

2.3.2.1 Conventional MRI

Standard MRI consists of two dimensional image acquisitions. Usually conventional T1 images and spin echo T2 weighted images are obtained. Proton density T2 weighted scans provide excellent soft-tissue definition (Figure 18). However, the long imaging time of conventional MRI hampers its ability to evaluate the movement of organs that are characteristic of POP.

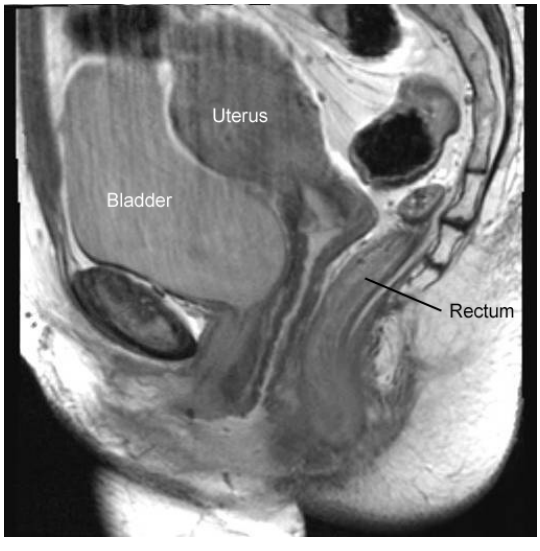

Figure 18: Sagittal mid pelvic section showing anatomical detail visible in static images made with Proton Density sequence.

2.3.2.2 Ultra Fast Image Acquisition and MR Sequences

Pelvic organ movement during Valsalva is identifiable using very fast single-shot MR sequences and the technical aspects have been summarized ina previous report (Figure 19) (ICI 2009). (15)(16)(22)(23). These sequential images are obtained approximately once per second, either as a series of images covering the entire pelvis (static imaging) or repetitively in one plane while the patient is straining (dynamic imaging). The patients are placed in the supine position with legs slightly spread apart, and knees bent and supported by a pillow. Most pelvic floor details can be seen without the need for bowel preparation, premedication, instrumentation or contrast medium but often, especially with MR defecography, ultrasound gel or other suitable agents are used to enhance visibility of the rectum and vagina. The MRI torso coil is centered at the symphysis pubis. Images are acquired in the sagittal plane using single-shot fast spin echo (SSFSE) or half Fourier acquisition, single shot turbo spin echo (HASTE) sequences. Single, mid sagittal views are obtained during 3 seconds of apnea with the patient relaxed and during various degrees of progressive abdominal straining.

Steady-state free precession gradient-echo imaging provides an alternative T2-like imaging contrast (T2- and T1-weighted imaging) with robust signal and a rapid acquisition time of less than 1 second, thereby permitting near real-time continuous imaging. This is an improvement on the HASTE approach that requires 1–2 seconds between acquisitions to allow T1 recovery; therefore, real-time imaging is not possible. Comparisons of the degree of POP shown on dynamic true fast imaging with steady-state precession (FISP) versus HASTE sequences in symptomatic patients reveal a greater degree of prolapse in all three compartments with a dynamic true FISP sequence. Near real-time continuous imaging with a dynamic true FISP sequence may therefore be useful to evaluate pelvic floor dysfunction in addition to dynamic multiplanar HASTE sequences (24).

During a typical study of pelvic organ movement two sets of images are obtained. The first set consists of static sagittal and para-sagittal images covering the pelvis from left to right sidewall. These images are used to select the mid-sagittal plane for the dynamic second set of images. This static sequence also allows for anatomic delineation of the pelvic sidewalls and muscular and fascial components of the pelvic floor (15)(16)(22)(23). The perineal membrane and the levator ani musculature, as well as the anal sphincter anatomy, are also clearly demonstrated(25)(26). The static set consists of 17-20 sequential images independently acquired in a total of about 18 seconds.

The second set of images consists of relaxed and straining mid-sagittal images used to assess the degree of pelvic floor relaxation and organ prolapse. Images can then be looped for viewing on a digital station as a cine stack.

Dynamic MRI allows detection of POP that may not be evident on conventional static sequences, as it permits both structural and functional evaluation. For example, in women with lower urinary tract symptoms, evaluation of the urethra may be of added value.(27)

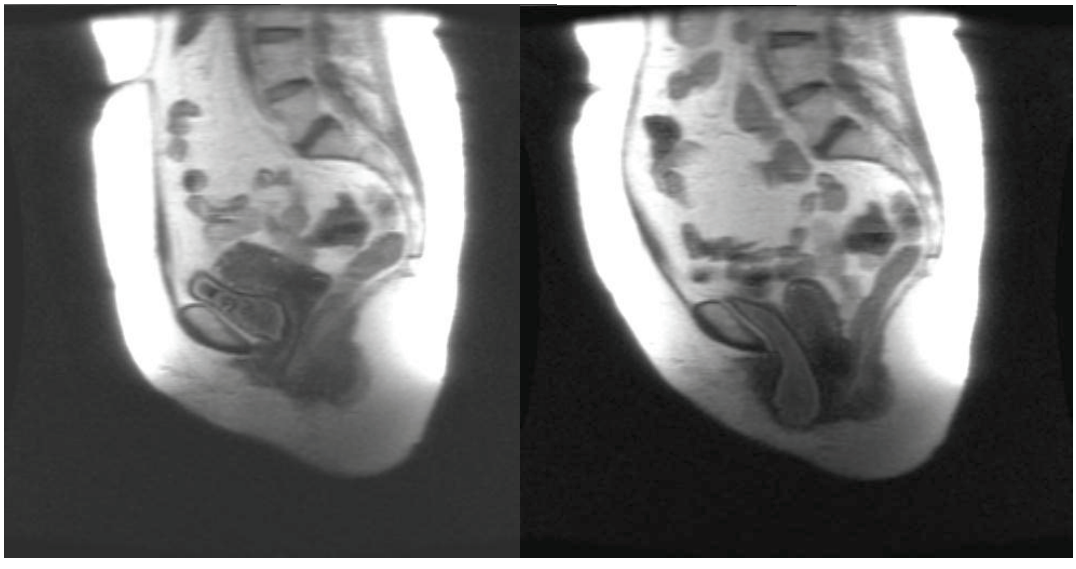

Figure 19: The rest and strain image taken from a mid-sagittal dynamic MR sequence revealing cystocele and uterine descent using SSFSE sequence.

The first time a woman performs a Valsalva maneuver, she may not get the prolapse to protrude to its maximal extent. Forty per cent of women have a greater than 2cm increase in prolapse size from their first to third Valsalva attempt and 95% of women extend their prolapse further with a third Valsalva(28). As with clinical examination, several attempts may therefore be required to have maximal anterior compartment prolapse present during dynamic MRI of the pelvic floor. Delaney et al evaluated whether the use of a speculum blade modifies the evaluation of pelvic organ prolapse (POP) as assessed by dynamic MRI. Twenty-seven women with POP Quantification (POPQ) stage II or greater, scheduled for POP surgery, were evaluated using MRI. The procedure was repeated using the posterior blade of a standard plastic Grave's speculum to successively retract the anterior and posterior vaginal walls. Standard POPQ was 15% stage II (n =4), 59% stage III (n =16) and 26% stage IV (n =7). The use of a blade evidenced hidden pelvic prolapsed compartments in 59% (n =16) of cases. For 48% of patients (n =13), the variation of the leading edge of at least one additional prolapsed compartment was diagnosed as more than 20 mm. In this series, the use of a speculum blade during dynamic MRI modified the POP evaluation in a large proportion of patients with POP stage > or =II (29).

More recently, open magnetic resonance imaging (MRO) with vertical magnets, has allowed imaging in a variety of upright postures. A pilot study compared distances between the lowest point of the bladder to the pubococcygeal (PC) and pubopromontoreal (PP) lines as well as the ratio of bladder area under the PC and PP lines to the total bladder area. Significant elongation between the PC line and lowest point of the bladder was evident in women with POP comparing supine and standing images ($p = 0.03$), but not controls ($p = 0.07$). Similarly, this axis was significantly longer in women with cystocele versus controls only in the standing position. Bladder area under the PC line was significantly increased between supine and standing positions only among women with cystocele ($p < 0.01$), and significantly larger among the study group in the standing position ($p < 0.005$), less significant in the supine position ($p = 0.015$), and not significant in the sitting position ($p = 0.3$)(30).

2.3.2.3 Three Dimensional MRI

Three dimensional (3-D) MRI provides precise detail of the bony and muscular pelvic structures (**Figure 20**) so that 3D models can be constructed based on these detailed images. In this technique, static or dynamic images are reconstructed using consecutive planes in the axial, sagittal and coronal dimensions. Anatomic variations of the insertion and path of the pubococcygeus and iliococcygeus muscles can be seen. Fielding et al. made 3D models of the pelvic viscera and supporting muscles and bones with the marching-cubes algorithmand a surface-rendering method in nulliparous continent female volunteers and found that the muscle morphology, signal intensity and volume are relatively uniform (25). They described an average volume of the levator ani of 46.6 cc, width of the levator hiatus of 41.7 mm and an average posterior urethrovesical angle of 143.5°. In addition, these 3D models made from multi-slice scans during a maximal Valsalva have allowed direct measurements of changes in the relationship between the vagina and pelvic walls.

Figure 20: Pelvic Organs as seen from caudal on a three-dimensional reconstruction from Magnetic resonance images. Copyright Mosby Inc.

3D MRI enables evaluation of paravaginal defects, apical descent and vaginal widening. Larson et al (31) studied the relative contributions of "midline defects" (widening of the vagina) and "paravaginal defects" (separation of the lateral vagina from the pelvic sidewall) in women with anterior prolapse using 3D MRI models of the anterior vaginal wall and found that changes in lateral anterior vaginal wall were considerably greater than changes in vaginal width in cases vs controls.These "paravaginal defects" were also highly correlated withapical descent.

The geometry of the arcus tendineus fascia pelvis (ATFP) and arcus tendineus levator ani (ATLA) in women with unilateral levator ani muscle defects and associated "architectural distortion" has been studied using 3D MRI. In those women, the ventral arcus anatomy is significantly altered in the presence of levator defects as well as architectural distortion, resulting in change of the supportive force direction along the lateral anterior vaginal wall, thus increasing the risk for anterior vaginal wall prolapse. (32)

Luo et al (33) developed a method to evaluate changes in apical ligament lengths and lines of action from rest to maximal Valsalva using 3D stress magnetic resonance imaging (MRI). In a case-control study, 3D reconstructions of the uterus and vagina, cardinal ligament (CL), deep uterosacral ligament (USL(d)), and pelvic bones were created using 3D Slicer software. At maximal Valsalva, CL elongation was greater in cases than controls, whereas USL(d) was not; CL also exhibited greater changes in ligament length, and USL(d) exhibited greater changes in ligament inclination angle.

Following studies that reported diffusion tensor imaging (DTI) as a method for detecting alterations in tissue organisation of injured striated skeletal muscles, the clinical application of DTI and fibre tractography in pelvic floorimaging was assessed by Zijta et al.(34) A two-dimensional (2D) spin-echo (SE) echo-planar imaging (EPI) sequence of the pelvic floor was acquired. Offline fibre tractography and morphological analysis of pelvic magnetic resonance imaging (MRI) were performed. Inter-rater agreement for quality assessment of fibre tracking results was evaluated. DTI with fibre tractography seems to enable 3D visualisation and quantification of elements of the female pelvic floor.

2.3.3 Normal Pelvic Floor Functional Anatomy

2.3.3.1 MR Imaging of Normal Pelvic Support Structures

MRI studies of normal subjects have improved our understanding of normal pelvic anatomy, its variations(25)(26)(35) as well as anatomic changes in pelvic floor dysfunction (20)(36)(37).

In the supine position the female pelvic floor is dome shaped at rest (37)(38). During voluntary pelvic floor contractions the levator musculature straightens and becomes more horizontal. With bearing down the muscle descends, the pelvic floor becomes basin-shaped, and the width of the genital hiatus widens.

With MRI the specific structures are identified and their normal variations described (Figure 21). Tan (36) demonstrated the anatomy of the female pelvic floor with MRI. The pelvic and the urogenital diaphragm were well depicted as were urethral supporting structures—the peri-urethral and paraurethral ligaments, and the zonal anatomy of the urethra. The MRI findings in volunteers correlated with the endovaginal MR findings and gross anatomy in cadavers. Chou (39)studied the urethral support structures relative to the arcuate pubic ligament including the arcus tendineus fasciae pelvis, the perineal membrane, the pubococcygeal levator ani muscle and its vaginal and bony attachments, and the pubovesical muscle. Tunn et al (40) showed that 2- to 3-fold differences occur in distance, area, or volume measures of continence system morphologic features in continent nulliparous women with normal pelvic organ support and urodynamics. The uterosacral ligaments also exhibit greater anatomic variation than their name would imply(41). Three dimensional simplified biomechanical models constructed from MRI scans showed thatthe CL is parallel to the body axis. The US ligament is dorsally directed. The tensions on these ligaments seem to be affected by their orientations according to this study (42).

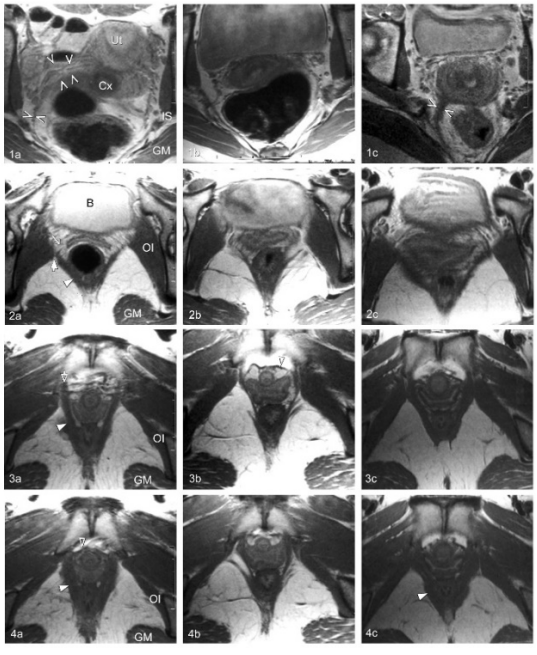

Figure 21: Axial images according , in 22-year-o ld (A, D, G, and J), 24-year-old (B, E, H, and K), and 34-year-old (C, F, I, and L) nulliparous women without urogynecologic problems. A-C, Level of cervix (Cx) and ischial spine (IS); uterus (Ut) with bright endometrium is also seen. Paracolpium and parametrium suspend (open tips) vagina and cervix from lateral and posterior pelvic sidewall. Smooth muscle of uterosacral ligament (open tips) is best seen in C. GM, Gluteus maximus muscle. D-F, Level of bladder (B) base. Upper vagina between bladder and rectum (R) and its attachment to pelvic sidewall by vascular and connective tissue mesentery (small arrow) are seen. Levator ani muscle (iliococcygeal part, filled arrowhead) arises from arcus tendineus of levator ani muscle (filled arrow). OI, Obturator internus muscle. G-I, At level of proximal urethra, levator ani muscle (pubovisceralis part, filled arrowhead) arises from pubic bone (open arrow). Pubovesicalis muscle (open arrowhead) is clearly seen in H. Vessels (white gap) are visualised between smooth muscle layer of lateral vaginal wall and levator ani muscle at this level. J-L, At level of middle urethra, pubovesicalis muscle is seen as shown in J (open arrowhead). Vessel layer (white gap) between lateral vaginal wall and levator ani muscle (filled arrowhead) has disappeared; direct connection between vagina and levator ani muscle is seen at this level. Small white gap in levator ani suggests fascia between puborectalis and pubococcygeal muscles (especially in J and L). (123)

Characteristic anatomic features of the posterior compartment and perineal body have been studied with MR cross-sectional anatomy and can be further elucidated and integrated with 3-D anatomy. In nulliparous asymptomatic women the posterior compartment's upper, mid, and lower segments are best visualized in MRI in the axial plane. It is bounded inferiorly by the perineal body, ventrally by the posterior vaginal wall, and dorsally by the levator ani muscles and coccyx. In the upper portion, the compartment is bordered laterally by the uterosacral ligaments, whereas in the middle portion, there is more direct contact with the lateral levator ani muscles. In the lower portion, the contact becomes obliterated because the vagina and levator ani muscles become fused to each another and to the perineal body (43)(figure 22). The perineal body anatomy has been possible to study using 2mm MR images. Visualisation of perineal body anatomy in living women and development of 3-D models enhanced our understanding of its 3 different regions: superficial, mid, and deep (44). The three distinct perineal body regions are (1) a superficial region at the level of the vestibular bulb, (2) a midregion at the proximal end of the superficial transverse perineal muscle, and (3) a deep region at the level of the midurethra and puborectalis muscle. Structures are best visualised on axial scans, whereas craniocaudal relationships are appreciated on sagittal scans. In the superficial portion at the level of the vestibular bulb (VB), the bulbospongiosus (BS) inserts into the lateral margins of the perineal body, whereas the superficial transverse perineal muscle (STP) and external anal sphincter (EAS)traverse the region. In the perineal body's midregion at the proximal end of the superficial transverse perineal muscle, the puboperinealis muscle inserts into the lateral margins of the perineal body and in some individuals can be seen to cross the midline. This region also contains the distal internal anal sphincter. The puboanalis muscle is also visible as it inserts in the intersphincteric groove between internal and external anal sphincters. The puboanalis muscle andinternal anal sphincter extend into the perineal body's most deep region at the level of the midurethra. Here the pubovaginalis muscle also becomes visible as it fuses with the vaginal side wall, sending fibres posteriorly to the perineal body. In this location, the longitudinal muscle of the rectum may be visible in the midline. The puborectalis muscle forms a loop behind the rectum at this level but does not contribute fibers to the perineal body. (Figures 23&24)

One of the key anatomical contributions MRI has made to the understanding of normal pelvic floor structure, regards the ability to make images of a wide variety of normal living women. The pelvic floor is greatly distorted in cadavers due to loss of muscle tone and pressures during embalming. Otcenasek et al have used MR images of a normal nulliparous woman to establish geometry and then added details from dissection to produce an anatomically based topographically normal 3-D model that displays the features of pelvic floor anatomy (Figure 25) (45).

Nardos et al (46) compared levator hiatus measurements between pelvic magnetic resonance imaging (MRI) and 3-dimensional pelvic ultrasound (US) in 37 asymptomatic nulliparous women.

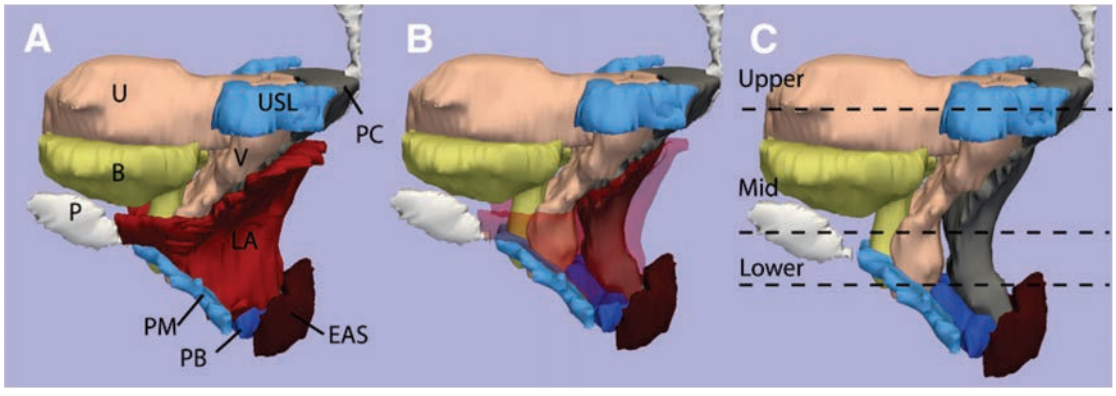

Figure 22: The outline of the midsagittal pubic bone (P) is shown. The bladder (B) is yellow; the uterus (U) and vagina (V) are pink; the uterosacral ligament (USL) and perineal membrane (PM) are turquoise blue; the levator ani muscle (LA) is red; the perineal body (PB) is royal blue; the external anal sphincter (EAS) is dark red; and the posterior compartment (PC) is gray. Image A, All organs are shown. B, Levator ani muscles have been faded to show the underlying structures. C, Levator ani muscles have been removed. The locations of the upper, mid, and lower axial cross-sections are shown(39). Reprinted with permission from John O. L. DeLancey.

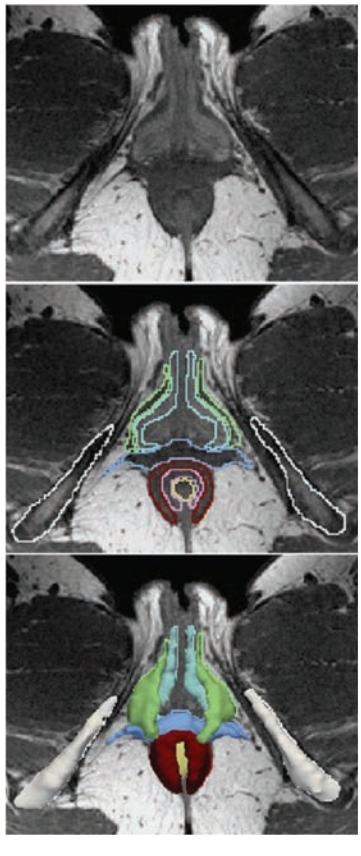

Figure 23: 3D Model of the perineal body (40)

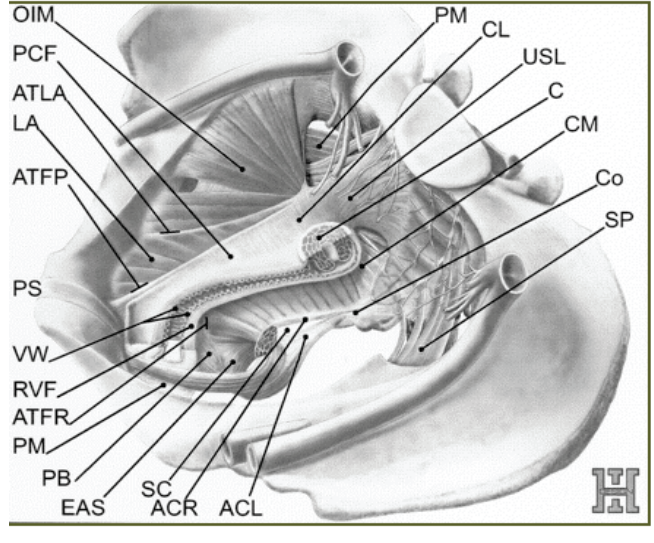

Figure 25: Left lateral view from above the female pelvis. The vagina, endopelvic fascia, and levator ani muscle are cut in the sagittal plane. Urethra, urinary bladder, and rectum have been removed. OIM, obturator internus muscle; PCF, pubocervical fascia; ATLA, arcus tendineus levator ani; LA, levator ani muscle; ATFP, arcus tendineus fasciae pelvis; PS, pubic symphysis; VW, vaginal wall; RVF, rectovaginal fascia; ATFR, arcus tendineus fasciae rectovaginalis; PM, perineal membrane; PB, perineal body; EAS, external anal sphincter; SC, space of Courtney; ACR, anococcygeal raphe; ACL, anococcygeal ligament; PM, piriformis muscle; CL, cardinal ligament; USL, uterosacral ligament; C, cervix of the uterus; CM, coccygeus muscle; Co, coccyx; SP, sacral plexus. B, bladder; Ba, Bartholins; IAS, internal anal sphincter; IC, iliococcygeus; PB, perineal body; PR, puborectalis; PS, pubic symphysis; PuR, pubic rami; R, rectum; U, urethra; V, vagina; VB, vestibular bulb (40).

They found that the MRI measurements obtained from the sagittal images were consistently greater than the ones obtained by US. However, there was no such difference between MRI and US for the axial images. The authors attributed this observation to acquisition planes for axial images or interpretation of landmarks for the sagittal images.

2.3.3.2 Levator Ani Muscle Functional Anatomy

Evidence from MR and CT images in volunteers and cadavers shows that the anterior transverse portion of the levator muscle is basin-shaped; the middle transverse portion funnel-shaped, while the posterior transverse portion dome-shaped. The puborectalis appears u-shaped outside the vertical portion(47). On MR images of the five Terminologia Anatomica-listed levator ani components: pubovisceral (pubovaginal, puboperineal, and puboanal), puborectal and iliococcygeal portions of the levator ani muscle muscles in women with normal pelvic support., the puborectal muscle can be seen lateral to the pubovisceral muscle and decussating dorsal to the rectum in the axial plane. The course of the puboperineal muscle near the perineal body is also seen best in the axial plane. The coronal view is perpendicular to the fibre direction of the puborectal and pubovisceral muscles and shows them as "clusters" of muscle on either side of the vagina. The sagittal plane consistently demonstrates the puborectal muscle passing dorsal to the rectum to form a sling that can be seen as a "bump". This plane is also parallel to the pubovisceral muscle fiber direction and shows the puboperineal muscle(48)(Figure 26).

Betschart et al (49) described a technique to quantify muscle fascicle directions in the levator ani (LA): Among levator subdivisions, significant angle differences were observed between PVM and PRM (60 degrees), and between ICM and PRM (52 degrees). An 84 degrees difference was observed between PVM and EAS. The smallest angle difference was between PVM and ICM (8 degrees). The difference between PRM and EAS was 24 degrees.

2.3.4 Pathophysiology of Pelvic Floor Disorders

2.3.4.1 Levator Ani (LA) Muscle Defects

Lammers et al (50) assessed the inter- and intraobserver reliability of the diagnosis of pubovisceral muscle avulsions and measurements of the levator hiatus on MRI and confirmed that pubovisceral muscle avulsions and levator hiatus measurements can be assessed with good to excellent reliability on MRI.

In (51) a case-control study with group matching for age, race, and hysterectomy status, women with prolapse (cases) were compared to those with normal support (controls). Major defects were those that lost more than 50% of the muscle bulk. Cases were more likely to have major levator ani defects than controls

(55% compared with 16%), but equally likely to have minor defects (16% compared with 22%) (Figure 27,28). Women with defects generated less vaginal closure force during a pelvic muscle contraction than women without defects (2.0 Newtons compared with 3.1 Newtons) and women with prolapse also generated less vaginal closure force during pelvic muscle contraction than controls (2.0 Newtons compared with 3.2 Newtons). This confirmed earlier uncontrolled observations with ultrasound (52).

It is important to distinguish between muscle thickness and muscle damage. A woman with a normally thin but intact muscle may have less muscle substance than a woman with naturally bulky muscles who has a defect that has involved 25% of her muscle bulk. The issue of muscle damage is relevant to seeing who is injured, while that of muscle bulk, with the capability of the muscle to close the hiatus. Hoyte et al (53) examined 10 women with prolapse, 10 with urodynamic stress incontinence, and 10 asymptomatic volunteers. Mean 3-dimensional parameters in the 3 groups showed levator volumes of 32.2, 23.3, and 18.4 cm^3 (P <0.005); hiatus widths of 25.7, 34.7, and 40.3 mm (P <0.005); left levator sling muscle gaps of 15.6, 20.3, and 23.8 mm (P =0.03), right levator sling muscle gaps of 15.6, 22.5, and 30.8 mm, (P =.003), and levator shape (90%, 40%, and 20% dome shaped; P <0.005). Subsequently, using a novel thickness mapping (54),they found thicker, bulkier anterior portions of the levators in asymptomatic women, compared with women with prolapse or urodynamic stress incontinence while the more posterior portions of the muscle were not affected.

Hsu and colleagues quantified levator ani muscle cross-sectional area as a function of prolapse and muscle defect status (55). Using muscle cross-sections from 3-D reconstructions they found that women with visible levator ani defects on MR have less muscle ventrally compared with women with intact muscles. Women with major levator ani defects had larger cross-sectional areas in the dorsal component than women with minor or no defects indicating a compensatory hypertrophy in this area. Furthermore, after controlling for prolapse, women with levator defects appear to have a more caudal location of their perineal structures and larger hiatuses at rest, maximum contraction, and maximum Valsalva maneuver (56).

Among women with POP, those with major LAD appear less likely to experience stress incontinence when "coughing, laughing, or sneezing" (odds ratio (OR) 0.27) and when "twisting, reaching, lifting, or bending over" (OR 0.26) than women with normal muscles. They are less likely to have obstructive symptoms characterised by assuming an "unusual toileting position" or "changing positions...to start or complete urination" (OR 0.27). Women with minor LAD appear more likely to experience stress incontinence with exercise (OR 3.1) and urge incontinence (OR 4.0) than those with normal muscles. Lower urinary tract symptoms are therefore less common among women with prolapse and major levator ani defects and more common among those with minor defects (57). This may be explained by the fact that the women with major LA defects have larger prolapses than those who do not have major LA defects. It is a clinical observation that prolapse often reduces the occurrence of stress incontinence (urethral kinking?) and this hypothesis is consistent with the observations mentioned above.

Cai et al (58)evaluated levator ani morphology and function in healthy nulliparous women using static and dynamic MRI. They found no morphologic abnormality in healthy nulliparous women. However, in 15% (12/80) of women, pelvic organ descent below the pubococcygeal line was observed. In these women, the width of the pubic portion of the levator ani was significantly reduced during straining, whereas the levator plate angle, the levator hiatus area, and the H and M line lengths were enlarged. These changes were associated with weakened levator ani function and pelvic floor laxity.

2.3.4.2 Identifying the Injury Zone within the Levator Ani Muscle Most Often Involved by Injury

MRI based 3D models show that in women with bilateral puborectal muscle avulsion after vaginal delivery, the damage affects the pubic origin of the muscle. This structural change alters the support to the whole endopelvic fascia and destabilises both the anerior and the posterior vaginal walls(59). In women with significant muscle on one side and damaged muscle in the same individual(60)the injury involves the muscle's origin from the posterior pubic bone (Figure 29).Distortion of the surrounding connective tissue with lateral spilling of the vagina towards the obturator internus muscle is observed in 50% of women. The defect is right sided in 71% of patients. The average difference of the amount of muscle lost in these types of injury between the normal side and the defective side is up to 81% at locations nearest the pubic origin(61). Almost all of the volume difference (13.7%, P=0.0004) is attributable to a reduction in the pubic portion (24.6%), not the iliococcygeal portion of the muscle.

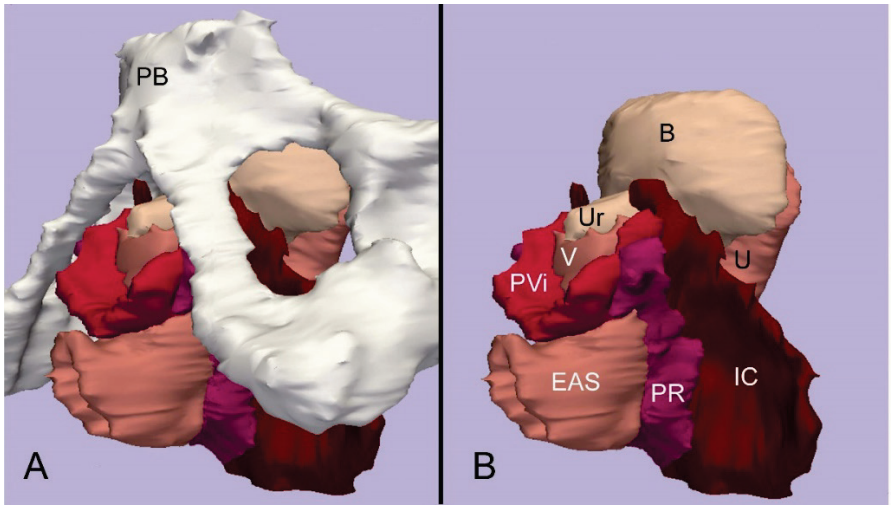

Figure 26: Three-dimensional model of levator ani subdivisions including the pubic bone and pelvic viscera. This model was created by using the magnetic resonance images shown in Figures 2, 3, and 4. The pubovaginal, puboperineal, and puboanal muscles are all combined into a single structure, the pubovisceral muscle. Inferior, left 3-quarter view. B. The same model without the pubic bone. 2.3.4.3 Changes in the Hiatus Size and Levator Plate Angle with Prolapse

The levator ani muscle's constant activity closes the genital hiatus. In addition to evaluating defect status and muscle bulk, MRI has revealed changes to the levator hiatus and angle of the levator plate (that midline portion of the muscle between the anus and the coccyx) which is presumed to be influenced by muscle action. Hsu and colleagues (62) studied 68 women with pelvic organ prolapse and 74 normal controls.During Valsalva, controls had a mean levator plate angle of 44.3 degrees. Cases had 9.1 degrees (21%) more caudally directed levator plate angle compared to controls (53.4 degrees vs. 44.3 degrees), 15% larger levator hiatus length (7.8 cm vs 6.8 cm), and 24% more caudal perineal body location (6.8 cm vs 5.5 cm). Increases in levator plate angle were correlated with increased levator hiatus length (r = 0.42) and perineal body location (r =.51). The bladder neck descent at straining is also correlated with the levator plate angle at rest, hiatus length at rest and at straining(63). Uterine cervix descent at straining is correlated with increased hiatus length and width at straining, and greater levator plate angle (p=0.007) at straining. Paradoxically anterior rectal bulging at straining is inversely correlated with the hiatus width at rest (p = 0.04).

Perineal descent and localised outward bulging of the levator ani during Valsalva was evaluated by Gearhart and colleagues (64). In this study, dynamic MRI of symptomatic patients with pelvic floor prolapse demonstrated unsuspected levator ani hernia. Patients with POP, fecal and/or urinary incontinence, or chronic constipation were evaluated. Fifteen percent of patients (12/80) had unilateral (n = 8) or bilateral (n = 4) levator ani hernias on MRI. Perineal descent on physical examination was associated with a levator ani hernia in nine patients.

2.3.4.4 MRI and the Bony Pelvis

Studies of the bony pelvis dimensions and their associations with POP, levator ani defects and stress incontinence have recently been undertaken. Stein et al showed that bony pelvis dimensions are similar at the level of the muscular pelvic floor in white women with and without POP (65). Further evaluation of the bony pelvis using MRI scans has also improved our understanding of the natural history of stress urinary incontinence as well as the associations of the bony pelvis dimensions with the prevalence of levator defects (66). Other studies investigating the role that different pelvis shapes play for specific diseases will be described in subsequent sections of this review.

2.3.4.5 MRI of Pelvic Floor After Vaginal Delivery

There are changes observed in the levator ani and pelvic floor musculature immediately after delivery, which change over time. Boreham (67) evaluated the normal visibility of the levator in post term nulliparas using 3-dimensional (3-D) MRI. LA insertion into the symphysis was visible in 93%, and the iliococcygeus muscle assumed a convex shape (arch) in 92% of 84 nulliparas. Mean LA volume was 13.5 (3.7) cm^3. Interestingly there was a positive association between LA volume and higher fetal station with increasing BMI. The muscle signal intensity appears

increased at 1 day postpartum on T2 weighted images, but normal by 6 months. The urogenital and levator hiatus decreases significantly by 2 weeks postpartum(68). Lienemann (69) found thinning of the puborectal muscle in primiparous women after vaginal delivery (0.6 cm vs. 0.8 cm) and increased descent of the bladder, vaginal fornix, and anorectal junction during straining compared to healthy asymptomatic nulliparous volunteers.

The descent of the bladder and cervix on straining appears greater in women who delivered vaginally compared tothose who had cesarean delivery and to nulliparous women. There is a positive correlation between the duration of labor and the area of the levator sling and also between birthweight and the descent of the cervix on straining(70).

The role of levator ani muscle damage and stress soon after birth has also been studied. An investigation of 80 nulliparous asymptomatic women and 160 vaginally primiparous women half of whom had new stress incontinence after their first birth was conducted 9 months after delivery. A visible defect in the levator ani muscle was identified in 32 primiparous. Twenty-nine of these 32 defects were in the pubovisceral portion of the levator and three were in the iliococcygeal portion. None of the nulliparous women showed these abnormalities(71). In a further study of this cohort (72)evaluation of obstetric factors associated with levator ani injury after first vaginal birth showed increased odds ratios for levator defect: forceps use 14.7, anal sphincter rupture 8.1 and episiotomy 3.1 but not vacuum delivery (0.9) epidural use (0.9) or oxytocin use (0.8). Women with levator injury were 3.5 years older and had a 78-minute longer second stage of labor. Differences in gestational age, birth weight, and head circumference were not statistically significant.

Dannecker (73)compared women after spontaneous vaginal delivery to those delivered by vacuum extraction and a control group of healthy nulliparous volunteers. Significant differences for individual POPQ component measurements were noted for points Aa and Ba, TVL, and GH (spontaneous delivery versus control) and in addition for Ap, Bp, and D (vacuum extraction versus control). Significant differences were observed for the position of bladder base, bladder neck, posterior vaginal fornix, anorectal junction, hiatus perimeter and depth of rectocele. Looking into comparisons with the spontaneous vaginal delivery group, on clinical examination, there was more evidence of anterior vaginal wall descent after vaginal delivery, and TVL and GH. Differences between the groups with regard to points Ap and Bp reached only marginal significance. With MRI measurements primiparous women who underwent spontaneous vaginal delivery as compared to nulliparous women showed considerable and statistically significant descent of almost all assessed structures at rest and on straining. Bladder base, bladder neck and the anorectal junction descended even below the respective reference lines. The bladder neck

showed considerably increased mobility, and the genital hiatus showed an increased change on straining. The depth of rectocele increased more than three times. One of 26 women (4%) had a rectocele >3 cm. POPQ measurements that differed significantly between primiparous women after vacuum extraction and nulliparous women of the control group indicated more evidence of anterior and posterior vaginal wall descent after vacuum extraction. In addition TVL and GH was increased and PB was decreased after vacuumextraction. MRI measurements after vacuum extraction, showed considerably increased descent and mobility of the bladder base and bladder neck on straining, and descent of the anorectal junction was prominent. The mean depth of rectocele was four times biggerthan in the nulliparous group. Four of 49 women (9%) had a rectocele >3 cm.

Branham and colleagues (74)evaluated postpartum changes in the levator ani muscle in relation to obstetric events. In those subjects recovering to normal MR by 6 months an average of nearly 60% increase in right puborectalis muscle thickness compared with that seen at 6 weeks indicated the extent of the injury. Younger white primiparous women had a better recovery at 6 months than older white women. Subjects experiencing more global injury, in particular to the iliococcygeous, tended not to recover muscle bulk.

Heilbrun and colleagues investigated the correlation between the presence of major LAM injuries on MRI with faecal incontinence (FI), POP, and urinary incontinence (UI) in primiparous women 6-12 months postpartum using a scoring system to characterise LAM injuries on MRI. Major LAM injuries were observed in 19.1% women who delivered vaginally with external anal sphincter (EAS) injuries, 3.5% who delivered vaginally without EAS injury, and 0% who delivered by cesarean section before labor (P=.0005). Among women with EAS injuries, those with major LAM injuries trended toward more FI, 35.3% vs. 16.7% (P=.10) and POP, 35.3% vs 15.5% (P=.09), but not UI (P=1.0). These data confirm that both EAS and LAM are important for faecal continence and that multiple injuries contribute to pelvic floor dysfunction (75) .

Handa and colleagues used MRI to measure bony and soft tissue pelvic dimensions in 246 primiparas, 6-12-months postpartum. A deeper sacral hollow was significantly associated with fecal incontinence (P = 0.005). Urinary incontinence was marginally associated with a wider intertuberous diameter (P = 0.017) and pelvic arch (P = 0.017). There were no significant differences in pelvimetry measures between women with and without prolapse in this study(76).

2.3.4.6 MRI and Biomechanical Investigation of the Pelvic Floor

MRI has allowed anatomically based biomechanical models to be constructed. Simulations have demonstrated important interactions between muscle and connective tissue in providing anterior vaginal wall support (77). MRI has enabled construction of finite element analysis (78)(79). It has also allowed for capture of 3D shape variation of the levator ani during straining where complete volumetric imaging is prohibited by the inherent temporal resolution of the scanning technique (80).

Chen recently developed and validated a 3D finite element computer model of the anterior vaginal wall and its supports based on spatial data from MR scans of normal women. They determined the combinations of muscle and connective tissue impairments that result in cystocele formation, as observed on dynamic MRI geometry from a healthy nulliparous woman. It included simplified representations of the anterior vaginal wall, levator muscle, cardinal and uterosacral ligaments, arcus tendineus fascia pelvis and levator ani, paravaginal attachments, and the posterior compartment. The authors found that development of a cystocele requires a levator muscle impairment, an increase in abdominal pressure, and weakening of apical and paravaginal support (81). These simulations provide a way to see what specific changes in structural components do to pelvic organ support in ways that would be impossible to study in living women.

Peng et al (82) assessed urethral support by developing a pelvic model from an asymptomatic female patient's MR images using the finite element method. Weakening the vaginal walls, puborectalis muscle, and pubococcygeus muscle generated the top three largest urethral excursion angles. Weakening all three levator ani components together caused a larger weakening effect than the sum of each individually weakened component, indicating a nonlinearly additive pattern. The authors concluded that the vaginal walls, puborectalis, and pubococcygeus are the most important individual structures in providing urethral support. The levator ani muscle group therefore provides urethral support in a well-coordinated way with a nonlinearly additive pattern according to the authors of this study.

2.3.4.7 Racial Differences in Pelvic Dimensions

There are differences in pelvic dimensions that exist in women from different racial backgrounds. Several groups have evaluated racial differences in the bony pelvis and the levator ani muscles (83)(84)(85). In a study by Handa et al (83), a wider transverse diameter (odds ratio 3.4) and a shorter obstetrical conjugate (odds ratio 0.2) were associated with pelvic floor dysfunction after controlling for age, race, and parity. Hoyte and colleagues found that levator ani volume was significantly greater in African-American (AA) asymptomatic nulliparous women without pelvic floor dysfunction compared to white American (WA) ones (mean = 26.8 vs. 19.8 cm3, P = .002). The levator-symphysis gap was smaller in the AA (left-18.2, right-18.8 mm) versus the WA group (22.4, 22.6 mm, P = .003, .048) on the left and right. Significant differences were also seen in bladder neck position, urethral angle, and the pubic arch angle(84). In another study with 3D MRI levator thickness was significantly greater bilaterally in black nulliparas compared to white ones, yet obturator internus muscle thicknesses were similar(85)..

Handa found that the pelvic inlet was wider among white women than African-American women (10.7+/-0.7 cm compared with 10.0.+0.7 cm, P<.001). The outlet was also wider (mean intertuberous diameter 12.3+/-1.0 cm compared with 11.8+/-0.9 cm, P<.001). There were no significant differences between racial groups in interspinous diameter, angle of the subpubic arch, anteroposterior conjugate, levator thickness, or levator hiatus.(86).

A broader group of races was studied by Rizk et al with MR in asymptomatic multiethnic nulliparous young volunteers from 5 ethnic groups (Emirati, other Arab, Filipino, Indian/Pakistani, and European/white volunteers), with the white volunteers as the reference group (87). The white volunteers were taller (P <.0001) than the other women. Their levator hiatus was longer than the Emirati women (P=.03) and wider than the Filipino women (P=.04). The bladder neck descent on straining was also greater than the other groups (P <.00001). The white women also had the longest transverse diameter of the pelvic inlet (P=.002). Their sagittal outlet diameter was longer than the Emirati and Arab women (P=.02), and their interspinous diameter was longer than the Arab women (P=.002).

2.3.5 Pelvic Organ Prolapse

MRI has proven to be a key assessment for understanding pelvic organ prolapse; a problem that arises from damage to connective tissue, muscles, and nerves that are invisible on standard radiography. With the advent of 3D ultrasound and MRI, the actual structures involved in the cause of prolapse can be seen and examined. This is possible not only in static scans that reveal morphological details of the pelvic structure, but also in dynamic scans where the movements of the various organs can be studied.

Evaluation of the degree of anterior compartment (bladder) and apical compartment (cervix) prolapse at maximal Valsalva using dynamic MRI showed a strong correlation between how far the bladder base and uterine cervix were below normal with $r^2 = 0.53$ indicating that slightly over half of the observed variation in anterior compartment support may be explained by apical support (88). Further analysis in the same patients showed that vaginal length was the strongest secondary factor determining 30% of the variation after apical descent was taken into account. This finding that a longer vaginal wall was associated

with increasing cystocele size was unexpected, but seems consistent with clinical observations (89).

Hsu et al found that vaginal thickness is similar in women with and those without pelvic organ prolapse. However, in prolapse patients the vaginal perimeter and cross-sectional areas are 11% and 20% larger respectively (90).

Broekhuis et al studied the relationship between patient symptoms using questionnaires' domain scores and the perineal position on dynamic MR imaging of 69 women. They found that POP symptoms were associated with the degree of descent of the perineum but perineal descent was not related to anorectal and/or urinary incontinence symptoms (91).

In another study examining correlations of patients' symptoms with findings on clinical examination and dynamic MR imaging of the pelvic floor, only the domain score genital prolapse was significantly correlated in the positive direction with the degree of POP as assessed by POP-Q and dynamic MR imaging (r(s) = 0.64 and 0.27, respectively), whereas the domain score urinary incontinence was inversely correlated (r(s) = -0.32 and -0.35, respectively). The sensation or visualisation of a bulge in the vagina was the only symptom which correlated positively with the degree of POP, with clinical examination and dynamic MR imaging showing similar correlation in this respect (92).

Broekhuis et al concluded that correlations for the POP staging with the use of POP-Q, dynamic MR imaging, and perineal ultrasonography are only observed in the anterior compartment (93).

MRI for clinical evaluation of prolapse

2.3.5.1 Enterocele

In the past, enteroceles were usually only appreciated on radiographic examination after repeated straining after evacuation and usually required opacification of the vagina in order to demonstrate the insinuation of small bowel loops between the rectum and vagina (94). MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In comparisons between physical examination, intraoperative findings and MR images in women with and without prolapse. MRI was significantly superior in detecting enterocele when compared to physical examinations with a sensitivity of 87%, specificity of 80%, and positive predictive value of 91%(16). (**Figure 30**). Similarly, MRI had a much higher sensitivity for detection of enteroceles when compared to physical exam and dynamic cystoproctography (95). Whether or not this technique alters clinical outcome remains to be seen.

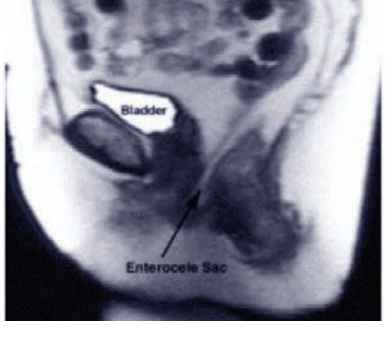
2.3.5.2 Cystocele

MRI has a sensitivity of 100%, specificity of 83%, and positive predictive value of 97% when evaluating for cystocele compared to intraoperative findings. In addition, urethral hypermobility and post-void urine residual can be documented, as well as evaluation of ureteric obstruction, hydroureteronephrosis and other pelvic abnormalities. **Figures 31**a, b

MRI can also be helpful in documenting the status of pelvic organ support as part of a program to assess operative efficacy (96)(97) and differentiating such problems as Müllerian remnant cysts from cystocele (98).

Larson et al showed that in women with anterior wall prolapse, Valsalva causes downward translation of the vagina along its length. A transition point separates a proximal region supported by levator muscles and a distal, unsupported region no longer in contact with the perineal body. In this latter region, sagittal and frontal plane "cupping" occurs. The distal vagina rotates inferiorly along an arc centered on the inferior pubis. Downward translation, cupping, and distal rotation are therefore novel characteristics of cystocele demonstrated by 3-D MR imaging (99). (figure 32,33)

In cystoceles, the distal anterior vaginal wall (AVW) may no longer be in contact with the posterior vaginal wall or perineal body as it bulges through the introitus. The exposed vaginal wall length has been quantified using dynamic MR imaging. The authors found a bilinear relationship between exposed vaginal wall length and most dependent bladder location as well as apical location. It is when the bladder descent is beyond the inflection point that exposed vaginal wall length increases significantly (100).



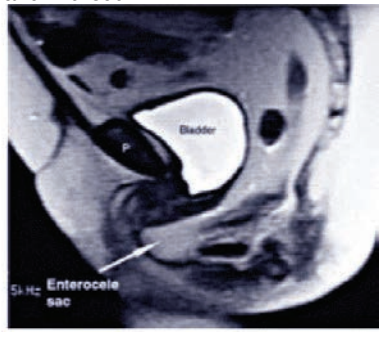


Figure 30:Pelvic floor MRI: Enterocele at rest a) and during Valsalva b).

Uterovaginal junction shown with dark pink square. c Addition of midsagittal pelvic bones (white) and anterior vaginal wall model. d Powerpoint image of both resting and straining anterior vaginal wall models and their relationship to the normalised ATFP, shown here as green line extending from the pubic symphysis to the ischial spines (green square), or the P-IS line. © DeLancey 2009 (89).

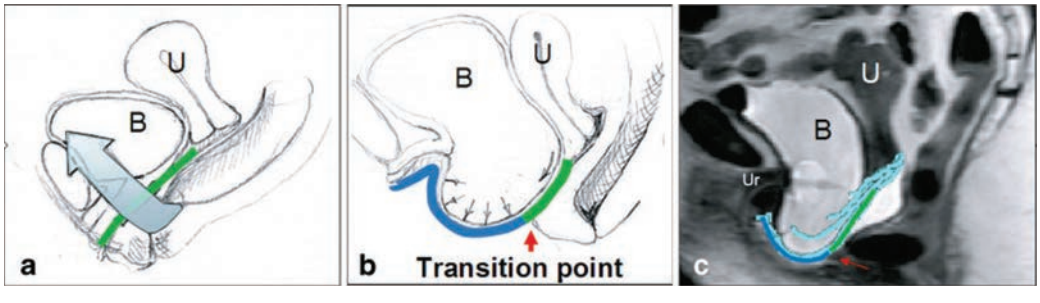

Figure 33: Midsagittal view of pelvis with normal support (a) and with prolapse (b). Green represents area where levators (blue arrow) provide cranial reaction forces to counteract the action of intraabdominal pressure and caudal movement of the anterior wall. The red arrow delineates the transition to unsupported region lacking this opposing set of reaction forces (blue line), thereby creating a pressure differential acting caudally on that region. c Red arrow illustrates this point on midsagittal MRI with modeled anterior vaginal wall. U uterus, B bladder, Ur urethra. © DeLancey 2009 (89).

2.3.5.3 Rectocele

The reported sensitivity of pelvic examination for diagnosis of rectocele ranges from 31% to 80% (3)(4)(6)(101)(102). This is usually secondary to organ competition for space in the vagina with other significant prolapse (7). In addition, it is often difficult to reliably distinguish an enterocele from a high rectocele. **Figure 34** shows a rectocele diagnosed by dynamic MRI. A rectocele is easily seen when filled with gas, fluid, or gel. Although highly specific, when no rectal or vaginal opacification is used, MRI can miss up to 24% or rectoceles (16). When rectal opacification is used, a correct diagnosis of rectocele can be made in 100% of patients studied when compared to intraoperative findings (19). Rectal opacification by introducing sonographic transmission gel or gadolinium into the rectum is therefore necessary to increase MRI's ability to diagnose rectocele.. In complex situations such as rectal intussusception (103) MR can provide important information by distinguishing mucosal from full-thickness descent. MR defecography also shows movements of the whole pelvic floor. In this study, 30% of the patients studied were found to have associated abnormal anterior and/or middle pelvic organ descent that would not necessarily be seen in

traditional evacuation proctography (unless opacification of vaginal, bladder and intestine are carried out).

At maximal Valsalva on MRI, structures are more caudal and the hiatus longer in women with posterior prolapse. The posterior vaginal wall is longer; this length and point Bp strongly correlate with MRI prolapse size (r=0.5; P=.002; r=0.7; P<.001, respectively) (104).

What remains unclear is the relationship between anatomical findings and functional problems. The diagnosis of an anatomical abnormality does not mandate surgery. Simply identifying a rectocele on an imaging study based on the location of the intestinal lumen to a reference line does not mean that correction of the rectocele will cure defecation problems. Rectocele surgery is not without complications and the risk of dyspareunia after posterior colporrhaphy is real. Attention should be paid to make sure that symptoms are truly depending on stool trapping and the condition must be shown on imaging.

2.3.5.4 Uterine Prolapse

Although uterine prolapse is easily diagnosed on physical examination MRI is an excellent modality to record the structural relationships with the bladder and rectum in patients with uterine prolapse (Figure 35). In addition to depicting the position of the uterus and adjacent organs, it has the ancillary benefits of evaluating uterine size, position, orientation (retroversion) and pathology (fibroids, tumors, Nabothian cysts. etc.), but also ovarian pathology (cyst or mass) which may sometimes prove useful if these problems have not been picked up on physical examination. This is helpful information in determining the route of hysterectomy. Furthermore, MR imaging provides information on the presence or absence of cystocele, rectocele, urethral hypermobility and urethral diverticula, and evaluates for ureteral obstruction(10)(11)(14)(15)(16)(105). Gousse et al. report a sensitivity of 83%, a specificity of 100% and a positive predictive value of 100% when comparing dynamic MR imaging to intraoperative findings. These numbers were similar when compared to physical examination alone(16). More importantly, MRI was able to clearly define the other compartments of the pelvic floor and diagnose uterine and/or ovarian disorders in 30 of 100 patients evaluated(16).

2.3.5.5 Grading of pelvic floor relaxation

A number of studies have described reference values for grading POP(15)(16)(18). In order to evaluate pelvic organ descent, certain anatomic landmarks are used. The pubococcygeal line (PCL) marks the distance from the pubis to the coccyx and serves as a fixed anatomical reference. In the nomenclature used by Comiter et al. (15), Gousse et al. (16), and Barbaric (23), the width of the levator hiatus is measured as the distance from the pubis to the pubococcygeus muscle (H-line). The hiatus is formed by the puborectalis muscle and encompasses urethra, vagina, and rectum. The M-line depicts the relaxation of the muscular pelvic floor by measuring the descent of the levator plate from the PCL. Using these three simple measurements, an MRI classification for degree of POP has been described (15)(23). In the normal population, during straining, the hiatus (H-line) is less than 6 cm long and does not descend (M-line) more than 2 cm below the PCL. The upper urethra, urethrovesical junction, bladder, upper vagina, uterus, small bowel, sigmoid colon, mesenteric fat and rectum are all above the H-line. A combination of hiatal enlargement and pelvic floor descent constitutes relaxation. As the pelvic floor descends, so do the organs above it. The grading system for prolapse of any pelvic organ is based on 2 cm increments below the H-line. By determining the degree of visceral prolapse beyond the H-line, the degree of rectocele, enterocele, cystocele, and uterine descent can be graded in a 0 to 3 scale as follows: 0=none, 1=minimal, 2=moderate, and 3=severe (**Table 1).** Other similar systems have been described (18)highlighting the need for standardization of nomenclature and grading of organ prolapse using MRI. In a small study, Ginath et al showed that MRI measurements of pelvic landmark angles can differentiate between women with and without uterine prolapse and correlate best with POPQ point C (106).

Novellas and colleagues evaluated two classification systems (using the PCL and the midpubic line, MPL) in 30 patients with symptoms of POP.

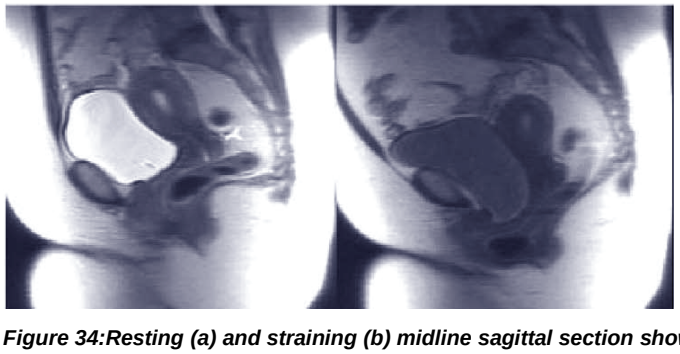

Figure 34:Resting (a) and straining (b) midline sagittal section showing a rectocele that traps intestinal contents.

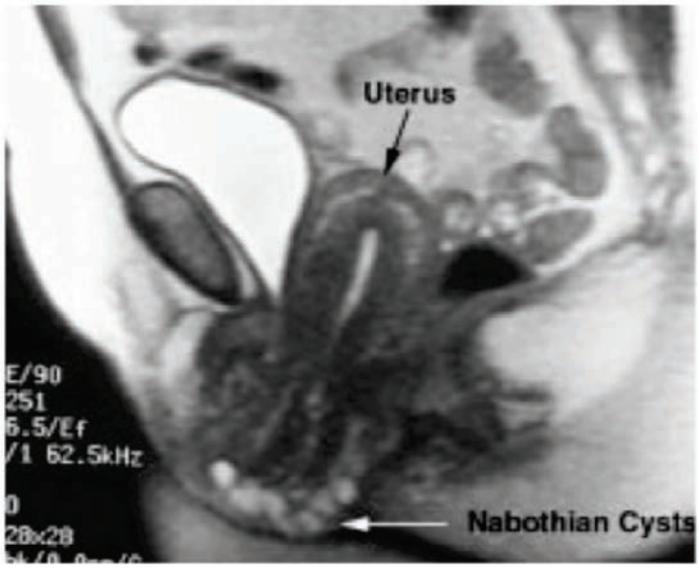

Figure 35:Pelvic Floor MRI:Uterine Prolapse

For prolapse detection, the correlation between clinical examination and MRI ranged between 74 and 89%. For prolapse staging, the correlation was poor to moderate. Inter-observer agreement was good to very good (kappa between 0.67 and 0.95). It was slightly better at the mid stage, with both systems (kappa between 0.83 and 0.97). Comparison of the inter-observer agreement between both MRI classification systems showed better results for the system using the pubococcygeal line ($p<0.005$). The classification system based on the pubococcygeal line appeared more reliable and simple for the evaluation of pelvic prolapse on MRI (107).In another study, agreement between clinical and PCL staging was fair in the anterior (kappa = 0.29) and poor in the apical (kappa = 0.03) and posterior (kappa = 0.08) compartments. Agreement between clinical and MPL staging was fair in the anterior (kappa = 0.37), apical (kappa = 0.31), and posterior (kappa = 0.25) compartments. The MPL had higher agreement with clinical staging than the PCL in this study. However, neither reference line had good agreement with clinical staging (108).The intra- and interobserver reliability of dynamic MR staging in POP patients has also been evaluated using various anatomical landmarks in relation to the PCL, H-line, and MPL. Clinical measurement points were assessed in relation to the mid-pubic line. Overall, the intra- and interobserver reliability of MR imaging measurements was excellent to good. The PCL showed superior reliability (intraclass correlation coefficients-ICC range 0.70-0.99). The reliability of clinical measurement points, however, were only moderate (ICC range 0.20-0.96). The intra- and interobserver reliability of quantitative prolapse staging on dynamic MR imaging were good to excellent. The PCL appeared the most reliable to use (109).

Singh et al (110)compared a new technique of grading POP by using dynamic MRI with the clinical staging proposed by the POP-Q system (111). A new reference line, the mid-pubic line, was drawn on the MR image to correspond to the hymenal ring marker used in the clinical staging. The proposed staging by MRI showed good correlation with the clinical staging (kappa = 0.61). Torricelli (112) also used MRI to evaluate functional disorders of female pelvic floor. In symptomatic women MRI confirmed the pelvic examination findings in all cases; MRI also detected additional alterations (4 cases of uterine prolapse and 3 of enterocele) that had been missed at clinical evaluation. Deval (113) compared dynamic MR imaging with physical examination as an alternative to dynamic cystoproctography for the evaluation of POP. PCL and puborectalis muscle were the reference points. The grading system is based on degree of organ prolapse through the hiatus and the degree of puborectalis descent and hiatal enlargement. They also used, the mid pubic line, which was drawn on the MR image to correspond to the hymenal ring marker used in clinical staging. Intra-operative findings were considered the gold standard against which physical examination, dynamic colpocystodefecography and MRI were compared. The sensitivity, specificity and positive predictive value of MRI were 70%, 100%, 100% for cystocele; 42%, 81%, 60% for vaginal vault or uterine prolapse; 100%, 83%, 75% for enterocele; 87%, 72% and 66% for rectocele. More recently Etlik (114)found physical examination and MR findings to be very concordant in the diagnosis of pelvic prolapse. Statistical correlations in the stages of prolapse between both of the methods were significant for anterior and middle compartment ($P<0.01$), as well as for posterior compartment ($P<0.05$).

Rosenkrantzet al evaluated the prevalence of pelvic organ prolapse as an incidental finding on dynamic magnetic resonance imaging (MRI) using the pubococcygeal line (PCL) and mid-pubic line (MPL) to diagnose and grade prolapse in all three pelvic compartments. Sixty women with symptoms unrelated to pelvic floor dysfunction who underwent dynamic MRI were included. In asymptomatic women, dynamic MRI identified the greatest degrees of prolapse in the posterior compartment. The MPL consistently yielded greater frequency of prolapse than the PCL. These findings however are of uncertain significance, requiring correlation with clinical examination (115).

Semiautomated pelvic floor measurement algorithmic models on dynamic MRI images have been developed and compared with manual pelvic floor measurements for pelvic organ prolapse (POP) evaluation. These models were shown to provide highly consistent and accurate locations for all reference points on MRI. The reference points can also be identified faster compared to manual-point identification. (116). A fully automated localization method for multiple pelvic bone structures on magnetic resonance images (MRI) has been developed by the same group. Identifying structures of interest such as the pubic bone, sacral promontory, and coccyx correctly, by a fully automated identification method may result in improved diagnosis of female pelvic organ prolapse according to the authors (117).

2.3.6 Assessing Treatment Outcome

2.3.6.1 Pelvic Organ Prolapse Operations

Several studies have evaluated the anatomic changes seen after surgical procedures using MRI to better understand how surgical therapies affect pelvic support and structures. Lienemann et al. (118) evaluated women after abdominal sacrocolpopexy and found that functional MRI identified the exact sacral fixation points after the procedure and easily identified the axis of the vagina and the exact position of the synthetic material used for the repairs. Sze (119) used MRI to study vaginal configuration on MR after abdominal sacrocolpopexy and sacrospinous ligament suspension. This study demonstrated the differences in the geometry of these two operations and should prove helpful in establishing outcome variables for different surgical procedures. Similarly Rane (120)used MRI to compare the vaginal configuration following transvaginal sacrospinous fixation (SSF), posterior intravaginal slingplasty (PIVS) (infracoccygeal sacropexy) and sacrocolpopexy (SCP) and demonstrated improvements in the restoration of vaginal configuration and differences between the procedures in final anatomy. Boukerrou (121) compared outcomes of 1) abdominal sacral cervicopexy, 2) vaginal hysterectomy with paravaginal repair, sacrospinous suspension and posterior colporrhaphy and 3) sacrospinous suspension and posterior repair without paravaginal suspension with MRI. The correction provided by vaginal route was found to result in a return of the bladder and the vaginal apex to their normal positions. In addition, vaginal shortening and postoperative change in vaginal orientation were not present postoperatively.

Nicolau-Toulouse et al (122) evaluated the anatomic outcomes of bilateral sacrospinous vault fixation (BSSVF) with synthetic, polypropylene mesh arms using MRI in a small case series of women with symptomatic pelvic organ prolapse (POP) with and without uterus. They confirmed that BSSVF with synthetic mesh restores the anatomy between the vagina and the ischial spines.

Relationships between assessment of surgical correction studied with MR imaging and symptoms have been studied. Gufler (123) compared preoperative evaluations with those two to four months after surgery. Of the seven patients who had symptoms postoperatively, only two had abnormal findings on physical examination but MRI showed pathologic findings in five of the seven patients. Huebner et al assessed symptomatic changes after anterior levatorplasty with morphologic changes visualized by MR defecography (124). Anterior levatorplasty improved quality of life in patients with symptomatic rectocele and correction of rectocele is accurately documented by MRdefecography, however only moderate correlation between morphologic and clinical improvements was observed.

MRI has also been used for the evaluation of the effectiveness of POP surgical mesh procedures.

Dynamic MRI may evaluate the support of anterior and posterior pelvic floor structures by anterior and posterior polypropylene implant respectively. But dynamic MRI evaluations in a small series by Siegmann and colleagues suggest that if one compartment of the pelvic floor is repaired another compartment frequently (73.3%) develops dysfunction. These results did not correspond to clinical symptoms on short-term follow-up (3 months) indicating the need for long-term follow-up studies to prove if dynamic MRI can reliably identify significant POP after surgery and before the onset of symptoms (125). In another small series of ten women by Kasturi et al (126) undergoing intervention for POP with Prolift, postoperative MRIs supported the inert nature of polypropylene mesh.

Larson et al examined structural relationships between anterior mesh kit suspension points and the upper vagina in women with normal support. Using MRI generated 3D models, they found that the anterior vagina extended above superior attachment points in 100% of women at rest and in 73% during Valsalva. It extended posterior to them in 82% and 100% (rest and Valsalva, respectively). The mean percentage of anterior vaginal length above superior anchoring sites was 40 +/- 14% at rest and 29 +/- 12%

during Valsalva. The upper vagina was therefore found to lie above and posterior to superior suspension points in the majority of women with normal support (127).

In an observational study, the 1-year outcomes after mesh repair in patients with POP were evaluated using clinical examination (CE), dynamic magnetic resonance imaging (dMRI), and the prolapse quality-of-life (P-QOL) questionnaire. Sixty-nine women were treated with Seratom(R) or Perigee mesh implants. Advanced cystoceles and enteroceles were underestimated by CE using the POP-Q system compared to dMRI ($P = 0.003$ and $P < 0.001$), vice versa dMRI overestimated POP compared to CE. (128).

2.3.6.2 Pelvic Muscle Exercises

Studies on the effects of pelvic muscle training on the pelvic floor (129) demonstrate reduced levator ani surface area and volume encircled by the levator ani muscle during contraction. When elite athletes are compared to normal women significant differences appear in the cross-sectional area and width of the pelvic floor muscles, (130). These types of studies are being facilitated by improved techniques of aligning contracted and non-contracted muscle (131).

2.3.6.3 Comparison of MRI with other Examinations and Assessment of Reliability

Dynamic contrast roentography and multiphasic fluoroscopic cystocolpoproctography (CCP) have previously been considered the best radiological studies for detecting POP. These studies rely on the opacification with contrast material of the bladder, vagina, small bowel, and rectum with all organs opacified together or in phases with each organ opacified individually prior to each straining phase(4)(120)(124)(129). These studies fail to detect up to 20 percent of all enteroceles (105)(132)(133)(134). Therefore, MRI has proven to be a much simpler and less invasive technique for the evaluation of enteroceles. In addition, MRI is able to differentiate the enteroceles according to their contents (small bowel, large bowel, rectosigmoidocele or mesenteric fat). MRI is also an excellent study to differentiate high rectoceles from enteroceles, thus allowing adequate surgical planning and safer planes of dissection (15)(16)(19)(95). Although multiphasic MRI with opacification of organs and multiphasic fluoroscopic cystocolpoproctography have similar detection rates for enterocele (132), excellent images can be obtained from dynamic MRI without contrast for opacification of the small bowel or rectal contrast. Thus the minimal added information obtained by contrast administration does not seem to warrant the invasiveness of organ opacification at this time (16)(94)(133). However, MRI without rectal contrast shows statistically fewer pelvic floor abnormalities than CCP. Except for enteroceles, MRI with rectal contrast shows statistically similar frequency of POP as CCP (135).

Evacuation proctography has been used to diagnose enterocele, rectoceles, perineal descent and rectal intussusception. Dynamic contrast roentography or fluoroscopic cystocolpoproctography have also been used (4)(101)(102)(132)(136) to diagnose rectoceles. The disadvantages of these techniques are the inability to visualise the soft tissue planes comprising the pelvic floor, their invasiveness, and their use of significant levels of ionizing radiation. Without the use of rectal opacification, MRI appears to be a poor choice for the evaluation of rectoceles missing up to 25% of such defects. With rectal opacification a correct diagnosis of rectocele can be made in 100% of patients in comparison to intraoperative findings (19). Triphasic dynamic MRI and triphasic fluoroscopic cystocolpoproctography have similar detection rates for rectocele (132). Upright dynamic MR defecating proctography has been reported (137). Although these studies might prove to be more sensitive in detecting anorectal anomalies, their utility seems to be more pronounced in patients with disorders of defecation include anismus, intussusception, and others, and may be too invasive to justify their routine use in the evaluation of rectocele.

Kaufman (138) evaluated dynamic pelvic MRI and dynamic cystocolpoproctography in the surgical management of females with complex pelvic floor disorders. Physical examination, dynamic MRI, and dynamic cystocolpoproctography were concordant for rectocele, enterocele, cystocele, and perineal descent in only 41% of patients. Dynamic imaging lead to changes in the initial operative plan for 41% of patients. Dynamic MR was the only modality that identified levator ani hernias. Dynamic cystocolpoproctography identified sigmoidoceles and internal rectal prolapse more often than physical examination or dynamic MR. Whether this type of imaging creates measurably better outcomes remains to be seen. Singh et al (110) showed a reasonably good correlation between clinical staging and MRI staging (Kappa = 0.61) with the mid pubic line being used as a surrogate for the hymenal ring. In addition, specific features such as the levator-vaginal angle the area of the genital hiatus could be assessed quantitatively on MRI.

Torricelli (112) studied ten healthy volunteers and 30 patients with suspected pelvic floor deficiency with and without POP. They found good concordance between physical examination and MRI with four cases of uterine prolapse and three cases of enterocele seen on MRI that had not been suspected on pelvic examination. Whether these would have been detected at the time of surgery was not discussed. Deval (113) compared intraoperative findings as a gold standard for MRI based diagnosis. The sensitivity, specificity, and positive predictive value of MRI were 70%, 100%, 100% for cystoceles; 42%, 81%, 60% for vaginal vault or uterine prolapse;

100%, 83%, 75% for enteroceles; 87%, 72%, 66% for rectocele. Although all of these measurements are somewhat subjective, these figures show that it is possible to quantify the individual elements of pelvic floor dysfunction in reasonable parameters.

In a recent study, the value of dynamic pelvic floor MRI was assessed in comparison to standard clinical examination in treatment decisions made by an interdisciplinary team of specialists including a urologist, gynecologist, a proctological, and colorectal surgeon. The authors concluded that MRI has the advantage of allowing diagnosis of clinically occult enteroceles. In addition, in nearly half of cases, MRI changed management or the surgical approach relative to the clinical evaluation. (139).

2.3.7 Conclusions

Proof that MR imaging has value will eventually need to come from increased operative success rates. Better documentation of preoperative and postoperative anatomy could allow us to seek reasons of operative failure. Because MR provides a detailed picture of a woman's pre-operative anatomy, once operative failures are discovered, it would be possible to look back at images from women with successful and unsuccessful operations to seek anatomical explanations for failure.

Advancements in MRI technology with the addition of 3D imaging as well as studies correlating imaging findings with clinical examination and symptom scores may establish further the clinical applications of these modalities.

2.3.8 Consensus Statement

MRI is not yet indicated in the routine evaluation of patients with (uncomplicated primary) pelvic organ prolapse. However data concerning the causes of prolapse are rapidly accumulating and this may change soon. It can provide useful information concerning complex prolapses and can be used in difficult cases.**(Level of evidence 3, Grade of Recommendation C)**

2.3.9 Future Research Areas

Studies that identify specific defects in the connective tissue and the muscles of the pelvic floor that correlate these findings with the clinical presentation in prolapse are needed.

Additional studies comparing MRI of healthy volunteers and patients with pelvic organ prolapse are needed to better evaluate the anatomical changes involved in pelvic floor prolapse.

Quality control in MRI, including: what manoeuvers are required to produce a maximal prolapse during MRI, bowel condition, bladder filling, pushing instructions, etc.)

3. SPECIAL ISSUES

3.1. Post-Void Residual

Post-void residual urine (PVR) is defined as "the volume of urine left in the bladder at the end of micturition(1). Evaluation of PVR prevalence in women with symptomatic pelvic floor dysfunction suggests that 81% have a post-void residual of 30 ml or less (2). This is not significantly different from asymptomatic perimenopausal and postmenopausal women in whom 15% of subjects had a PVR greater than 50 ml (3). If symptoms cannot predict elevated PVR, a urogenital prolapse beyond the hymen seems to be associated with incomplete bladder emptying (4). Among patients older than 55 years with symptoms of overactive bladder,previous incontinence surgery, history of multiple sclerosis and vaginal prolapse stage 2 or greater, were found to be independent predictors of elevated PVR (5). Similar data were obtained by Fitzgerald in patients with urgency incontinence, the presence of pelvic organ prolapse ≥stage 2, symptoms of voiding difficulty and absence of stress incontinence symptoms predicted 82% of patients with elevated PVR (6). Higher prevalence of post-void residual was found in patients with stress urinary incontinence with 35.5% of women having a PVR >50 ml suggesting they have some degree of voiding dysfunction (7). Although elevated PVR and bacteriuria are common among elderly residents in nursing homes, no association between the two was observed in a Swedish study (8). Analysis of elderly patients with urinary incontinence failed to identify any significant association between PVR and any other clinical or urodynamic parameter (9). Sanders and co-workers addressed the issue of the real need for measuring flow rates and post-void residual urine in women with urinary incontinence. Analysis of 408 women suggested a 4% incidence of PVR 200 ml or greater and a 6% rate of PVR 149 ml or greater. The authors calculated that only 1.5% of patients (6 of 408) had their management modified because of the results of free uroflowmetry and PVR measurement. In their opinion, these data do not justify the inclusion of these tests in the "minimal care" programme for assessing primary, uncomplicated, urinary incontinence in female patients (10).

PVR is often considered a safety parameter, which needs to be monitored in the follow-up of medical or surgical management of urinary incontinence. A number of studies have addressed the effect of antimuscarinic treatment in men with symptoms of overactive bladder to rule out the old dogma that banned the use of these drugs in elderly men. Actually, all published data suggest that antimuscarinic treatment is safe for men with benign prostatic enlargement and no significant change in PVR values was found in active treatment groups compared to placebo (11, 12). In male patients with bladder outlet obstruction, antimuscarinic treatment may result in a significantly larger PVR

(25 vs. 0 ml) that seems to be of no clinical relevance and with higher incidence of adverse events (13).

Measuring PVR is of importance in patients receiving intravesical injections of Botulinum toxin A for UUI. Significant increase of post void residual urine is observed following injection of onabolutinumtoxinA in patients with neurogenic urinary incontinence due to detrusor overactivity with 30 to 42% of patients needing to start clean intermittent catheterisation compared to 12 % in the placebo group (14). In patients with idiopathic UUI, increase of PVR was observed in those receiving onabolutinumtoxinA compared to placebo although only 8 of 70 patients required CIC and only 3 patients had a PVR >200 ml at day 8 and only one at 6 months (15).

Although the prevalence of incomplete bladder emptying among male and female patients with urinary incontinence and pelvic floor dysfunction is low, there is a general consensus that PVR should be measured in incontinent patients (16) although the evidence suggests that only patients with UI and symptoms of voiding dysfunction are at risk (17).

3.1.1 Measuring PVR

The measurement of PVR can be performed by invasive and noninvasive means. Invasive methods include: in-and-out catheterisation and endoscopy. Noninvasive means are transabdominal ultrasonography with real-time ultrasound or fully automated systems, and radioisotope studies. In-and-out catheterisation has been considered for some time, the goldstandard for the measurement of PVR. Nevertheless the method is subject to inaccuracies, if the person performing the catheterisation is not fully instructed as to the procedures and techniques to assure complete emptying (moving the catheter in and out slowly, twisting it, suctioning with syringe, suprapubic pressure), especially in cases of bladder diverticula and vesicoureteric reflux (18). The interval between voiding and PVR measurement should be as short as possible. It is advisable to ask the patients if the voiding was similar to a typical micturition in his/her daily life. Stoller and Millard showed inaccuracies in 26% of 515 male patients evaluated by full-time urology nurses with a mean difference between the initial and the actual residual volume of 76 ml in those measurements that were found to be inaccurate (19). After further education of the nurses, inaccurate assessments were reduced to 14% with a mean difference of 85 ml. PVR can be measured at the time of endoscopy, provided there is a blinded insertion of the instrument to avoid irrigation fluid inflow. Both invasive means are usually performed with local anaesthesia and carry a small risk of urethral damage and urinary infection. Before the era of ultrasonography, PVR was measured non-invasively by the phenolsulfonphthaleine excretion test or with isotopes (20, 21).

In 1967, Holmes described the use of ultrasonography in the evaluation of bladder volume and this technique rapidly gained widespread acceptance as a satisfactory level of accuracy was demonstrated (22, 23). Using either three diameters (length, height, width) or the surface area in the transverse image and the length obtained in the longitudinal image, various volume formulae for a spherical or ellipsoid body are utilised to estimate the bladder volume **(**Table 3). Twenty-one different formulae have been proposed over the years making assumptions about bladder shape which have often been questioned (24)r volumes obtained using different formulae did not result in any significant difference amongst the various calculations 25)report sufficient accuracy with ultrasound estimation of PVR 23, 24, 26-29)30)by portable ultrasound with measurements by catheterisation, the mean absolute error of the scanner was 52 ml 31)s suggest a good level of accuracy in both female and paediatric populations 32, 33)ly referred to as an absolute value, but it can be measured as a percentage of bladder capacity.ly referred to as an absolute value, but it can be measured as a percentage of bladder capacity.

The intra-individual variability of PVR is high from day to day and even within a 24 hours period. This was reported in men with BPH by Birch et al. and by Bruskevitz et al. (34, 35). Griffiths et al. examined the variability of PVR among 14 geriatric patients (mean age 77 years), measured by ultrasound at three different times of day on each of two visits separated by 2-4 weeks (36). Within-patient variability was large (SD 128 ml) because of a large systematic variation with time of day, with greatest volumes in the early morning. The inherent random variability of the measurement was much smaller (SD 44 ml). Several factors can influence PVR variability: voiding in unfamiliar surroundings, voiding on command with a partially filled or overfilled bladder, the interval between voiding and the estimation of residual (it should be as short as possible), the presence of vesicoureteric reflux or bladder diverticula. Several studies reported the questionable value of PVR as an important outcome prognosticator in male patients with benign prostatic enlargement and benign prostatic obstruction (37-42). The cause of PVR is probably mutifactorial, and no consensus exists on the relation of PVR, bladder outlet obstruction and detrusor contractility.

Table 3. Comparison of different formulae to assess PVR by transabdominal ultrasound in 30 men with BPH scanned three times(35).

3.1.2 Conclusions

Knowledge regarding pathophysiology of PVR remains unclear. In patients with urinary incontinence there is no consensus as to its value as a safety parameter and particularly its relationship with upper tract dilatation, bacteriuria and urinary infection. The intra-individual variability of PVR has been investigated mainly in male patients with bladder outlet obstruction but little information is available as to its variability in patients with urinary incontinence.

Ultrasound is the recommended method for assessing PVR because it is the least invasive and it is sufficiently accurate for clinical purposes yet it is the most expensive. In-and-out catheterisation is invasive and can be inaccurate even if carefully performed.

The general opinion is that PVR measurement forms an integral part of the study of urinary incontinence, as a safety parameter to exclude voiding dysfunction associated with incontinence. Measurement of PVR is recommended in guidelines and recommendations on the management of LUTS and urinary incontinence, but the level of evidence for this measurement is not high. This manuscript summarises the evidence and provides practice recommendations for teaching purposes in the framework of an ICS teaching module (48).

3.1.3 Consensus Statements

1. Residual urine measurement is recommended in the initial assessment of urinary incontinence as a safety parameter and in the evaluation of treatment outcome (**Level of evidence 3- Grade of recommendation C**)
2. Measurements should be performed using realtime sonography or a portable scanner or in and-out catheterisation (**Level of evidence 3- Grade of recommendation C**).
3. Due to intra-individual variability, in cases where significant PVR is detected by the first measurement, several measurements should be performed (**Level of evidence 3- Grade of recommendation C**)
4. The method of measurement should be recorded

3.1.4 Future Research Areas

1. Pathophysiology of PVR in male and female populations with UI;
2. Circadian variation of residual urine in patients with UI;
3. Determination of the cut off value of significant residual urine in different patient populations with UI
4. Residual urine as a prognostic indicator of outcome in the treatment of incontinence

3.2. Open Bladder Neck and Proximal Urethra at Rest

The significance of open bladder neck and proximal urethra at rest observated during a voiding cystourethrogram or pelvic floor ultrasound scan remains doubtful (1) and the peer-reviewed literature is equally divided into papersassociating such a condition with storage disorders and those suggesting this is a chance finding with no negative implications.

A 21% prevalence in nulliparous asymptomatic women has been reported (2). In the non-neurogenic population there is no pathophysiological correlation between this and urinary incontinence, Digesu and co-workers reported a prevalence of 1:3 amongst females suffering LUTS. An open bladder neck at rest is not pathognomonic of sphincter incompetence although it is associated with USI (3). In patients with stress incontinence, but also in asymptomatic women (4), funnelling of the internal urethral meatus may be observed on Valsalva (Fig. 5) and sometimes even at rest; funneling is often associated with leakage. However, funnelling may also be observed in urgency incontinence and cannot be used to prove USI. Marked funnelling has been shown to be associated with poor urethral closure pressures (5, 6). Furthermore Shobeiri et al investigated the association between the levator ani muscle atrophy (levator ani deficiency) and the urethral sphincter muscle measurements using 3D endovaginal ultrasonography in female patients found no significant association. The authors concluded that although the rhabdomyosphincter deteriorated along with thelevator ani muscle, this was not statistically significant. Themost valuable finding was that the smooth muscle was significantly smaller in patients with levator ani deficiency, and that patients with levator ani deficiency weremore likely to have urodynamic stress urinary incontinence.

Reports in the peer reviewed literature suggest that an open bladder neck and proximal urethra at rest, during the storage phase, may be observed during cystography, videourodynamics or bladder ultrasound, both in patients with and without neurological disease and is interpreted as a sign of internal sphincter denervation as occurs in 53% of patients with Multiple System Atrophy (7). Distal spinal cord injury has been associated with an open smooth sphincter area, but whether this is due to sympathetic or parasympathetic decentralisation or defunctionalisation remains

uncertain (8). Relative incompetence of the smooth sphincter area may also result from interruption of the peripheral reflex arc very similar to the dysfunction observed in the distal spinal cord injury. Twenty-one out of 54 patients with spinal stenosis were found to have an open bladder neck at rest (9). In a review of 550 patients (10), 29 out of 33 patients with an open bladder neck had neurological disease. Although the association was more commonly seen in patients with thoracic, lumbar and sacral lesions, the difference when compared to cervical and supraspinal lesions was not significant. Damage to the sympathetic innervation to the bladder was also frequently observed in patients undergoing major pelvic surgery, such as, abdominal perineal resection of the rectum. Patients with myelodysplasia had an inordinately high incidence of open bladder neck (10 out of 18 patients versus 19 out of 290 having different neurological disorders).

Patients with sacral agenesis are included in the larger category of myelodysplastic patients and suffer from an open bladder neck with an underactive bladder. Shy-Drager syndrome is a Parkinson-like disorder with peripheral autonomic dysfunction. Neurogenic detrusor overactivity is usually found in association with an open bladder neck at rest and a denervated external sphincter (11). Peripheral sympathetic injury results in an open bladder neck and proximal urethra from a compromised alpha-adrenergic innervation to the smooth muscle fibres of the bladder neck and proximal urethra (12). Although it can occur as an isolated injury it is usually associated with partial detrusor denervation and preservation of sphincter EMG activity. The loss of bladder neck closure suggests an autonomic neural deficit. The site and nature of the requisite deficit is unclear.

Most authors agree on the importance of the sympathetic system in maintaining the integrity of the bladder neck (13-16) although the possible role of parasympathetic innervation has been proposed by others (17, 18). An open bladder neck at rest in children or in women without neurological disease can represent a different disorder, either related to a congenital anomaly or secondary to an anatomical pelvic floor defect. Stanton and Williams (19) described an abnormality in girls with both diurnal incontinence and bed-wetting, based primarily on voidingcystourethrography, in which the bladder neck was wide open at rest. Murray et al (20) reported the “wide bladder neck anomaly” in 24.5% of the girls (35) and 9.3% of the boys (10) out of 251 children (143 girls and 108 boys) undergoing videourodynamics for the assessment of non-neurogenic bladder dysfunction (mainly diurnal incontinence). The authors considered the anomaly congenital and made the hypothesis that wide bladder neck anomaly in girls may provide a basis for the development of USI in later life.

The presence of an open bladder neck has been proposed to explain the pathophysiology of urinary incontinence but such hypothesis did not stand the test of time. An open bladder neck was a key point in defining type III stress incontinence according to the classification of Blaivas and Olsson (21). This classification, no longer used in our daily practice, was based on history, imaging, and urodynamics, and distinguished five diagnostic categories of stress incontinence. Incontinence type III was diagnosed by the presence of an open bladder neck and proximal urethra at rest in the absence of any detrusor contraction suggesting an intrinsic sphincter deficiency.

In pelvic fracture with membranous urethral distraction defects, when cystography (and/or cystoscopy) reveals an open bladder neck before urethroplasty, the probability of postoperative urinary incontinence may be significant, although the necessity of a simultaneous (or sequential) bladder neck reconstruction is controversial (22-24). Skala and co-workers suggest that an open bladder neck at rest is associated with an increased risk of postoperative complications and failure after open colposuspension (25).

3.2.1 Conclusions

In conclusion, the diagnosis of open bladder neck at rest does not seem to be helpful to diagnose the underlying cause of urinary incontinence.

3.2.2 Consensus Statements

When observing an open bladder neck and proximal urethra at rest in male patients, during the storage phase, whatever imaging technique is used, it may be worthwhile to evaluate the possibility of an underlying autonomic neural deficit. **(Level of Evidence 3, Grade of Recommendation C)**

3.2.3 Future Research Areas

1. The relation of open bladder neck and proximal urethra at rest to the different neurogenic disorder
2. Longitudinal study of wide bladder neck and proximal urethra at rest in asymptomatic women
3. Evaluate the prognostic value of the open bladder neck and proximal urethra at rest

3.3. Female Urethral Diverticula

The prevalence of urethral diverticula ranges between 1 and 6% with rates up to 10% in among symptomatic women from tertiary referral centres (1, 2). The suspicion of a urethral diverticulum stems from LUTS or urethral masses on physical examination. Urethral masses include leiomyoma, vaginal cysts, malignancy, ectopic ureter, granuloma and urethral diverticula. The first case of female urethral diverticulum was reported in 1805 (3) . Since the report from Davis and Cian in 1956 (4) using positive-pressure urethrography (PPU), the diagnosis has become much more common even though, despite increased clinical awareness, this pathology continues to be frequently overlooked. Urinary incontinence is often associated with a urethral diverticulum. Incontinence may be a sequel to urine loss from the diverticulum

itself with stress manoeuvres, USI or UUI (5). Aldrige et al. (6) reported urethral diverticula in 1.4% of patients with SUI.

The presenting symptoms of a urethral diverticulum have classically been described as the three Ds (Dysuria, postvoid Dribbling, and Dyspareunia). Since most patients present with nonspecific lower urinary tract symptoms, and the pathognomonic presentation (postvoid dribbling, urethral pain, tender periurethral mass and expression of pus from the urethra) is very uncommon, these patients undergo extensive evaluation and treatment before a correct diagnosis is established (7, 8). The diagnosis of a urethral diverticulum may be achieved by physical examination, voiding cystourethrography, positive-pressure (double-balloon) urethrography, urethroscopy, endocavitary (transurethral or transvaginal) or pelvic floor ultrasonography, urethral pressure profile or MRI. Positive pressure urethrography is usually accomplished using a double balloon catheter according to the method described by Davis and Cian (4). Two different models exist: the Davis-TeLinde and the Tratner catheter. Positive-pressure urethrography (and voiding urethrography) may result in a false negative study when the inflammation of the diverticulum neck prevents contrast medium from flowing into the diverticulum cavity.

The accuracy of a diagnostic test may depend upon the characteristics of the study population and conflicting data are often reported in the peer-review literature. Blaivas et al reported a diagnostic accuracy of VCUG of 97% in a series of 66 patients and similar results (95%) were obtained by Ganabathi et al. (7, 9). Less favourable results have been reported by others. Comparison of VCUG versus PPU in the diagnosis of urethral diverticula showed a clear superiority of the latter with good consistency among different studies (10, 11). In some patients, VCUG only delineated the lower part of the diverticulum (12). Ultrasound scanning and MRI should theoretically be free of such false negative imaging. Particularly, the emergence of high definition 3D endovaginal probes enables the operator to place the probe directly adjacent to the area of interest.

Chancellor et al. (13) described the use of intraoperative intraluminal echographic evaluation which may be of help in dissecting the diverticulum and achieving complete excision without damaging the bladder neck and urethra. A number of studies have shown that MRI is better than both voiding cystourethrography and positive-pressure urethrography and can be considered, if available, the imaging of choice when the diagnosis of urethral diverticulum is suspected (14-19) (Figure 36). MRI is superior to VCUG or double-balloon urethrography, particularly in diagnosing diverticula with narrow, noncommunicating necks (15, 16). MRI proved to be superior to radiological studies because diverticula can go undiagnosed on voiding cystourethrogram, furthermore size and complexity of the diverticulum is better defined on MRI (17). Endoluminal MRI is considered to be of particular importance in the diagnosis of a circumferential urethral diverticulum, a condition that is relatively rare but the diagnosis may increase with the increased use of this imaging technique.

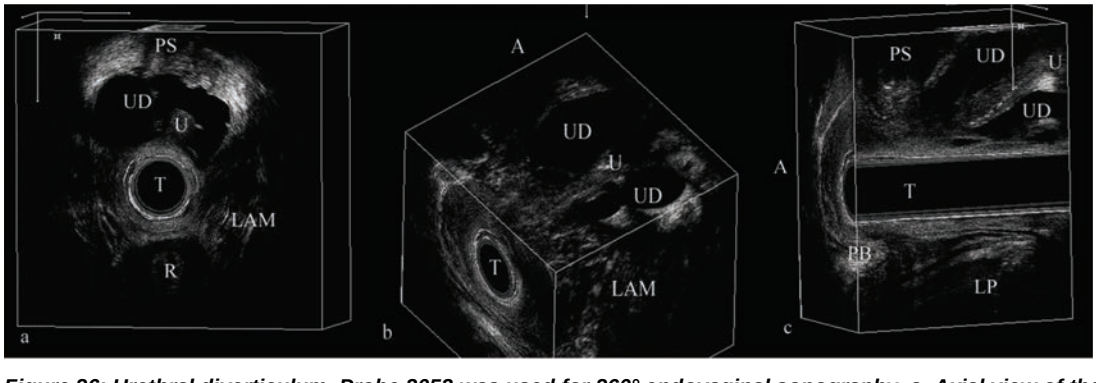

Figure 36: Urethral diverticulum. Probe 2052 was used for 360° endovaginal sonography. a, Axial view of the urethral diverticulum. The urethra is surrounded by the diverticulum. Anatomic landmarks are the pubic symphysis and pubic ramus superiorly, urethra medially, and vagina inferiorly. b, Coronal view showing the diverticulum along both sides of the middle and proximal parts of the urethra. Cephalad extension of the diverticulum can be evaluated in this view. c, Midsagittal view confirming the diagnosis, with an anechoic cavity adjacent to the urethra that starts in the middle third of the urethra and extends near to the bladder. A indicates anterior; LAM, levator ani muscle; LP, levator plate; PB, perineal body; PS, pubic symphysis; R, rectum; T, transducer; U, urethra; and UD, urethral diverticulum.

Proper evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery (1, 20). MRI also proved to be useful in diagnosing inflammation or tumour in the diverticulum (21, 22). Endoluminal MRI with either a vaginal or rectal coil, may provide even better image quality than simple MRI (18).

A comparison of MRI versus urethrography and urethroscopy, in a group of 20 women with urethral diverticulum, reported a 69 and 77 per cent accuracy of the two latter imaging studies versus MRI (14). When surgical findings were compared to MRI, urethrography and urethroscopy, the diagnostic ability of the three methods was 70, 55 and 55 per cent, respectively. Diverticula ostia could not be identified by MRI not withstanding the use of contrast material. Neitlich et al. (15) reported in a series of 19 patients that MRI (using a fast spin echo T2-weighted pulse sequence and a dedicated pelvic multicoil) had a higher sensitivity for detecting urethral diverticula and a higher negative predictive rate in comparison to double balloon urethrography. Blander et al.(17), compared MRI and VGUG in 27 patients with urethral diverticula and found that endoluminal (endorectal or endovaginal) MRI was extremely accurate in determining the size and extent of urethral diverticula compared to VCUG; the related information can be critical when planning surgical approach, dissection and reconstruction. In conclusion, review of the peer reviewed literature suggests that positive pressure urethrography is still a valuable tool to diagnose female urethra diverticula not withstanding both ultrasound sonography and particularly MRI represent better alternatives with a significantly higher diagnostic accuracy.

In males, both VCUG and ultrasonography can be successfully used to diagnose syringocele (cystic dilatation of the Cowper's gland), congenital and acquired diverticula (23).

3.3.1 Conclusions

Proper imaging of female diverticula is essential to diagnose the condition and, in planning and conducting proper surgical repair. Ultrasonography may suffice to identify size and location of the diverticulum although MRI imaging in preferable whenever available.

3.3.2 Consensus Statements

In cases of female urinary incontinence if a urethral diverticulum is suspected, appropriate imaging (positive pressure urethrography, voiding cystourethrography, urethroscopy, ultrasound, MRI) is recommended. (The choice of the type of imaging depends on their availability. Data show a higher accuracy of MRI.) (**Level of Evidence 3 – Grade of Recommendation C)**

3.3.3 Future Research Areas

Properly conducted prospective studies are needed to compare the accuracy of ultrasonography and MRI in the diagnosis and staging of female and male diverticula

3.4. Imaging of the Nervous System

Lower urinary tract dysfunction often depends upon derangements of its neural control mechanism. Imaging of the spinal chord and central nervous system may help identifying occult neurological conditions or the site and extent of known neural damage. Functional imaging of the nervous system is a formidable research tool to better understand mechanisms of signal integration at the central level and its possible malfunctioning.

3.4.1 Lumbosacral Spine X-Rays

In children with lower urinary tract dysfunction and urinary incontinence, the presence of a spinal dysraphism must be ruled out. Although in most of the cases abnormalities of the gluteosacral region and/or legs and foot are clearly visible, antero-posterior and lateral films of the lumbosacral spine have to be evaluated in order to identify vertebral anomalies. Sacral agenesis involves the congenital absence of part or all of two or more sacral vertebrae. In the absence of two or more sacral vertebrae a neurogenic bladder is usually found. Spina bifida occulta has a variable significance. Simple failure to fuse the laminae of the fourth and fifth lumbar vertebrae is unlikely to be important, but if the spinal canal is noticeably widened, there may be cord involvement (diastematomyelia, tethered cord syndrome).

3.4.2 CT, MRI, SPECT and PET

Numerous papers refer to rare neurological conditions presenting with different symptoms including urinary incontinence in which CT scan, MRI, SPECT, and PET imaging were carried out to identifying the underlying CNS disease. These references have little impact on daily practice although they can he helpful in occasional difficult cases.

With regards to the clinical diagnostic use of CT or MRI, a few papers evaluated the role of fetal MRI imaging. Fetal MRI has higher contrast resolution than prenatal sonography and allows better identification of normal and abnormal tissue. Moreover, MRI can diagnose some abnormalities such as cerebral malformations and destructive lesions which can be occult on prenatal sonography, where the more anterior cerebral hemisphere cannot be properly evaluated due to reverberations by the overlying structures (2). Common indications for fetal MRI include the evaluation of all the sonographically diagnosed abnormalities of ventriculi, corpus callosum, or posterior fossa, as well as all those fetuses at increased risk for brain abnormalities, such as in families with a history of a prior child or fetus with anomalies, genetic disorders, complications of monochorionic twinning, and maternal illness (such as maternal infection or major cardiac event). Moreover, with recent advances in fetal surgical techniques, fetal MRI is being increasingly used before surgical intervention (3). The results of fetal MRI, whether verifying absence of abnormality, confirming sonographically detected abnormalities, or discovering additional abnormalities that were not apparent by sonography, have been shown to affect clinical decision-making during pregnancy, both by physicians and parents, resulting in changes in pregnancy management in nearly half of cases (2). With regard to myelomeningocele, prenatal ultrasound can easily identify the absence of posterior elements of

the vertebral bodies at affected levels and extension of the subarachnoid space posteriorly through the bony spina bifida, as well as the frequently associated presence of small posterior fossa alteration and herniation of cerebellar tissue into the cervical subarachnoid, which define the Chiari II malformation. However, fetal MRI can be a helpful adjunct when sonography analysis is limited, such as in cases of large maternal body habitus, oligohydramnios, low position of the fetal head, or when the fetal spine is positioned posteriorly with respect to the mother. Moreover, fetal MRI can be very useful to detect additional associated anomalies, such as callosal agenesis or hypogenesis, periventricular nodular heterotopia, cerebellar dysplasia, syringohydromyelia, and diastematomyelia (3). If fetal surgery will be shown to improve long-term outcome, fetal MRI will surely become a routine examination for affected fetuses.

MRI is also recommended in children with anorectal abnormalities as abnormalities of the spine and of the spinal cord are diagnosed in 42 to 46% of cases and in about 50% of cases the spinal cord is involved (1). Wraige et Borzyskowski suggested that spinal cord imaging should be considered in children in whom day-time wetting is associated with impaired bladder sensation or poor bladder emptying even in the absence of clinical or radiological suspicion of lumbosacral spine abnormalities. Four out of 10 children with these symptoms had a spinal cord defect diagnosed on MRI(4).

MRI of the lumbar spine is now the gold standard for evaluating children with spina bifida and adults in which an occult form of spina bifida is suspected. A potential technical update might be the use of intrathecal contrast medium to perform cisternography and ventriculography contrast-enhanced MRI. Munoz et al., evaluated a series of 10 patients with complex cerebrospinal fluid diseases, where other imaging techniques had been unclear or inconclusive, performing MRI with intrathecal administration of gadopentate dimeglumine. In 8 out of the 10 patients, imaging findings influenced or changed the clinical decision-making program and the surgical planning (5).

Sharma et al. recently evaluated with MRI the surgical outcome in patients with spinal dysraphism. Specifically, MRI spectroscopy was used to evaluated the composition of cerebrospinal fluid before and after surgery. Before surgery, high levels of lactate, alanine, acetate, glycerophosphorylcholine, and choline were observed in the cerebrospinal fluid of patients with spinal dysraphism, while these levels normalised postoperatively to those observed in control subjects. However, in those patients where cord tethering occurred, increased concentrations of lactate and alanine were found, suggesting that MRI spectroscopy might be a promising tool in the assessment of surgical outcomes in patients with spinal dysraphism (6).

Several papers refer to the use of CNS imaging in clinical research of voiding dysfunction and pathophysiology. Positron emission tomography (PET) and functional MRI studies provided information on specific brain structures involved in micturition in humans. During micturition an increase in regional blood flow was shown in the dorsomedial part of the pons close to the fourth ventricle, in the pontine micturition centre (PMC), in the mesencephalic periacqueductal grey (PAG) area, as well as in the hypothalamus including the preoptical area (1). A good review onCNS imaging and lower urinary tract function was recently published by Drake and co-workers (7)

A couple of significant original studies have been published recently on the role of functional MRI in stress and urgency urinary incontinence. Specifically, previous brain imaging studies showed that during pelvic floor muscle contraction there was activity in the superior medial precentral gyrus, anterior cingulate cortex (ACC), cerebellum, supplementary motor cortex (SMA) and the thalamus (8, 9). Similarly, during anal spincter contractions multifocal cerebral activity was shown in the primary and secondary sensory/motor cortices, the insula as well as the cingulate gyrus, prefrontal cortex, and the parietooccipital region (10). Di Gangi Herms et al. evaluated the neuroplastic changes of cortical representation of pelvic floor motor function induced with pelvic floor muscle training (PFMT) by biofeedback in patients with SUI (11). Specifically, the authors used functional MRI to evaluate 10 patients with SUI before and after a 12-week PFMT with EMG-biofeedback program. In the MRI performed before the beginning of PFMT, the authors identified significant brain activation in superior lateral and medial precentral gyrus and the superior lateral postcentral gyrus, in the SMA, the left premotor area, and in the left and middle cerebellum, as well as in the insula and in the ACC. In the MRI film after PFMT, less brain areas were activated, mainly the superior lateral and medial precentral gyrus, superior lateral postcentral gyrus and the insula. In other words, after PFMT there was more focused activation in the primary motor (superior lateral and superior medial precentral gyrus) and somatosensory areas, which is consistent with automation of the relearned skillful behavior (11). PFMT with biofeedback may improve muscular strength therefore enhancing support of the urethra and also optimise central muscular control of the pelvic floor, modulate bladder sensation, and reflect the emotional neutralisation related to symptom reduction.

With regard to UUI, Tadic et al. reported a small study, which used functional MRI to investigate 11 patients with UUI and 10 healthy controls. Specifically, the connections of the right insula (RI) and anterior cingulate gyrus (ACG) to other cortical area were evaluated, based on the assumption that the two areas were among the most important regions of the supraspinal neuronal network controlling the bladder. In normal subjects, there were significant positive effective connections with many of the regions involved in supraspinal bladder control, including left insula and frontotemporal and parietal regions, thalamus, putamen and claustrum, posterior cortex, cerebellum,

pontine micturition centre and mesencephalic periacqueductal grey. Vice versa, in the patients with urgency incontinence, significant negative connections to left parieto-temporal lobes, hippocampus, parahippocampal gyrus and cerebellum were found, with few positive connections (12). In subjects with normal bladder function, RI and/or ACG have been reconfirmed to have effective connections with many of the brain regions involved in bladder control such as the frontotemporal and sensorimotor regions, thalamus, putamen, cerebellum and midbrain, as well as to the posterior cortex, a region which may have a role in the control of bladder function. Vice versa, in the patients with urgency incontinence, the connections were shifted to an alternative complex of brain regions, such as left parieto-temporal lobes, parahippocampal gyrus and parts of cerebellum, which might represent expression of the recruitment of accessory pathways in order to control urgency and the voiding reflex as well as the emotional charge due to the abnormal sensation of urgency (12). On the whole the data from these recently published studies have improved our knowledge of nervous functional anatomy related to vesicourethral function and dysfunction but, to date, have no clear clinical relevance.

In conclusion, central nervous system imaging is rarely indicated in urinary incontinence. Spinal cord imaging is recommended in cases of children with anorectal malformation and whenever spina bifida occulta is suspected. In the case of clinical neurological signs and/or symptoms suggestive of central nervous lesions, imaging may be indicated along with more specific neurophysiological tests (e.g., signal latency, testing, evoked potential, etc.). Further improvements in the knowledge of the correlation between morphological and functional evaluation of the CNS is foreseeable using present CNS functional imaging technology.

3.4.3 Consensus Statements

In patients with suspected congenital neurogenic incontinence, with or without abnormalities of neurourological physical examination, lumbo-sacral spine anteroposterior and lateral radiological evaluation (or MRI) is indicated. (Level Evidence 3, Grade of Recommendation C)

Neuroimaging should be considered when a nervous system disorder is suspected on the basis of clinical and/or neurophysiologic test findings (Level of Evidence 3 - Grade of Recommendation C)

3.4.4 Future Research Areas

To investigate the effect of antimuscarinics and neuromodulation on brain activity;

To standardise bladder filling parameters to investigate brain activity during different types and levels of bladder sensations;

To investigate the effect of environmental and behavioural factors on brain activity in patients with UUI

To define the sequence of brain activation during bladder filling.

3.5. Endoscopy of the Lower Urinary Tract

Since the introduction of the cystoscope by Bozinni in 1805, endoscopy has played a critical role in the evaluation of lower urinary tract disorders (1). Many investigators have proposed the routine use of urethrocystoscopy in the evaluation of urinary incontinence. These recommendations have rarely been based on evidence. There are five specific areas pertaining to urinary incontinence in which urethrocystoscopy has been advocated.

1. Observation of the female urethral sphincter to assess its ability to close and coapt. Urethrocystoscopy has been advocated in the static state to assess intrinsic sphincter deficiency (ISD) as well as in the dynamic state, when the patient is straining, to evaluate hypermobility and urethral closure while the patient is straining. It has been reported that sluggish closure of the bladder neck during periods of a rise in intra-abdominal pressure is associated with anatomical stress urinary incontinence. Intrinsic sphincter deficiency has classically been described as a fibrotic or pipe-stem urethra. It has been suggested that endoscopy can even help to differentiate between the hypermobile urethra and the intrinsically damaged urethra.

2. Assessment of the bladder, to rule out concomitant bladder conditions which may be the cause of DO and UI or may simply require treatment.

3. Search of extraurethral causes of urinary incontinence, such as vesico-vaginal fistula and ectopic ureter.

4. Intraoperative cystourethroscopy during correction of USI to assess for bladder damage and ureteral patency.

5. Evaluation of the membranous and prostatic urethra in male patients with post-prostatectomy stress incontinence to evaluate possible iatrogenic damage of the external sphincter region. Assessment of bladder outlet in males with urgency incontinence considered to be secondary to bladder outlet obstruction to appraise prostate morphology.

3.5.1 Evaluation of the Female Bladder Outlet

Robertson described the procedure of dynamic urethroscopy to evaluate the bladder neck (2). In this procedure a gas urethroscope is used to observe the urethra, bladder neck, and portions of the bladder. During visualisation manometric recording can be performed. Robertson described the appearance of SUI as a sluggish closure of the bladder neck and the appearance of the overactive bladder as a bladder neck that closes and then opens like the shutter of a camera. This procedure was reported to be extremely

useful in patients with urinary incontinence as the bladder neck can then be observed at rest, with straining, and Valsalva manoeuvres. Unfortunately, in Robertson's original description of this procedure, it was never compared to other standard methods of measuring outlet resistance. Others who advocate the technique of Robertson reported that only 43% of patients with SUI actually had loss of bladder neck support on urethroscopy (3). Scotti, et al performed a retrospective review of 204 patients who underwent dynamic urethroscopy for the evaluation of USI (4). Of the 204 patients, 99 had USI. Urethroscopy was found to be an imprecise predictor of USI with a 62% sensitivity, a 74.6% positive predictive value and a specificity of 79.1%. Moreover, there were many equivocal studies. The authors concluded that urodynamic evaluation rather than urethroscopy was a more accurate predictor of stress incontinence. Sand, and associates compared supine urethroscopic cystometry (dynamic urethroscopy) to the gold standard of multichannel urethrocystometry (5). They found a sensitivity of only 24.6% and a positive predictive value of only 65.2% in predicting detrusor overactivity.

Horbach and Ostergard tried to predict urethral sphincter insufficiency in women with SUI using urethroscopy (6). They retrospectively reviewed the records of 263 women who had a diagnosis of USI. They defined ISD as a maximal urethra closure pressure of 20 cm H_2O or less with the patient upright with a symptomatically full bladder. They then divided patients into two groups, those with ISD and those with maximal urethral closure pressures of more than 20 cm H_2O. Based on this classification, 132 women, or 50.2%, had evidence of ISD. However, when urethral function was assessed by endoscopy, only six of 132 patients with ISD were found to have an open or partially open proximal urethra and urethrovesical junction at rest during urethrocystoscopy. Clinically, these patients had very low urethral pressures and reported difficulty with continuous leakage of urine. Endoscopy appeared to have little predictive value for ISD as defined by urethral pressure profilometry. Govier et al compared cystoscopic appearance of the female urethral sphincter mechanism to videourodynamic studies in 100 consecutive women with complex types of UI (7). Sphincter dysfunction was classified as minimal, moderate, and severe based on the radiographic appearance of the bladder neck with straining. Urethrocystoscopy underestimated the degree of sphincter deficiency 74% of the time in patients with moderate sphincter dysfunction and 44% of the time in patients with severe sphincter dysfunction. The authors concluded that cystoscopy is inadequate to judge the functional integrity of the bladder outlet. Furthermore, cystoscopy alone will underestimate intrinsic sphincter deficiency in a large number of patients.

3.5.2 Evaluation of the Bladder

Is cystoscopy necessary to rule out concomitant bladder pathology in patients with urinary incontinence? Langmade and Oliver reported on 253 patients who were operated on for SUI (8). They used a simple evaluation that consisted of history, stress tests, and urinalysis alone. They did, however, recommend cystoscopic evaluation if the patient also complained of symptoms of urgency. Although this dogmatic approach was recommended, it was never clearly stated if it made a difference to the treatment or outcome in these patients. Fischer-Rasmussen, et al performed extensive evaluation of women with urinary incontinence (9). This included cystoscopy in 190 patients. They found cystoscopy to be abnormal in only 12 patients, 8 who had SUI and 4 who had other types of UI. Abnormal findings were trabeculated bladder in five patients, benign bladder papillomas in four, and metaplasia of the trigone in two. None of these was considered to be a significant finding. The authors concluded that cystoscopic examination did not contribute to the classification of incontinence in any case. Cardozo and Stanton evaluated 200 patients with SUI and detrusor overcativity (10). Cystoscopy revealed no abnormalities amongst the 100 patients with USI. Fourteen of the 100 patients with detrusor overactivity had cystoscopic abnormalities, eg trabeculation-11, injected mucosa- 1, sacculation Ð1, a bladder capacity of less than 100 cc-1. However, in none of these patients was the treatment affected by the results of cystoscopy. In support of these findings, Mundy has stated that there is no direct diagnostic value of endoscopy in a patient with an overactive bladder. It may sometimes be helpful to look for and exclude a cause of hypersensitivity when this is in the differential diagnosis (11). Duldulao and colleagues found this necessary only in patients with haematuria (12). They performed urinalysis, urine cytology, and cystoscopy on 128 women who presented with urgency incontinence and/or storage voiding symptoms. Of these, 68 patients had UUI, 35 of whom also had microscopic haematuria. One patient with UUI and haematuria was found to have a transitional cell carcinoma of the bladder. None of the patients with urgency incontinence (or storage symptoms only) and no haematuria were found to have significant cystoscopic findings. This would support the routine use of cystoscopy for patients with urgency incontinence only if haematuria is present.

3.5.3 Extra-Urethral Urinary Incontinence

Endoscopy can be an invaluable tool in the diagnosis and treatment of extraurethral incontinence due to vesico-vaginal fistula and ectopic ureter. With respect to vesico-vaginal fistula, cystoscopy can precisely localise the fistula site in the bladder and help plan surgical correction. Occasionally, a small fistula that is not seen on physical examination or radiographic studies, can only be diagnosed by cystoscopy. Incontinence due to ectopic ureter in the female is usually diagnosed by radiographic studies. However, the exact location of the ureteral orifice in urethra or vagina can be identified by cystourethroscopy and/or vaginoscopy. This can be extremely helpful in the planning corrective surgery.

3.5.4 Intraoperative Lower Urinary Tract Evaluation

Several authors have studied the value of routine cystoscopy during operative procedures for incontinence and prolapse. The approach may be transurethral (13) or transvesical(14). The American College of OB/GYN has published a Bulletin on Operative Lower Urinary Tract Injuries (15) in which is stated "at the conclusion of the procedure, when hemostasis has been ensured, both ureters and the bladder should be inspected to confirm their integrity." Harris and coworkers (13) reported 9 unsuspected ureteral or bladder injuries during urogynaecological surgery, which included 6 ureteral ligations, with four of these occurring after Burch cystourethropexy. Burch sutures were also found in the bladder as well as fascia lata from a sling procedure.

3.5.5 Evaluation of the Male Bladder Outlet

Urgency incontinence is one of the lower urinary tract symptoms associated with benign prostatic hyperplasia, bladder outlet obstruction, and aging in the male population. Based on the available evidence and world literature, The World Health Organisation Fifth International Consultation on BPH made the following recommendation: "Diagnostic endoscopy of the lower urinary tract is an optional test in the standard patient with LUTS (lower urinary tract symptoms) because: 1) the outcomes of intervention are unknown, 2) the benefits do not outweigh the harms of the invasive study, 3) the patients' preferences are expected to be divided However, endoscopy is recommended as a guideline at the time of surgical treatment to rule out other pathology and to assess the shape and size of the prostate, which may have an impact on the treatment modality chosen" (16). Several contemporary series have described the value of urodynamics in the diagnosis of post-prostatectomy UI (17-21). However, only one describes the routine use of urethrocystoscopy. In that series 67% of patents had urethral fibrosis confirmed by endoscopy (18). However, how this finding affected treatment was not discussed. In the study by Leach and Yun treatment of incontinence was based solely on urodynamic findings and was successful in 87% of patients (22). Anastomotic strictures may be suspected based on uroflow and urodynamic (pressure-flow) studies and can be confirmed by voiding cystourethrogram or videourodynamics as well as by endoscopy. However, if intervention for the stricture is deemed necessary, endoscopy would be a more critical part of the evaluation. Furthermore if surgical treatment of incontinence, such as, an artificial urinary sphincter, is planned it would seem to make good clinical sense to evaluate the urethro-vesical anastomosis with endoscopy prior to surgery.

3.5.6 Evaluation of Urethral Sphincter in Post-Prostatectomy Incontinence.

Iatrogenic UI in males usually occurs after prostate surgery for benign and malignant conditions. The pathophysiology of UI following transurethral surgery for BPH includes sphincter damage from extending the resection too distal, particularly in the ventral aspect of the sphincter where muscle fibres are more abundant. Endoscopy in post-TURP incontinence reveals insufficient closure at rest with tissue loss in the ventral aspect of the sphincter area, voluntary muscle recruitment is often good. The pathophysiology of UI in post-radical prostatectomy patients is unclear. Numerous studies have investigated the relationship between parameters of urethral pressure profile, morphology of the prostate apex and length of the external sphincter area to post-prostatectomy incontinence. Although the results of these studies suggest a relationship between sphincter competence and UI, no consensus has been reached regarding the gold standard test to be performed prior to surgery to assess the individual patient risk of incontinence. Recently, Gozzi and Rehder suggested that post-radical prostatectomy incontinence may be related to prolapse of the sphincter complex and that repositioning of it by a transobturator sling may be successful. Preoperative selection of surgical candidates for such intervention include endoscopy of membranous urethra testing whether manual push-up of the centrus tendineus perinei results in recruitment of the sphincter fibres comparable to a voluntary contraction. Contraction of the sphincter muscle upon repositioning in a more cranial position is used as an indication for a transobturator sling with the Gozzi and Rehder technique (23-25). Further research is required to confirm such an interesting pathophysiological explanation of post-radical prostatectomy UIand to support the role of endoscopy in the evaluation of these patients.

3.5.7 Consensus Statements

- Routine urethro-cystoscopy is NOT indicated in primary female UI, when other pathologies are not suspected **(Level of Evidence 3, Grade of Recommendation C)**
- Endoscopy can be considered **(Level of Evidence 3, Grade of Recommendation C)**:
    - in urgency incontinence to rule out other pathologies, especially in case of microscopic haematuria (e.g., bladder tumour, interstitial cystitis, etc)
    - in the evaluation of recurrent or iatrogenic cases when surgery is indicated and planned
- Endoscopy is indicated in the evaluation of vesico vaginal fistula and extra-urethral urinary incontinence **(Level of Evidence 3, Grade of Recommendation C)**.
- Endoscopy is indicated intraoperatively in incontinence surgery to look for ureteral or vesical injury **(Level of Evidence 3, Grade of Recommendation C)**.

B.3.e.8 FUTURE RESEARCH AREAS

- The relationship between bladder endoscopy and symptoms of voiding dysfunction in female patients with UI

III. IMAGING IN ANAL INCONTINENCE

Anal incontinence may result from anatomical and/or neurological disruption of the anal sphincter complex. Prior to the development of anorectal imagining techniques, anal sphincter disruption was detected by digital palpation supported by EMG needle mapping and ano-rectal manometry. Use of endoanal ultrasonograpghy (EAUS) for anal sphincter imaging was first described by Wild in 1956 (1) but remained neglected for many decades because of the limitation of technology then available (2). In 1989 Law and Bartum defined the technique of EAUS and endosonographic anatomy of the anal sphincter complex (3). Since then EAUS has become the gold standard of imaging the anal sphincter complex.

Development of 3-D rendering technique over the last decade has enabled better quality imaging of the anal sphincter complex using the EAUS. Recently other imaging modalities such as transvaginal, transperineal and translabial ultrasonography, MRI, Defaecography and Sonoelastography have been described to assess the anal sphincter complex in patients with anal incontinence.

1. INDICATIONS

Anal sphincter imaging has become an integral part of the assessment of anal incontinence. Following detailed history and examination, the patient should be offered anal sphincter imaging (either 2D or 3D EAUS) depending on the availability of imaging modalities and the expertise. Even though ano-rectal physiological studies indicate dysfunction of the anal sphincter complex, they do not identify the anatomical site and the degree of anal sphincter disruption. EAUS has been the gold standard for detecting anal sphincter disruption or atrophy. EAUS is also used in the follow up of women after obstetric anal sphincter injuries to assess the success of the primary repair and to advise on subsequent delivery4. EAUS has been used intra-operatively to identify the damaged EAS prior to secondary repair and also to identify the IAS defects prior to injecting bulking agents.

2. IMAGING MODALITIES

2.1. Ultrasonography

The increased availability of ultrasound scanners to urologists and urogynaecologists and its high resolution in the near field makes this the perfect tool to investigate patients with anal incontinence as a part of their physical examination.

2.1.1 Endoanal Ultrasound (EAUS)

EAUS is performed using a 360° rotating rectal probe with a 7 - 10 MHz transducer (focal range 2-4.5cm) with minimum beam width of 1.1mm. Several systems are currently available, and recently integrated 3D systems are also available (B&K Medical, Sandoften 9, 2820 Gentofte, Denmark). Women should be examined prone with an endoanal system to minimise anatomical distortion. Figure 37 shows a schematic diagram of the anal sphincter complex in relation to the endoanal probe (4).

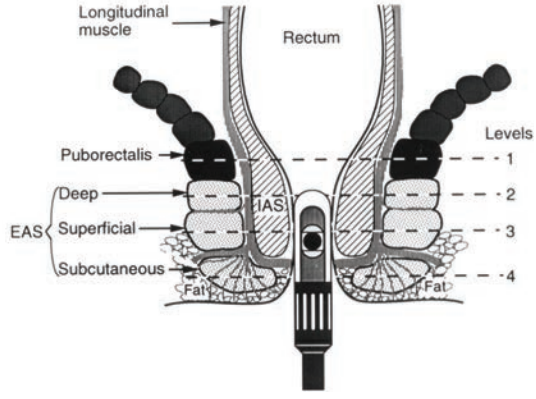

Figure 37: A schematic diagram of the anal sphincter complex in relation to endoanal probe.

The standard EAUS image of the anal canal is of 4 layers (Figure 38):

1. The subepithelial layer is moderately reflective.
2. The internal sphincter is the most obvious landmark and is a well-defined low reflective ring. The internal sphincter varies in thickness with age, being <1mm in neonate, 1-2mm in young adults, 2-3 in middle age and >3mm in the elderly.
3. The longitudinal layer is a complex structure with a large fibroelastic and muscle component, the latter formed from the puboanalis as well as the longitudinal muscle of the rectum (Figure 38).
4. The external sphincter is better defined in men than women, where it tends to be less hypoechoic. It is distinguished mainly by interface reflections between muscle/fat planes either side (Figure 38). In women the external sphincter is shorter anteriorly than posteriorly, which must not be misinterpreted as a tear. The transverse

perineii muscles fuse anterior with the sphincter, whereas in men they remain separate.

With experience the examination can be performed in about 5 minutes and provides an ideal method for a rapid assessment of sphincter integrity and thickness.

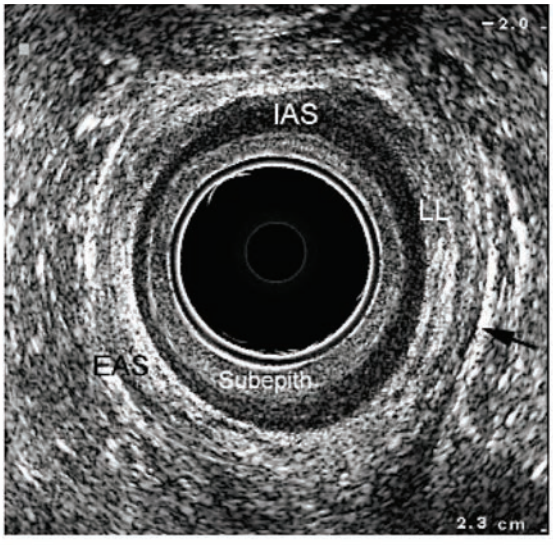

Figure 38: Axial endosonography in the mid canal in a normal 38yr old female. Subepith: subepithial layer; IAS: internal anal sphincter; LL: longitudinal layer; EAS: external anal sphincter. The outer border of the external sphincter is defined by an inter- face reflection at the fat/muscle boundary (arrow).

2.1.2 3-Dimensional Endoanal Ultrasonography (3-D EAUS)

With 3D-EAUS, the anal canal is scanned in a conventional manner, and dedicated software provides a final 3D appearance (3D rendering). The data obtained from a series of closely spaced EUS images (0.25 mm) are combined to create a 3D volume displayed as a cube. The image can then be freely rotated and it is possible to visualise defects at different angles and to obtain the most information from the data (5).The advent of 3 D ultrasonographic multiplanar reconstruction of the anal canal has further improved the detection of anal sphincter injuries with nearly 95-100% sensitivity and specificity[6].With 3D-EAUS, the aspect, localisation (circumference involved, height), size (in degrees or percentageof circumference) and number of sphincter defects can be described in detail, together with a calculation of the volume of such defects[7]. Defects of the puborectalis fibres of the levator ani are less common and these can be seen as heterogeneous remodelling or shortening of the two bands is visible after episiotomy orpelvic floor injury during vaginal delivery.

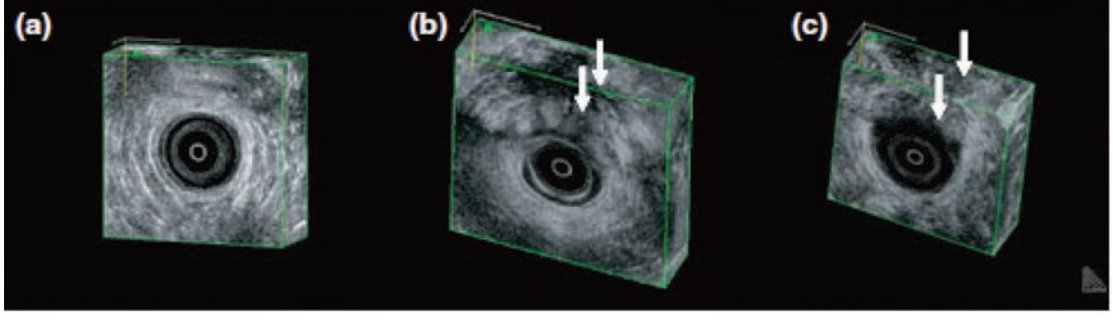

Figure 39: Three-dimensional endoanal ultrasound showing no (a), partial (b) or complete EAS defect (c). Arrows indicate an EAS defect in the sagittal view (10).

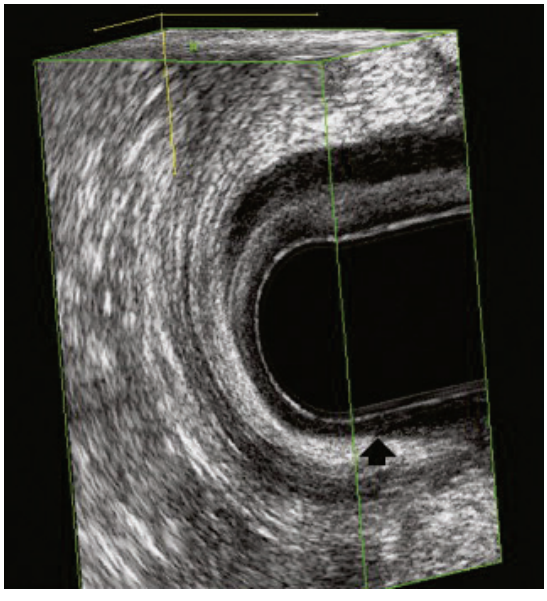

Figure 40: Complete defect of the internal anal sphincter (6).

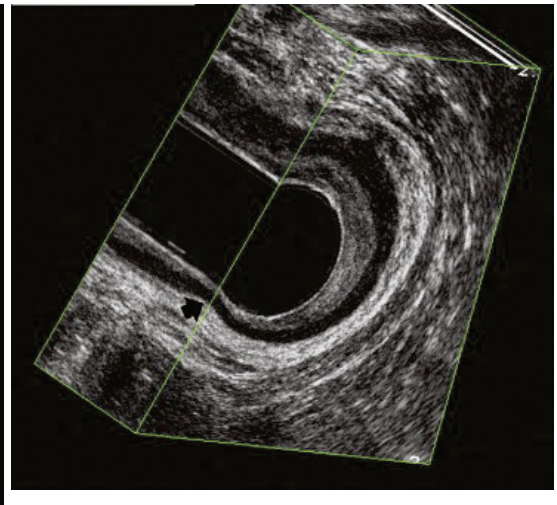

Figure 41: Partial defect of the internal anal sphincter (6).

Its role in the development of AI is probably underestimated and characterisation, particularly in terms of volume, would be of interest to assess the functional impact (6). Two scoring systems has been introduced to objectively evaluate the anal sphincter defects detected in 3D EAUS (8, 9) and both these scoring system have shown acceptable intra observer and inter observer agreement (9).

Although EAUS has been accepted as the gold standard of imaging anal sphincter complex, the equipment and the expertise may not be readily available in some centres. Some patients may find EAUS technique embarrassing and unacceptable. Hard endoanal cone of EAUS may cause the disruption of normal anal canal anatomy. Because of these drawbacks, other imaging modalities such as endovaginal, transperineal and translabial ultrasonography have been evaluated to assess the anal sphincter complex.

Sultan et all first described the vaginal use of 360^0 rotating probe used for the EAUS and obtained clear images of anal sphincter complex (11). Since then different types of probes including side-fire transrectal probe, a standard transvaginal probe and modified vaginal probe has been used to evaluate the anal sphincter complex with variable sensitivity and specificity for detecting anal sphincter injury (12).

2.1.3 Transperineal ultrasonography

Transperineal ultrasonography (TPU) to image the anal sphincter complex was first described by Peschers et al. (13) and found to have a good inter observer reliability in detecting IAS and EAS defects compared with EAUS (14). A recent study by Roos et al. (12) comparing endovaginal and transperineal ultrasonography to detect obstetric anal sphincter have concluded that neither of these modalities is sensitive enough to detect anal sphincter defects.

2.1.4 Translabial Ultrasonography

Translabial ultrasound (TLU) offers an alternative imaging modality of the anal sphincter complex and has proven to be well-tolerated by patients. It has been used to describe anal sphincter complex integrity (13, 15). Hall et all evaluated 60 women with TLU and reported that mean sphincter measurements are given for symptomatic and asymptomatic intact women and are comparable to previously reported endoanal MRI and endoanal ultrasound measurements(16). The advantages of TLU are that the equipment needed is readily available to all gynaecology and radiology imaging laboratories.

2.1.5 Integrated Multicompartmental Pelvic Floor Ultrasonography

Pelvic organ dysfunction includes multiple conditions such as pelvic organ prolapse, urinary incontinence, anal incontinence, defaecatory disorders and sexual dysfunction. Based on this concept integrated multicompartmental Pelvic Floor imaging including two-dimensional (2D), three-dimensional (3D) and 4D pelvic floor ultrasonography as well as transvaginal, endoanal and transperineal techniques, has been described from a global and multicompartmental perspective (17). The value of this approach in routine assessment of pelvic floor dysfunction is yet to be evaluated.

2.1.6 Dynamic Anorectal Endosonography (DAE).

DAE uses a rigid biplane transrectal probe with a frequency of 7 MHz with the tip of the probe covered with a water-filled balloon to maintain the acoustic window for the ultrasound waves. By slowly and manually rotating the linear probe through 360°, various layers constituting the anal wall (mucosa, internal anal sphincter, and external anal sphincter), the layer forming the rectal wall, and the perirectal tissues (puborectalis muscle, bladder, and vagina, or prostate) has been demonstrated. After the initial examination, the patient simulates defaecation with the probe left in the same position (18). In a study of 56 women using DAE and Dynamic MRI Defaecography significantly more internal anal sphincter defects were found with DAE than with dynamic MRI defaecography, but there was no significant difference for the diagnosis of external anal sphincter defects (18).

2.1.7 Sonoelastography

Sonoelastography is a new imaging technique based on differences in radiofrequency signals following endogenous/exogenous compression due to different elastic properties of the targeted tissues or organs (19). This technique has been evaluated in pathological conditions of breast, thyroid, pancreas and prostate. The elastographic pictures registered simultaneously with conventional grayscale B-mode images during sonography or endosonography are assumed to distinguish malignant from inflamed areas and thus facilitate diagnosis. Based on this concept it is assumed that Sonoelastograhy is able to diagnose different conditions causing anal incontinence. However there is only one published study comparing the conventional endoanal ultrasonography and elastography (20). This prospective study included 50 patients with faecal incontinence following ano-rectal surgery and Crohn's disease. Elastogram colour distribution within the sphincter representing elastic properties was quantified using a visual analogue scale and an off-line computerised area calculation program. The IAS, a smooth muscle, and the EAS, a striated muscle, have different elastogram colour distributions, probably reflecting their different elastic properties. The absence of significant correlations with the major clinical and functional parameters suggests that in routine clinical practice ultrasound real-time elastography may not yield additional information in patients with faecal incontinence except in patients who have had radiation.

2.2. MRI

Anatomy of the anal sphincter complex has been redefined over the past 20 years by the use of body coil, endoanal coil and phased-array coil magnetic resonance imaging (MRI). However these different MRI techniques have led to conflicting anatomical descriptions of the anal sphincter complex (21). Endoanal coil MRI studies by Rociu et al. (22, 23) have suggested that the levator ani muscle has only a transverse portion and that the EAS muscle is composed of only a subcutaneous and a superficial portion describing five image layers. (Fig 41)

However, body coil MRI studies by Guo and Li (24) suggested that the levator ani muscle also has a vertical portion (vertical levator), and separate body coil MRI studies by Hsu et al. (25) suggested that the EAS muscle has 3 separate components which has been identified in EAUS as well.

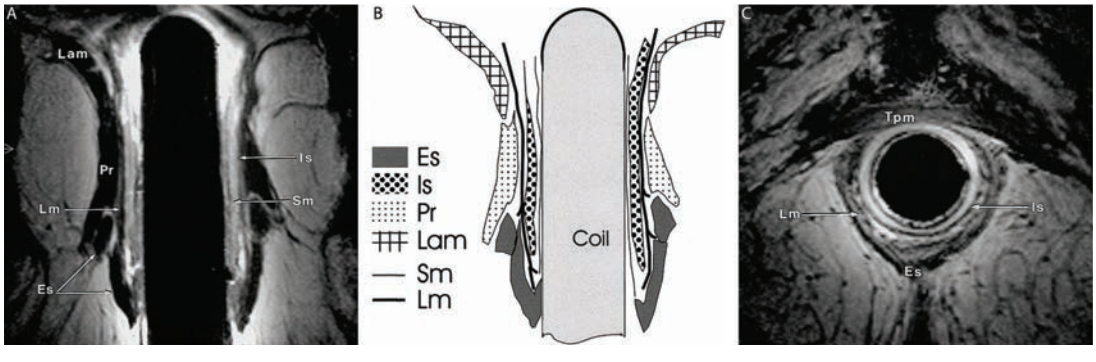

FIGURE 42:T2-weighted turbo spin-echo endoanal coil MRI studies by Rociu et al.

B, 3-layer intersphincteric space.

C, Drawing of anal midcoronal section.

A - imaging anal canal; ASM - anal smooth muscle; Deep -deep sphincter; If -ischioanal fossa; Iom -internal obturator muscle; ISS -intersphincteric space; Pr -puborectalis; R- rectum; SC -SC sphincter; Sup -superficial sphincter; TP- transverse levator; VP -vertical portion of the levator ani. (26)

More recent study by Guo et al. (26) using multiplanar body-coil MRI studies demonstrated that the anal region actually has 7 image layers: the mucosa, submucosa, anal smooth muscle, inner space, vertical levator, outer space, and the EAS muscle (Figure 42). The authors reported that endoanal MRI does not reliably outline the superficial layers of the anal region because a blind zone is created in the anal canal near the coil. This blind zone led investigators to effectively ignore the mucosa, submucosa, anal smooth muscle, intersphincteric groove, and subcutaneous sphincter and this accounts for the early endoanal MRI description of the anal region as comprising only 5 image layers.Images of the anal sphincter complex obtained using endoanal MRI are thought to be superior to MRI performed with a body coil because of increased signal to noise ratio resulting in high spatial resolution images. Although the endoanal MRI allows comprehensive assessment of atrophy and focal defects of the external canal, the internal sphincter has been less well defined (27). A meta analysis of nine studies, comparing endoanal MRI with endoanal ultrasound or surgical diagnosis in 157 patients by Tan et al. (28) has shown that endoanal MRI was sensitive and specific for the detection of external sphincter injury and especially sphincter atrophy. It may be useful as an alternative to endoanal ultrasound in patients presenting with faecal incontinence. However, the limited availability of dedicated endoanal coils outside specialist units has resulted in less widespread familiarity with this technique and further clinical studies are needed to identify its best application in clinical practice.

In addition to the damage to the anal sphincter complex, levator ani muscle (LAM) injury has also been postulated as a cause for anal incontinence especially after childbirth. A recent MRI study by Helliburn et al. (29) reported major LAM injuries in 19% of women who delivered vaginally with external anal sphincter (EAS) injuries compared to 3% delivered vaginally without EAS injury, and 0% delivered by cesarean section before labour. Among women with EAS injuries, those with major LAM injuries tend to have more anal incontinence symptoms than those who did not have LAM injury. These data suggest that both EAS and LAM are important to maintain faecal continence.

2.3. Evacuation Defaecography (Proctography)

Evacuation defaecography is indicated in patients with constipation, and in those with obstructive defaection associated with anal incontinence caused by overflow incontinence or post defaecation leakage. In these patients, defaecography is useful to visualise outlet obstruction due to an anatomical (e.g. enterocele, rectocele, intussusception) or a functional (e.g. anismus) cause. Evacuation defaecography is also useful to demonstrate bladder and uterovaginal prolapse as well as pelvic floor descent (Figure 43 a-b)but gives limited information as to rectal function. Evacuation defaecography has shown good reproducibility in the diagnoses of enterocele, anterior rectocele and their grading in patients with faecal incontinence (30).

The rectum is opacified with 120 mls of a barium paste and the small bowel with a dilute barium suspension given orally about 30mins before defaecography starts. The patient is seated sideways within the fluoroscopic unit on a radiolucent commode. Evacuation of the barium paste is recorded either on video or on cut film at 1 frame/sec using a low dose protocol. At rest the anorectal junction is at the level of the ischial tuberosities and the anal canal closed. Evacuation is rapid (<30sec) and the rectum below the main fold should be emptied completely. During

evacuation the anorectal angle widens as the anorectal junction descends and the anal canal opens. At the end of evacuation pelvic floor tone returns and the puborectalis pulls the anorectal junction upwards and forwards back to the resting position. Intra-anal intussusception creates a thick double fold of rectum, which impacts into the anal canal on straining at the end of rectal evacuation. Rectal prolapse represents an extension of this process, with passage of the intussusception through the anal canal and inversion of the rectum (Figure 44 a-c)

Compared to conventional evacuation defaecography, dynamic MR defaecography at a vertical open magnet unit has become popular recently as it produces multiplanar images with increased soft tissue contrast and avoids radiation exposure. However the comparative results between conventional defaecography and dynamic MR defaecography in patients with prolapse and anal incontinence are variable (31, 32). Some of these variations have been attributed to the difference in technique. The main drawback of MR defaecography is the supine position required which causes sub optimal assessment of prolapse and evacation (31). Since vertical open-magnet MR imaging units are not widely available, the role of MR defaecography in the diagnostic work-up of faecal incontinence is still limited.

Figure 44: Sagittal views from a dynamic MRI examination.

The dotted line indicates the position of the puboccoccygeal line. At rest (a) there is some descent as the anorectal junction (ARJ) is more than 1 cm below this. During pelvic stress (b) there is marked pelvic floor descent, with descent of the cervix (Cx) and bladder base (Bl).

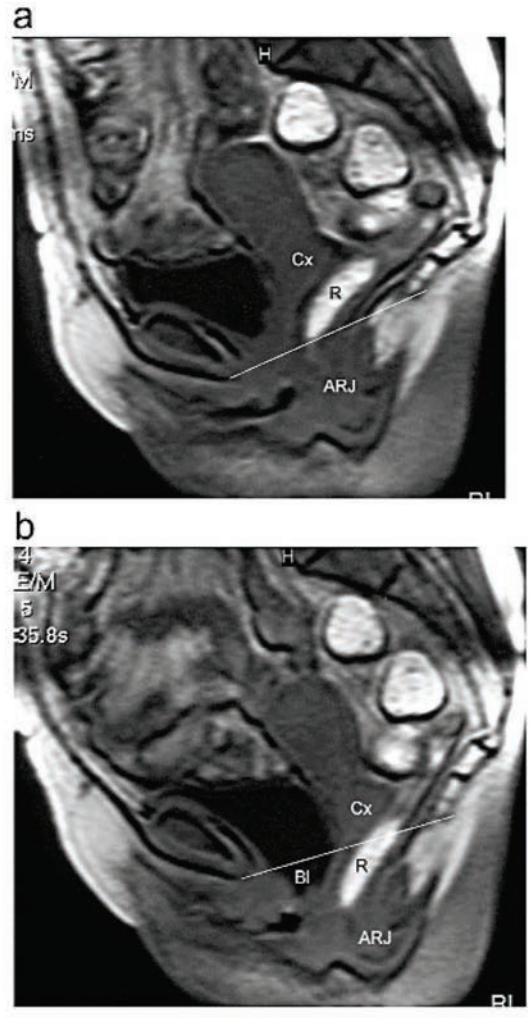

Figure 45: Evacuation proctogram showing the development of rectal prolapse. Intussusception starts at the end of rectal emptying (a) and rapidly passes through the anal canal (b) to form the external prolapse(c).

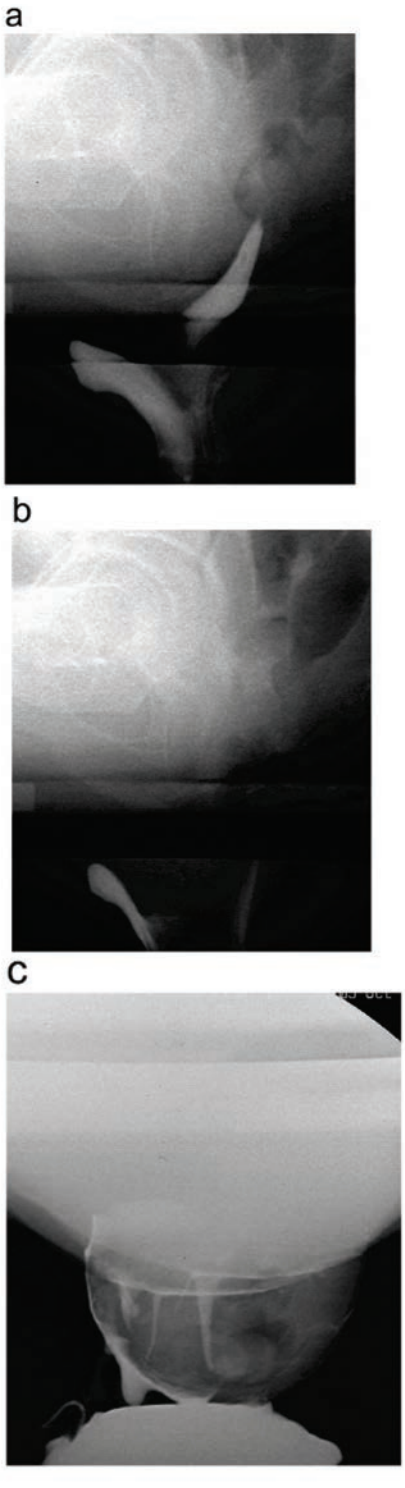

Figure 46: Endosonography with an axial image in the mid canal of an elderly patient, aged 73yrs with passive faecal incontinence. The internal sphincter measures only 1.1mm (markers) indicative of internal sphincter degeneration.

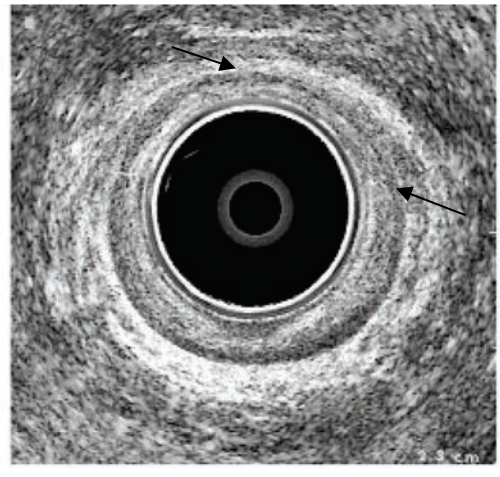

3. SPHINCTERIC DISORDERS

3.1. The Internal Anal Sphincter (IAS)

IAS is responsible for the maintenance of resting anal pressure and plays a vital role in maintaining anal continence. Isolated IAS defects are associated with surgery for ano-rectal malignancies, anal fissure and undetected obstetric anal sphincter injuries. These patients may present with passive faecal soiling and seepage rather than frank faecal incontinence.

Abnormalities of thickness are usually related to the patient's age. A sphincter less than 2mm thick in a patient more than 50 years of age is indicative of internal sphincter degeneration (Figure 45) and is associated with passive faecal incontinence.

Obstetric trauma to the internal sphincter parallels that of the external sphincter in extent, but should always be in the anterior half, so that any defect between 3 and 9 is due to some other cause.

Sphincterotomy may be more extensive than was planned, particularly in women, and 3D studies are especially helpful to assess the longitudinal extent of the defect. The length of the sphincter divided relates directly to the risk of incontinence (33). Dilatation procedures are hazardous and may completely fragment (Fig 46) the internal sphincter.

3.2. The External Anal Sphincter

When striated muscle is stretched beyond the limits of its elasticity fibres rupture and heal with granulation tissue and eventually fibrosis. Most chronic tears are seen with scar formation, and present as a uniform area of low reflectivity distorting and obliterating normal anatomical planes (Figure 44). A key to the diagnosis is lack of symmetry with the anterior part of the

external sphincter not fusing at 12 o'clock as the probe is moved slowly down the canal. This may also be seen on 3D studies in the coronal plane (Figure 45). Other perineal structures, such as the puboanalis and transverse perineii are frequently torn and distinguishing these tears from external sphincter trauma requires experience, and again may be helped by 3D multiplanar imaging. The distinction is important as tears of the puboanalis or transverse perineii are not associated with a significant fall in squeeze pressure (34), and it is only damage to the external sphincter that results in a significant change. Childbirth damage to the puborectalis part of the levator ani muscle with intact EAS and IAS has been reported as a distinct cause of anal incontinence. 3-D EAUS is reported to be superior in detecting this type of injury (35).

In healthy young adults a good correlation has been found between measurements of layers thicknesses on endosonography and endocoil MRI, with an Ri of 0.96 for the external sphincter (36). The outer border of the external sphincter is easier to see on MRI, but fibrosis is not so markedly different in signal from normal muscle, so that the conspicuity of tears may not be as obvious as with endosonography.

Atrophy of EAS is a more difficult problem. Determining the thickness of the external sphincter on EAUS depends on visualising its borders from interface reflections between the longitudinal layer on the inside and subadventitial fat on the outer border. As atrophy involves a reduction of muscle fibres and an increase in fat, the outer interface reflection is lost and the thickness of the external sphincter cannot be measured. Such loss of definition of the outer border of the external sphincter on endosonography has a positive predictive value of 71% for atrophy (37). Using 3D EAUS and a grading system based on definition (Figure 47) and echogenicity of the external sphincter showed a comparable accuracy to endocoil MRI in detecting atrophy (38).

4. CONCLUSIONS

Claims for superiority of one or other modality for the detection of sphincter tears probably depend largely on individual experience, but the relative low cost and speed of EAUS makes this an ideal screening procedure to assess sphincter integrity. A leading issue is the significance of occult sphincter tears (diagnosed on endosonography but not apparent clinically) following vaginal delivery. Although these may be detected by careful examination immediately post partum (39), retrospective detection will still require EAUS. A meta-analysis of 717 vaginal deliveries revealed a 26.9% incidence of anal sphincter tears in primiparous, with 8.5% new tears in multiparous women. Overall 29.7% of women with tears were symptomatic, compared to only 3.4% without tears. The probability of faecal incontinence being due to a sphincter tear was 76.8-82.8% (40). Recent studies confirm the strong relationship between obstetric sphincter damage and faecal incontinence (41), and its late onset (42,43). Subsequent deliveries increase the risk of incontinence particularly if there has been a tear at the first delivery (44). Tears that involve the internal sphincter increase the severity of incontinence (45). A sphincter tear at EAUS is therefore an important finding, but how this is used to decide management is a little more controversial. Secondary anal sphincter repair has fallen out of fashion following the finding that results deteriorate over a few years[46], although a more recent study (47) suggests a better response.

Fluoroscopic studies have little role in faecal incontinence, unless there is an underlying rectal abnormality such as obstructive defaectory symptoms and prolapse. Dynamic MRI studies have the added value of demonstrating prolapse in the rest of the pelvis, but apart from the lack of ionising radiation, has no real advantage for studying rectal function.

EAUS therefore remains the first line imaging investigation for anal incontinence, giving accurate information regarding the external and/or internal sphincter tears and the likelihood of atrophy. Dynamic studies of rectal evacuation are required only if there is some other problem suspected, such as prolapse. The advantages of using MRI are the lack of ionising radiation and a global view of the pelvic floor. Although imaging gives hard evidence of sphincter damage, this is really only part of a much more complex functional problem, and colorectal abnormalities may be just as important (48) with tears accounting for perhaps only 45% of incontinence (49).

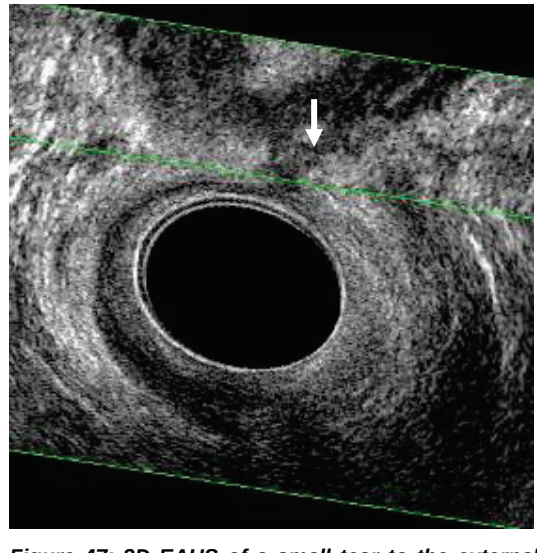

Figure 47: 3D EAUS of a small tear to the external sphincter (arrow).

5. CONSENSUS STATEMENTS

- EAUS is the first line imaging investigation for faecal incontinence providing accurate information regarding external and/or internal sphincter tears and the likelihood of atrophy. (Level of Evidence 3, Grade of Recommendation C).
- 3-D EAUS offer better quality images and diagnosis of the depth of anal sphincter injury.(Level of Evidence 3, Grade of Recommendation C)
- Routine use of 3-D EAUS is not recommended because of the cost.(Level of Evidence 3, Grade of Recommendation C)
- Routine use of transperineal, transvaginal and translabial ultrasonography to image the anal sphincter complex are not recommended. (Level of Evidence 3, Grade of Recommendation C).
- Dynamic imaging of rectal function is required when rectal abnormalities such as prolapse are suspected (Level of Evidence 3, Grade of Recommendation C).
- MRI offers no advantage over other imaging modalities except for the lack of ionising radiation and global view of the pelvis (Level of Evidence 3, Grade of Recommendation C)

6. FUTUREC RESEARCH AREAS

Better image quality with 3D EAUS and MRI have improved our understanding of pelvic floor anatomy, and this in turn has enabled sonographic anatomy to be re-evaluated, however, conflicting views of anal sphincter anatomy remain.

- Are clinical symptoms related to the size and the site of anal sphincter defect (50) or not (51)?
- Significance of imaging in detecting anal sphincter injury especially immediately after childbirth in preventing future anal incontinence (39,52).
- The value of ano-rectal physiological studies combined with imaging in assessing the success of surgical repair of the anal sphincter complex (53).
- Identify (and modify) the risk factors leading to anal sphincter injury especially during childbirth and develop preventive strategies (54).

The most valuable aspect of 3-D ultrasonography and MRI imaging is that they give a global view of the pelvis, capable of investigating urological, gynaecological and coloproctological problems at the same time (17). Many patients do not have faecal incontinence as an isolated symptom, but also have urinary, prolapse or defaecatory problems. The overview provided by imaging sets the way for a combined approach to the pelvic floor and should be the prime area of future investigation (17).

IV. PAD TESTING

The use of a perineal electronic nappy using electrical conductivity to estimate the amount of urine leakage was first proposed by James et al.(1, 2). Accuracy of this technique was, however, questioned by others and the technique was improved (3-8). Walsh & Mills and Sutherst et al. introduced a more simple approach by estimating leakage by perineal pad weight gain (9, 10). These tests were not standardised until Bates et al. described a “structured” one hour pad test which was endorsed by the International Continence Society in 1988 (11). This test, however, was shown to have poor interdepartmental correlation and to be highly dependent on bladder volume (12, 13). In an attempt to make pad tests more reliable 24 hour and 48 hour pad tests were developed. A more precise estimation of urine loss was shown, but they were more cumbersome. The Pyridium pad test was also proposed for diagnosing urinary incontinence (14).

1. DEFINITION

The pad test is a diagnostic method to detect and quantify urine loss based on weight gain of absorbent pads during a test period under standardised conditions.

2. INDICATION AND METHODOLOGY

A pad test allows the detection and quantification of urine loss, but it is not diagnostic of the cause of the incontinence. Several different standards have been developed. Tests can be divided into four groups according to the length of the test: <1h, 1h, 24h and 48 h. (Table 4)

Table 4: types of pad test

Author	Time	Bladder load	Exercise
Hahn & Fall (15)	20 min	50% of MCC*	stair climbing, 100 steps, coughing (10x), running (1 min), wash hands (1 min) jumping(1 min)
ICS (11)	1h	Drink 500 ml (15 min) before test	walking & stair climbing (30 min), standing up 10x, coughing (10x), running (1 min), bending (5x), wash hands (1 min)
Jorgensen et al. (16)	24h		Everyday activities
Jakobseny et al. (17)	48h		Everyday activities

*Maximum Cystometric Capacity

3. OFFICE-BASED PAD TESTING

Pad tests up to 2 hours were developed to be performed in outpatient clinics or hospital wards under supervised conditions. Bladder volume is predefined to reduce variability and a structured set of exercises is usually implemented to elicit the occurrence of urine loss.

3.1. Short Pad Test

Quantification:

These tests are based on a fixed bladder volume and a standard set of activities to facilitate the occurrence of urine loss, if any, over a short period of time. Jakobseny et al. found that the 40 minute test with a bladder volume of 75% maximum cystometric capacity and similar activities as a 1-hour ward test produced consistently larger amounts of urine loss than a standard 1-hour ward test (17). The difference was attributed to significantly larger bladder volumes during performance of physical activity in a 40 minute pad test.

Kinn & Larsson reported no correlation between a short 10 minute test with fixed bladder volume and the degree of incontinence as judged from the symptoms (18).

Hahn & Fall in a 20 minute test with half cystometric capacity showed no false negative results in 50 women with stress urinary incontinence although there was a discrepancy in 12% of patients between the perception of incontinence severity and pad test results (15).

These data suggest that short pad tests are more provocative than activities of daily living.

Reproducibility:

The correlation factor (Pitman's nonparametric permutation test) between two separate 20 minute tests was 0.94 ($p<0.001$) (15). Kinn and Kinn & Larsson showed that the 10 minute test with a fixed pre-test bladder volume of 75% of maximal capacity was moderatey reproducible ($r=0.74$) (18). Using a 1 hour pad test, a standardised bladder volume of 300ml and standardised physical activity mean differences of leakage was 8.5 ml and coefficient of repeatability was 33.6 ml (19).

3.2. One-Hour Pad Test

The use of a one-hour pad test has been investigated thoroughly for validity, reproducibility and sensitivity to change.

Quantification

Jakobseny et al. reported that a one hour test detected less leakage at 3 g compared to a 40 minute (7 g) and a 48 hour pad test (37 g) (17). In the elderly, a one-hour ward test did not demonstrate incontinence in 66% of those complaining of incontinence compared to 90% with a 24 in-patient monitoring of urine leakage (20). A one hour pad test was found to reflect everyday incontinence in only 48% of patients in comparison to 81% with a 48 hour test and 77% with a 40 minute test. Jorgensen et al. noted that 90% completed the test and 69% had test results which correlated with daily leakage (16). Lose et al. found a poor to moderate correlation of the modified one-hour test (200-300 ml in the bladder) with a history of stress urinary incontinence (n=31) (21). Mouritsen et al. showed that a 1-hour ward pad test did not detect grade I stress incontinence in 46%, grade II in 27% and grade III in 66% (22). Thind & Gerstenberg compared a 1-hour ward pad test to a 24-hour home pad test and found that a 1-hour pad test had a 36% false-negative rate as compared to a 24-hour home pad test (23).

Reproducibility

Klarskov & Hald demonstrated in 3 consecutive 1-hour pad tests, a correlation coefficient of 0.75 and 0.97 depending on the activity regimen (24). The test, however, was quite demanding and a lot of patients did not complete the full testing. Christensen et al. compared a one-hour pad test in two different urological and one obstetrics & gynaecological departments (20 women) (13). The test results in two urological departments did not differ with an average pad gain of 24g and 21 g ($p>0.1$). However, pad test results

between the departments of urology and gynaecology differed significantly, with average pad weight gain 9 g and 24 g respectively ($p<0.05$).

Lose and co-workers showed a significant variation between 1-hour ward test and retest in 18 patients (correlation coefficient 0.68) (12). In 50% of patients the leakage volume was variable due to differing bladder volume. When the results of the 1-hour pad test were corrected for urine volume, the correlation coefficient value increased to 0.96. Simons et al found the reproducibility of the standard 1 hour pad test to be poor (25).

Validity

Walsh & Mills in the elderly and Holm-Bentzen et al. in patients with an AMS artificial sphincter showed that the one hour pad test did not correlate with subjective patient satisfaction but this may due to other lower urinary tract symptoms (9, 26).

Bladder volume

Jorgensen et al showed test-retest correlation was improved when the bladder volume was taken into account and the correlation value (r) raised from 0.68 to 0.93 (16). Fantl et al used a one hour test with the bladder filled to capacity and had a test-retest correlation of 0.97 which was improved if the fluid loss was expressed as a percentage of bladder volume (27). Lose et al. using a 1-hour pad test with standardised bladder volume of 50% of maximal cystometric capacity (MCC) showed in 25 women a test retest correlation of 0.97 but the intertest variation was up to 24g (28). Jakobsen et al. compared a 1-hour pad test with a bladder filled to 50% and 75% of maximal cystometric capacity and found that the final bladder volume was equal in both groups showing the importance of diuresis even with equal starting bladder capacities (29). The amount of leakage in both groups was the same. Simons et al. found the volume in the bladder after a standard 1 hour pad test varies by –44 to +66g in a test-retest situation (25). The fluid volume in the bladder appears to be critical in making the pad test reproducible and increasing the sensitivity of the test for detecting leakage.

Aslan et al compared a 1 hour pad test loss with the symptom impact index (SII) and the symptom severity index (SSI) (30). Only the SSI showed a relationship between the severity of the score and the pad test loss. The 1 hour pad test has also been used in assessing the validity of the Incontinence Impact Questionnaire and the Urogenital Distress Inventory unfortunately both had poor correlations with the pad test (31). This is to be expected as the questionnaires assess other urinary symptoms rather than just leakage.

Diagnosis

Fluid loss was significantly greater in patients with detrusor overactivity in comparison to urodynamic stress incontinence (27, 32). The reverse finding was reported by Matharu and co-workers (33). There is high variability in patients with detrusor overactivity making the test impractical as a diagnostic tool.

Sensitivity to change

The 1 hour pad test has been shown to be useful in detecting significant improvements after pelvic floor exercises for men suffering urinary incontinence after radical prostatectomy (34). Ward et al. found the standard 1 hour pad test to show significant reductions in loss after tension free vaginal tape procedures from 18g (IQR 6-37) and Burch colposuspension from 16g (IQR 6-38) both decreasing to 0g (IQR 0) (35). The 1 hour pad test has also been tested for the reduction in loss after conservative and surgical therapy (36). The changes were significant but there was moderate correlation ($r = 0.53$) with the changes in the St. George Urinary Incontinence Score.

3.3. Two-Hour Pad Test

A test period of 60-120 minutes after a 1 litre fluid load was proposed as the optimal duration for the pad test because of a consistently high bladder volume (37). Han et al showed, however, that a 1-hour pad test is more practical (38). In children a 2-hour ward pad test yielded 70% positive results for incontinence (39). Richmond et al. compared two exercise regimens with a 2-hour pad test and showed no significant differences regarding which order the exercises were performed (40). Walters et al. performed a 2-hour pad test with standard exercise in 40 women with SUI showing 78% positive tests (>1g pad gain) after 1 hour and 98% after the second hour (41). Overall, the two-hour pad test was found to be superior to the one-hour one. There was no correlation between pad test results and the severity of a symptoms score.

4. HOME BASED PAD TESTING

These tests were developed to diagnose and measure urine loss in a situation as close as possible to standard daily life of the patient. The longer observation period usually requires a less structured procedure.

4.1. 12-Hour Pad Test

Quantification:

Hellstrom et al. demonstrated in 30 children with incontinence a positive 12-hour home pad test in 68%. When a standard fluid load (13 ml/kg) was instituted in 20 children, the frequency of the positive test increased to 80% (39).

4.2. 24-Hour Pad Test

Quantification:

Lose et al. found a 90% correlation of a 24-hour pad test with a history of stress incontinence in 31 women (21). This was better than the results of a 1-hour test. Thirteen of 31 patients were found to be continent after a 1-hour ward test in comparison to only 3 with a 24-hour home pad test. Mouritsen et al. showed that

the 24-h home test was well tolerated and as good at detecting incontinence as a 48-h test (22). Griffiths et al. found only a 10% false negative rate of a 24-hour pad test in an elderly population (20). Using non-parametric coefficient of correlation, they found a significant difference between the 1-hour test and the 24 hour test. Lose et al. found that a 24h home test performed during daily activities was more sensitive that a 1-hour ward test with standardised bladder volume of 200-300 ml (21). High fluid intake did not change the results of a 24-h home test, but a low fluid intake reduced a positive test by 56% (42). Ryhammer et al. showed that 24-h test is superior to subjective self-reported assessment of urinary incontinence (43).

Reproducibility

Lose et al showed poor correlation in a test-retest study with a variation of more than 100% (21) although Groutz et al. using Lin's concordance correlation coefficient (CCC), found the 24-h test to be very reliable instrument (44). Increasing test duration to 48 and 72 hours slightly improved reliability but decreased patient compliance.

The values for the pad test increase in asymptomatic men and women were reported by Karantanis et al with the median value 0.3g (IQR 0.2 – 0.6; 95th centile 1.3g). It is surprising that the loss is so low and the same for men and women (45).

Diagnosis

Matharu et al found women with urodynamic stress incontinence leaked more than women with detrusor overactivity but the amounts were not diagnostic for the individual abnormalities (33). Pad test loss is unaffected by the degree of hypermobility however there is increased loss associated with urethral sphincter incompetence diagnosed by a vesical leak point pressure less than 60 cmH_2O (46).

Validity

Karantanis et al found the 24-hour pad test was poorly correlated in women with urodynamic stress incontinence with incontinence episodes on a 3 day urinary diary (Kendall's corr coeff b = 0.4) and the ICIQ-SF (r = 0.4) (47). Singh et al. reported that fewer (52%) women after surgery were willing to complete a 24 hour pad test at follow up (48).

4.3. 48-Hour Pad Test

Quantification:

Jakobseny et al. showed that 48-hour pad test reflects everyday incontinence in 81% of patients (17). No statistical analysis data were given. Ekelund et al., found patients own weighing correlate well to control weighing at the clinic in 48-h pad test (r=0.99) (49).

Table 5: test-retest correlation

Author	Test	Correlation coefficient	Symptoms
Klarskov &Hald 1984 (24)	1-h	0.96	SUI&UUI
Lose et al 1986 (12)	1-h	0.68	SUI & MIX

Versi et al. 1996 (51)	48h	15	7.13		4.32		

Nygaard and Zmolek in 14 continent women showed a mean pad weight, attributed to sweat for all exercise sessions of 3.19 $\pm$ 3.16 g (the Kendall coefficient of concordance of the test-retest reliability was 0.96) but there was a lot of variation between patients (53). Pyridium staining was not helpful in increasing specificity. Similar results with Pyridium were reported by Wall et al. in a 1-hour ward test (14). In his study (n=18) the Pyridium test was 100% positive in patients with SUI but had false positive results in normal women (52%).

Mean pad weight loss due to evaporation or leakage (was calculated to be 1.003 g, and ranged from -6.5 to +3.85 g (SD 1.85 g) (9). Lose et al. showed no evidence of evaporation over 7 days if the pad was stored in a plastic bag (21). Versi et al. showed pads wetted with saline showed no difference in weight after 1 week and less than 10% weight loss after 8 weeks (51). Twelve pads were weighed by the patient and a healthcare worker with a coefficient of variance =1.55% with a mean deviation of 49%.

Comments

Pad tests can either be used as a qualitative diagnostic tool to diagnose urinary incontinence and as a quantitative test to grade its severity. Pad test is unable to distinguish among different types of incontinence such as stress, urgency or mixed urinary incontinence. The ICS definition of urinary incontinence (the complaint of any involuntary leakage of urine) does not describe how the diagnosis is made but clearly refers to a patient's complaint that excludes urodynamics and rather points at the patient perception of the condition. Following this line of thought, research in this area has moved away from the evaluation of diagnostic accuracy of pad test versus a urodynamic diagnosis of UI and entered the more interesting field of the relationship between the patient perception of UI and pad test. Franco and co-workers in London, UK tested the correlation between different questionnaires for UI and 1-hour pad test showing that only the ICIQ-SF reached statistical significance with a Kendall's τb of 0.177 and a P value of 0.037 while no significant correlation was found for a 0 to 10 Vas score, a patient-based 3-point symptom severity scale, Stamey grade, Urogenital Distress Inventory and the Incontinence Impact Questionnaire (IIQ-7) (56). In another study from Wijma and co-workers, the diagnostic accuracy of pad test for self-reported symptoms of UI was evaluated during pregnancy and after childbirth and the authors conclude that the diagnostic value of pad testing has no clinical relevance in this setting (57). A similar analysis, performed in a male population undergoing sling surgery for post-radical prostatectomy incontinence suggested a good correlation between ICIQ-SF and the Patient Global

Perception of Improvement (PGPI) with a 24-hour pad test (58).

Studies from the Urinary Incontinence Treatment Network in US investigated the relation between different measures of incontinence severity and showed how pad weight from a 24-hour test had a good correlation with the incontinence episode frequency derived from a 3-day bladder diary (Spearman correlation coefficient 0.61 but a much lower degree of correlation was found with questionnaires such as the Medical, Epidemiological, and Social Aspect of Aging (r=0.33), the Urogenital Distress Inventory (r=0.17) and the Incontinence Impact Questionnaire (r=0.34) (59). In the same study, the use of pad testing as a prognostic parameter for treatment outcome was investigated but 24-hour pad testing showed no prognostic value for treatment failure in a study of Burch colposuspension versus autologous rectus fascia sling (60). An interesting result was obtained in a predominantely female population of patients receiving neuromodulation for refractory urgency incontinence in which a 24-hour pad test performed after the initial test stimulation was able to predict long term satisfaction in this difficult patient population (61). In this, as in other studies, the number of pads used per day proved to be an unreliable measure of urinary incontinence (62).

A couple of important methodological issues have been raised concerning the use of pad testing. Khan & Chien eloquently pointed out that test-retest comparison should include methods of blinding and use of an appropriate index of degree of agreement which is the intra-class correlation coefficient. In most of the literature this was not implemented (63). Kromann-Andersen et al. argued that with considerable inter- and intra-individual variation of urine loss, the correlation of test/retest results may be overestimated and suggested different trials for small, modest and large leakage in large numbers of patients(64). This trial has not been carried out.

A recent Health Technology Assessment of pad testing concluded that although high sensitivity and specificity for the diagnosis of UI was reported in some studies, it was difficult to draw any conclusions about the diagnostic accuracy for SUI because of the differences existing in pad test methodology. The number of studies comparing the same pad tests with adequate reporting is insufficient and no formal pooling of published data could be performed (65).

Role of the investigation

The test has been standardised by ICS in 1988 for quantification of urine loss and suggested uses for assessment and comparison of treatment results for different types of urinary incontinence in different centres. Also, the AUA report on Surgical Management of Female Stress Urinary Incontinence includes a pad test (pretreatment evaluation) as a standard of efficiency for clinical trials (66). The Urodynamic Society included a pad test in a Standards of Efficacy for Evaluation of Treatment Outcomes in Urinary Incontinence (67). No suggestion was made in the last two reports of which test to use.

5. CONCLUSIONS

- The 1-hour pad test is not very accurate unless a fixed bladder volume is applied
- Set exercises during the test improve test-retest reliability
- The sequence of exercises has little effect on test results
- A pad weight gain $\geq$1 g suggests a positive 1h test
- A 24 hour test correlates well with symptoms of incontinence
- A 24-hour test has good reproducibility but poorer compliance
- A pad weight gain $\geq$1.3g = positive 24 h test
- A test lasting longer than 24 h has little advantage
- A pad test cannot distinguish between USI and DO

6. CONSENSUS STATEMENTS

- The pad test is an optional investigative tool in the routine evaluation of UI **(Level of Evidence 3, Grade of Recommendation C)**
- Pad test is a useful outcome measure in clinical trials and research studies. **(Level of Evidence 3, Grade of Recommendation C)**

The following standards are suggested:

- 20 min-1 h ward/office test with fixed bladder volume (pad weight gain ≥ 1g = positive test) **(Level of Evidence 3, Grade of Recommendation C)**
- 24 h home pad test during daily activity (pad weight gain ≥ 1.3g/24h = positive test) **(Level of Evidence 3, Grade of Recommendation C)**

7. FUTURE RESEARCH AREAS

Proper validation analysis using the coefficient of variability

Evaluation of the ability to detect all the spectrum of urinary incontinence (from mild to severe)

Sensitivity to change in time of incontinence status for 24 hour pad tests

Validity of pad tests with other measures of incontinence such as urinary diaries and symptom questionnaires.

V. NEUROPHYSIOLOGY

1. INTRODUCTION

Neurophysiological investigations of muscles and nerves in the perineum and pelvis originated in the 1930-ties, and have evolved with the developments in general clinical neurophysiology. The data from these investigations can assist clinicians in diagnosing neurological disease or injury; the tests can be used intraoperatively for identification of nerves and muscles.

This text details the investigations, their applications and limitations, enabling investigators and clinicians to make a well informed decision about using these tests.

The present text is based on the previous chapter on clinical neurophysiology prepared for the International Consultations on Incontinence (1), which has been updated by a literature search in Medline using key words incontinence, clinical neurophysiology, electromyography, reflex, evoked potentials, autonomic nervous system tests.

1.1. Classification of Clinical Neurophysiological Tests

Although different types of tests may be included under the term “neurophysiological”, it is particularly the electrophysiological tests that shall be discussed in the present text.

Electrophysiological tests are an extension of the clinical examination, and a functional anatomic approach to classification makes most sense. For the purpose of this categorisation, the nervous system is divided into the somatic and the autonomic nervous systems. The somatic nervous system provides motor innervation to the skeletal muscles and joints, and sensory innervation from skin and muscle spindles. The autonomic nervous system provides motor innervation to the viscera and other end-organs not under voluntary control (e.g., sweat glands). Its sensory fibres are referred to as visceral afferents. Both systems have central pathways (neurons participating in spinal cord and supraspinal control) and peripheral nerves (those going to and from end-organs).

Thus, electrophysiological tests can be divided into: a) somatic motor system tests (EMG, terminal motor latency measurements/ motor nerve conduction studies, and motor evoked potentials (MEP)); b) somatosensory system tests (sensory neurography, somatosensory evoked potentials (SEP)); c) reflexes; and d) the autonomic nervous system tests (for sympathetic or parasympathetic fibres).

Electrophysiological tests may also be categorised “technically” into those limited to simple recording some bioelectrical activity (for instance: electromyography), and those which record particular biological responses to anatomically localised stimulation (these may be subsumed under the term “conduction tests”).

1.2. Biological Correlates Of Electrophysiological Tests

1.2.1 Conduction Tests: Nerve Conduction, Evoked Potential and Reflex Studies

The electrophysiological responses obtained on stimulation are compound action potentials and relate to populations of biological units (neurons, axons, motor units, muscle fibres, etc.). Latency and amplitude are commonly measured parameters of responses during neurophysiological testing. If the onset of the potential is measured, the latency of a compound potential represents the fastest conduction through a particular neural channel. As a general rule, latency measurements are not markedly affected by technical factors, but provide little information about the loss of biological units (e.g., motor neurons or axons). The amplitude of the compound potential correlates with the number of activated biological units. In theory, the amplitudes are the more relevant physiological parameter, as they reflect the functional or structural loss of biological units. Unfortunately, amplitudes are also strongly influenced by many poorly controllable technical factors. Measurements of latencies and amplitudes of evoked potentials and reflex responses, including sympathetic skin responses, relate not only to conduction in peripheral and central neural pathways, but also to trans-synaptic transmission.

1.2.2 Electromyography (EMG)

Knowledge of the structure and function of the motor unit (Figure 47) is fundamental to understanding the application of EMG. Motor neurons, which innervate striated muscle, lie in the anterior horn of the spinal cord and are called “lower motor neurons”. (Neurons that innervate the sphincters lie in Onuf’s nucleus in the sacral spinal cord; they are somewhat smaller than those innervating skeletal limb and trunk muscles). Within the muscle, the motor axon branches to innervate a certain number of muscle fibres, which are scattered throughout the muscle. All muscle fibres innervated by one lower motor neuron are activated simultaneously; all these constituents together are called “motor unit”. The innervation of muscle fibres is such that it is unlikely that muscle fibres that are part of the same motor unit will be adjacent to one another.

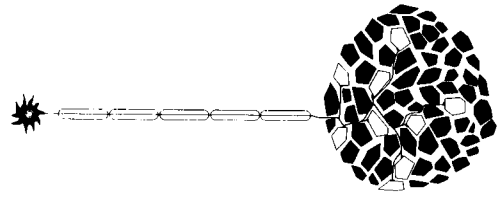

Figure 47: Schematic representation of a motor unit. The alpha motor neuron with its cell body, its myelinated axon and the peripheral nerve endings is shown. The muscle fibres innervated by this alpha motor neuron are shown in white. (Note that the muscle fibres from one motor unit are intermingled with motor fibres from other motor units).

It is difficult to estimate the number of muscle fibres innervated by a single axon (i.e., the "innervation ratio") or the number of motor units supplying a muscle, by clinically available neurophysiological techniques.

1.3. General Methodological Considerations

To date, there are no universally accepted standards for conducting individual uro-genital-anal neurophysiological tests, but the variations of testing in different laboratories are minor.

There are technical standards on equipment safety.

1.3.1 Equipment

Clinical neurophysiological tests are conducted with complex electronic instruments and various devices that come into contact with the patient. Though this equipment is mostly standard, some specially constructed electrodes or stimulating devices have been devised to conform to uro-genito-anal anatomy. As long as the standards of electrical safety are adhered to, the risk to patients is negligible.

Surface electrodes, which are applied to skin or mucosal surfaces, or needle electrodes are used for electrical stimulation and to record bioelectrical activity. The important neurophysiological difference between surface and needle electrodes is their selectivity, and the practical difference is their invasiveness. The choice and application of electrodes is guided by the need for selective recording or stimulation. Less commonly, special devices are used for magnetic and mechanical stimulation.

The electrical stimulation should be specified and characterised both in technical (e.g., rectangular electrical pulse, 0.2 ms, 15 mA) and physiological terms (e.g., 3-times sensory threshold). A stimulus with defined technical parameters may have variable biological effects because of the variable influences of electrode condition, contact, tissue conductivity etc. Supramaximal stimulation is preferred to elicit a compound muscle action potential (CMAP) or sensory nerve action potential. Supramaximal stimuli yield responses with the largest amplitude and shortest latency, and are the least variable and most reproducible. The sites at which stimulation electrodes are applied should be described using anatomical terms.

1.3.2 Recording

1.3.2.1 Apparatus settings

For recording, the apparatus settings (gain, sweep speed) have to be adapted to the known range of amplitudes, latencies, and duration of the response and it has to be appropriately displayed for analysis. Particularly important is the frequency setting of filters: for surface electrode recordings it is typically 2 Hz – 1 kHz; for concentric needle EMG recordings, it is 5 Hz – 10 kHz.

Placement of electrodes on the scalp for evoked potential recordings is defined according to the 10-20 International EEG System

1.3.2.2 Reproducibility and Reliability

Any potential recorded should be reproducible; therefore, as a rule, at least two to three consecutive recording procedures need to be performed. To improve the signal-to-noise ratio some small amplitude responses need to be averaged. Therefore, many repetitions of stimulation/recording need to be done (typically 100-200). Even such an averaged recording needs to be repeated at least twice. Responses whose nervous pathways include synapses may show marked fatiguability with stimulus repetition (e.g., SSR), others are facilitated (the bulbocavernosus reflex).

1.3.2.3 Waveform Analysis

For a particular recorded potential, its shape, latency, and amplitude are analysed. Morphologically, a particular response (or part of it) needs to be recognised as present or absent. The shape of potentials is important to accurately determine the latency and duration (if applicable) and amplitude of the response. The onset of the response obtained on stimulation (for M-waves, MEP and sacral reflex testing) or the individual peaks of the potentials (for SEP) are used to determine the latency. The amplitudes are analysed relative to the baseline or "peak to peak".

2. CLINICAL NEUROPHYSIOLOGICAL TESTS

2.1. Somatic Motor System Tests

2.1.1 Electromyography (EMG)

The term "EMG" is used for several different procedures, the common denominator of which is the recording of bioelectrical activity from muscle. In practice, EMG is used a) to record the activity of a particular striated muscle as a functional unit (as for instance in combined urethral sphincter EMG and a pressure-flow study - see kinesiological EMG); b) to indicate that a particular muscle has been activated, either by stimulation applied to its motor innervation (M-wave, MEP) or to sensory pathways (reflex response); c) to differentiate between normal, denervated, reinnervated, and myopathic striated muscle; and d) to measure neuromuscular transmission (the later is not relevant for clinical diagnostics in pelvic floor muscles).

EMG recordings from smooth muscles are as yet only experimental.

2.1.1.1 General Technique for Needle EMG in Pelvic Floor Striated Muscles

All tests requiring needle electrodes are invasive and some pain is inevitable, even with use of local anaesthetics. Local anaesthesia is infrequently used for needle EMG examination. Intramuscular electrodes need to be appropriately placed in the target muscle.

The pelvic floor and perineal muscles can be examined, including the levator ani, the bulbocavernosus muscle and the striated anal and urethral sphincter muscle. Facility with needle examination requires some practice. As a rule, several sites from one or more skin penetrations are sampled, which is difficult in small muscles.

The audio output from the loudspeaker of the EMG apparatus helps in assessment of the quality of recording as well as in recognition of the electrophysiological phenomena.

2.1.1.2 Concentric needle EMG (CNEMG)

The examination is conducted with a single use, disposable electrode, and all different "types of EMG" mentioned above can be performed with this electrode. It consists of a central insulated platinum wire inserted through a steel cannula and the tip ground to give an elliptical area which can record spike or near activity from about 20 muscle fibres.2 what's this? The number of motor units recorded therefore depends both upon the local arrangement of motor units within the muscle fascicle and the level of contraction of the muscle.

In principle, CNEMG can provide information on a) muscle insertion activity, b) abnormal spontaneous activity within the muscle (FIGURE 48), c) MUPs, d) interference pattern (IP), neuromuscular jitter.

In normal striated muscle, needle movement elicits a short burst of "insertion activity," which is due to mechanical stimulation of excitable muscle cell membranes. This is recorded at a gain setting of 50 µV per division (sweep speed 5 – 10 ms/division), which is also used to record spontaneous activity. Absence of insertion activity with appropriately placed needle electrode usually means a complete denervation atrophy of the examined muscle.

The amount of recruitable motor units during voluntary and reflex activation can also be estimated. Normally, MUPs should intermingle to produce an "interference" pattern on the oscilloscope during muscle contraction, and during a strong cough. In addition, the number of continuously active MUPs during relaxation,3 MUP variability (neuromuscular jitter) as well as MUP recruitment on reflex and voluntary activation (kinesiological parameters) can be observed.4

MUPs (and occasionally encountered end-plate activity) are recordable in normal resting sphincter muscles in a relaxed subject. This is in contrast to limb muscles where relaxation is associated with "electrical silence" by EMG. In addition to continuously firing motor units, new MUPs are recruited voluntarily and reflexly in the sphincters. It has been shown that the two MUP populations differ in their characteristics: reflexly or voluntarily activated "high-threshold MUPs" being larger than continuously active "low-threshold MUPs". As a consequence, standardised level of activity at which a template based multi-MUP analysis obtains 3-5 MUPs on a single muscle site was suggested.5

Although EMG abnormalities of striated muscle are detected as a result of a host of different lesions and diseases, there are in principle only two standard manifestations which can occur: a) disease of the muscle fibres themselves ("myogenic" changes), and b) changes in their innervation ("neuropathic" changes).

Myogenic changes may result from muscle disease, probably also from direct trauma (e.g., the anal sphincter tear during vaginal delivery). Neurogenic changes may be attributable to injury at any level along the lower motor neuron supplying the particular muscle, extending from the motor neuron body, sacral nerve roots to the small branches within the muscle. (In the pelvic floor muscles, only neurogenic changes are well recognised and routinely evaluated).

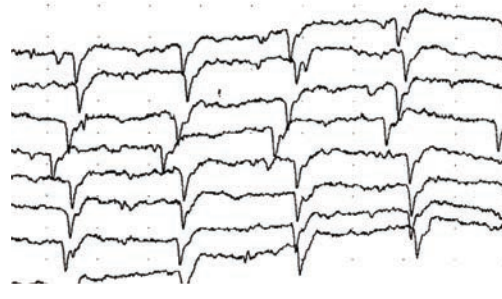

Figure 48: Concentric needle EMG recording from right bulbocavernosus muscle of a 49-years old male with urinary incontinence diagnosed as possible Multiple system atrophy. Pathological spontaneous activity (a burst of positive sharp waves) is shown.

In partially denervated sphincter muscle there is – by definition – a loss of motor units (MUs).

This can be estimated during relaxation by counting the number of continuously firing low-threshold MUPs. In patients with cauda equina or conus medullaris lesions, fewer MUPs fire continuously during relaxation,6 probably due to partial axonal loss. The main obstacle to qualified assessment of reduced number of activated MUs and activation of MUs at increased firing rates (as occurs in limb muscles) is a lack of concomitant measurement of level of contraction of the examined muscle (this can be readily assessed when studying limb muscles).

There are two approaches to analysing the bioelectrical activity of motor units: either analysis of individual motor unit potentials (MUPs), or analysis of the overall activity of intermingled MUPs. (This is the so called "interference pattern" – IP. Exploring different sites of the activated muscle with a needle electrode provides "samples" of intermingled motor unit potentials (IP epochs), which can be analysed).

Generally three different techniques of MUP analysis (manual-MUP, single-MUP and multi-MUP) and 1 technique of IP analysis (turn/amplitude – T/A) are available on advanced EMG systems.6

It is easy to grasp the "motor unit potential analysis", as it is simply a measurement (by different methods) of the "parameters" of single individual MUPs (ie. its amplitude, duration, number of phases…). The changes in MUP parameters furthermore are "direct" results of understandable physiological changes, and are thus "meaningful" to the interpreter.

The changes in IP parameters are, however, less readily grasped. These are: numbers of turns per second (any peak or trough of the signal where the activity changes by more than 100 μV); amplitude/turn (change in volts between two turns); number of short segments (parts of signal that has "sharp" activity) percent activity (percent of epoch with sharp activity); envelope (peak to trough amplitude exceeded by 1% of peaks/troughs). These parameters relate both to MUP parameters and to the activation level of the muscle. Recorded data are log transformed and linear regression lines are created. Amplitude/turn, and number of turns/second data from normal subjects can be used to create upper and lower boundaries (95 % confidence intervals) for assembly of future data from individual patients. Individual data create a scatter plot ("cloud") which compares to the normative boundaries. (See Figure 49). It has been asserted that this approach does not require a standardised muscle contraction, but the shape of the "cloud" is dependent on the strength of muscle contraction. Therefore it has been suggested to standardisze the method by measuring pressure exerted by the contracting sphincter.7

Both the template based multi-MUP analysis of MUP and T/A analysis of IP are fast (5-10 and 2-3 minutes per muscle, respectively), easy to apply, and, technically, represent clinically useful techniques.

2.1.1.2.1 CNEMG Findings Due to Denervation and Reinnervation

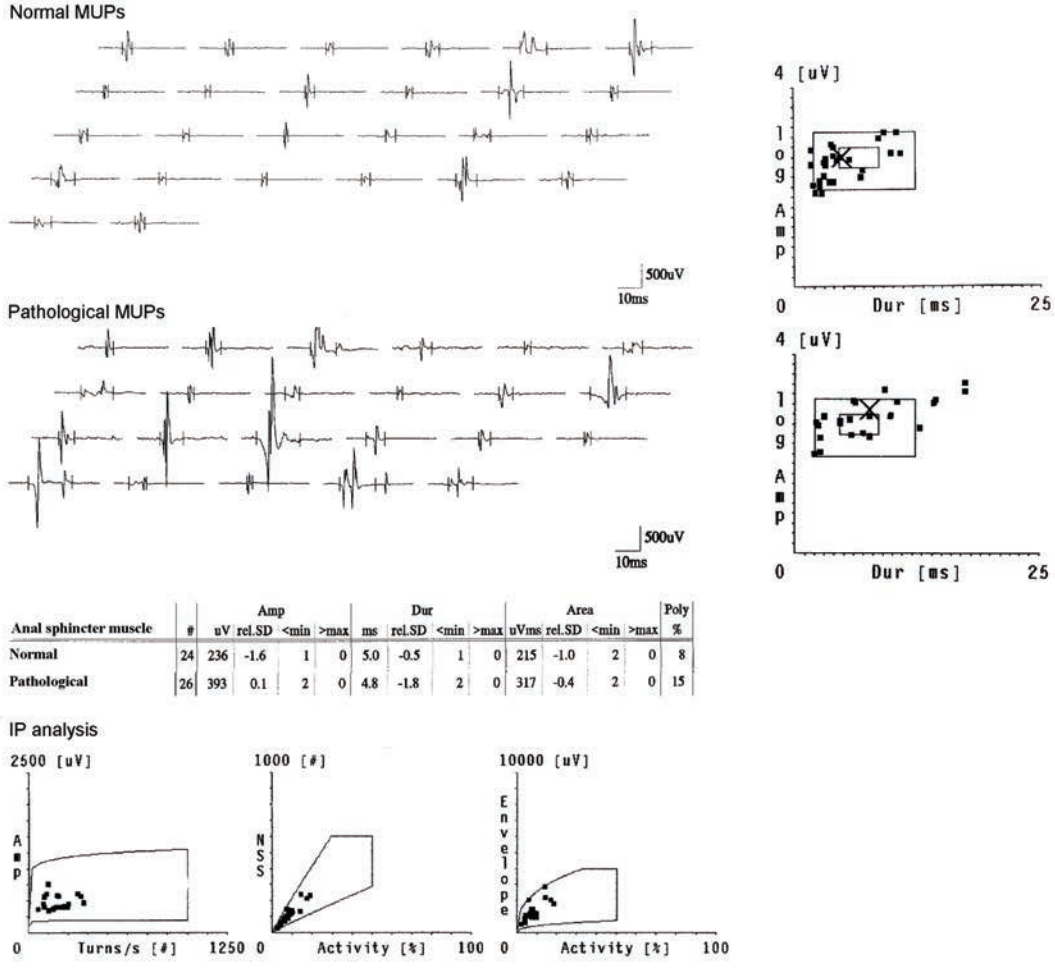
After complete denervation, all motor unit activity ceases. In a denervated muscle, complete "electrical silence" is noted in the first days after such an event. The diagnosis of complete denervation is confirmed by the absence of muscle response during electrical stimulation. Because motor axons take days to degenerate after injury, this proof is not available for up to 5-7 days after a denervation injury. However, it is rarely necessary to demonstrate complete denervation in the acute stage because the clinical condition is usually obvious. Denervated muscle fibres become hyperexcitable and start to fire spontaneously giving rise to abnormal spontaneous activity, but these may take up to three weeks to appear. The "insertion activity" becomes prolonged and short biphasic spikes (fibrillation potentials) and biphasic potentials with prominent positive deflections (positive sharp waves) appear (Fig 48). Thus, concentric needle EMG (CNEMG) correlates of denervation are pathologically prolonged insertion activity and pathological spontaneous activity. Completely denervated muscle may be reinnervated by axonal regrowth from the proximal nerve stump with few muscle fibres constituting "nascent" motor units. These are short, bi- and triphasic, soon becoming polyphasic, serrated and with prolonged duration. In partially denervated muscle, collateral reinnervation takes place. Surviving motor axons will sprout and grow out to reinnervate those muscle fibres that have lost their nerve supply. This results in a change in the arrangement of muscle fibres within the unit. Whereas in healthy muscle, it is unusual for two adjacent muscle fibres to be part of the same motor unit, following reinnervation, several muscle fibres belonging to the same motor unit come to be adjacent to one another. CNEMG correlates are changes in MUPs (duration, amplitude, number of phases, turns, etc). Early in the process of reinnervation, the newly outgrown motor sprouts are thin. Therefore, they conduct slowly such that the time taken for excitatory impulses to spread through the axonal tree is abnormally prolonged. Moreover, the neuromuscular transmission is unstable due to immaturity of the motor end-plates. The CNEMG correlate is instability of long-duration complex potentials.

In partially denervated muscle, some MUPs remain and mingle eventually with abnormal spontaneous activity. Changes due to collateral reinnervation are reflected by: prolongation of the wave form of the MUP (Fig 49) which may have small, late components ("satellite potentials"). MUPs show "instability" due to insecure transmission in newly formed axon sprouts and end-plates. This "instability of potentials" (meaning both "jitter" and "blocking" of individual components in a complex potential) is not routinely assessed during sphincter EMG.8 In striated muscle, the diameter of reinnervating axonal sprouts and conduction velocity increase with time, thereby improving

synchrony of activation in the reinnervated motor unit. Thus MUP amplitude increases while MUP duration reverts towards normal. However, in degenerative neurological diseases (such as multiple system atrophy), long duration motor units are a prominent feature of anal sphincter reinnervation.9 It is important to note that in patients with more severe neurogenic lesions, reinnervation may be inefficient resulting in MUP with parameters below confidence limits describing size (area, duration).10

The changes in MUP parameters (along with changed number of MUPs and changes in activation frequency of MUPs) will be reflected also in IP parameters.

Abnormalities of parameters evaluated by needle EMG are in principle non-specific, i.e. most abnormalities can occur both in neuropathic or myopathic conditions. It is the overall clinical picture that dictates interpretation of results. It has been suggested that the combination of MUP thickness and number of turns might be even more accurate11 than previously suggested combination of MUP area, duration, and number of turns.12



Anal sphincter muscle	#	Amp uV	Amp rel.SD	Amp <min	Amp >max	Dur ms	Dur rel.SD	Dur <min	Dur >max	Area uVms	Area rel.SD	Area <min	Area >max	Poly %
Normal	24	236	-1.6	1	0	5.0	-0.5	1	0	215	-1.0	2	0	8
Pathological	26	393	0.1	2	0	4.8	-1.8	2	0	317	-0.4	2	0	15

Figure 49: Comparison of normal (above) and pathological (below) motor unit potentials (MUPs) sampled by multi-MUP analysis from the right halves of the subcutaneous parts of the external anal sphincter (EAS) muscles. To the right logarithm (amplitude) vs. duration plots of the MUPs are shown; the inner rectangle presents normative range for mean

2.1.1.2.2 CNEMG of the External Anal Sphincter

The external anal sphincter (EAS) is the most practical indicator muscle for sacral myotomes because it is easy to access, has enough muscle bulk for exact EMG analysis, and its examination is not too uncomfortable.

The needle electrode is inserted into the subcutaneous EAS muscle about 1 cm from the anal orifice, to

a depth of a 3-6 mm under the non-keratinised epithelium. For the deeper part of the EAS muscle 1-3 cm deep insertions are made at the anal orifice, at an angle of about 30° to the anal canal axis.13 In most patients only examination of the subcutaneous EAS muscle is necessary. Separate examinations of the left and right EAS muscles are recommended. The needle is inserted into the middle of the anterior and posterior halves of each side ("quadrants") of the EAS muscle. After insertion in two positions on each side the electrode is turned backwards and forwards in a systematic manner. At least 4 sites in each of the subcutaneous and/or the deeper EAS muscle are thus analysed.13, 14

Use of quantitative MUP and IP analyses of the EAS is further facilitated by the availability of normative values15 that can be introduced into the EMG systems' software. It has been shown that normative data are not significantly affected by age, gender,15 number of uncomplicated vaginal deliveries,16 mild chronic constipation,17 and the part of EAS muscle (i.e. subcutaneous or deeper) examined.16

Intramuscular electrode insertion into other perineal muscles and pelvic floor muscles is not standardized and is described in textbooks and primary literature.

2.1.1.3 Single fibre EMG (SFEMG)

SFEMG is nowadays used practically only in diagnostics of neuromuscular transmission disorders, and not anymore in the pelvic floor muscles.

The SFEMG electrode has similar external proportions to a concentric needle electrode, but with a smaller recording surface. It will pick up activity from within a hemispherical muscle volume 300 µm in diameter, much smaller than the volume of 2-3 mm diameter from which a concentric needle electrode records.2 Apart from the neuromuscular jitter it can also record data which reflect motor unit morphology (muscle fiber density)8 but for this purpose it has several disadvantages in comparison to the concentric needle EMG.

2.1.1.4 Kinesiological EMG

Kinesiological EMG is the term for the type of EMG recording aimed only to assess the pattern of an individual muscle's activity/inactivity during defined manoeuvres (Fig 50), typically during urodynamics. Any type of electrode can be used to make kinesiological recordings. The electrical activity of a muscle is described as present or absent (and can also be quantified). Technical issues will be dealt here; the relevance for diagnostics will be discussed in the Chapter on dynamic testing.

Although either standard EMG equipment or EMG facilities contained within urodynamic systems can be used, the better visual and audio control provided by standard EMG equipment facilitate optimal electrode placement and improve recordings.18 When using surface electrodes there are problems related to validity of signal (e.g., artefacts, contamination from other muscles). The quality of the EMG recorded from the external urethral sphincter (EUS) muscle is improved by a catheter-mounted surface electrode device that applies mild suction.19 With intramuscular electrodes, the procedure is more invasive, and there are questions as to whether the whole muscle in large pelvic floor muscles is properly represented by the sampled muscle portions. Intramuscular electrodes should ideally be fine wire electrodes, as they do not dislodge, and no pain is induced with muscle contraction.

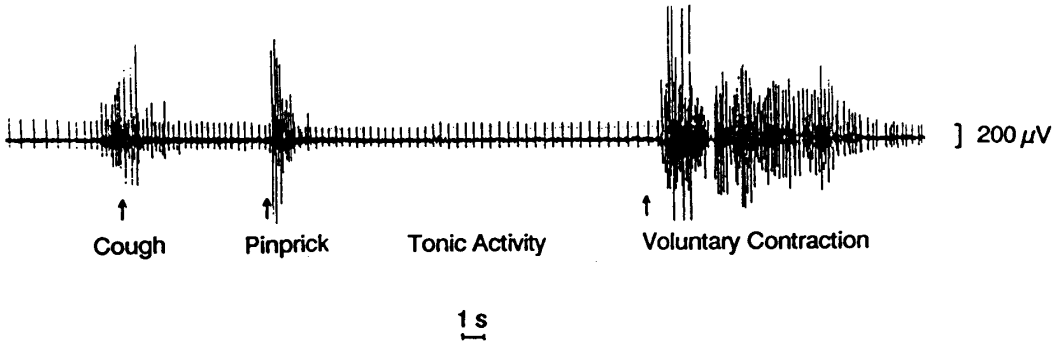


Figure 50: Kinesiological EMG recording from the urethral sphincter muscle of a healthy 53 years old continent female. Recruitment of motor units on reflex manoeuvres and on a command to contract is shown; regular continuous activity of motor units represents "tonic activity". (Recorded with concentric needle electrode).

The kinesiological sphincter EMG recordings in health show continuous activity of MUPs at rest. It can be recorded in many but not all detection sites of the levator ani muscle. The urethral and anal sphincter as well as the other pelvic floor musculature (e.g. puboccocigei) can be voluntarily activated typically for less than 1 minute.20 Timely activation of the levator ani muscle has been demonstrated to be an important aspect of stable bladder neck support; its activation precedes activity of other muscles in the cough re-

flex.21 A consistent contraction sequence of the superficial and deep pelvic floor muscles is found in continent but not in incontinent women.22

Sphincter activity during voiding is characterised by the cessation of all EMG activity prior to detrusor contraction. Needle electrodes are more useful than perineal patch electrodes to demonstrate MU quiescence during voiding.23,24

Pathologic incoordination of the detrusor and sphincter is called detrusor sphincter dyssynergia. In selected patients with neurogenic detrusor overactivity, EMG of the EUS muscle can be used to demonstrate the onset of detrusor contractions.20

Apart from polygraph urodynamic recordings to assess detrusor-sphincter coordination, thediagnostic usefulness of kinesiologic EMG has not been established.

2.1.1.4.1 Surface Electromyography Using Noninvasive Electrode Arrays

Surface EMG recording using noninvasive electrode arrays and multichannel EMG amplifiers can localize muscle innervation zones and asymmetry in muscle innervation,25 and analyze discharge patterns of MUPs, and propagation velocities along the muscle fibers.26 While it is expected that the new sophisticated computer assisted analysis techniques will help diagnosing sphincter function (for instance the “circumferential urinary sphincter surface electromyography«27) the clinical value of new methods has not yet been widely explored and validated.

2.1.1.5 Clinical application of EMG

2.1.1.5.1 Neurogenic Conditions

Trauma, surgery (for instance: radical prostatectomy 28), and neurological disease have all been implicated in denervation of pelvic floor and perineal muscles and pelvic organs. In a series of 194 consecutive patients referred for electrodiagnostic evaluation, quantitative needle EMG of the EAS muscles supported a diagnosis of a cauda equina or conus medullaris lesion in 36 patients, a lesion of the EAS muscle in 6, a pudendal nerve lesion in 2, and a sacral plexus lesion in 1 patient. Furthermore, neuropathic findings in the EAS were compatible with a diagnosis of multisystem atrophy in 11, and were most probably caused by severe polyneuropathy in 2 patients. In another 11 patients, the aetiology of the pathological findings could not be established at time of electrodiagnostic testing.29

Lesions of the cauda equina or conus medullaris commonly cause pelvic floor dysfunction. These have mainly been a consequence of neural compression within the spinal canal caused by intervertebral disc herniation, spinal fractures, epidural hematomas, and intraspinal tumours; or a result of spinal surgery, mainly on lumbar discs.30 Electrodiagnostic tests are also useful in the assessment of neurogenic lesions in children with spinal dysraphism.31 After detailed clinical examination of the lumbosacral segments (with particular emphasis on perianal sensation), neurophysiologialc testing assesses the severity of the lesion and may clarify the diagnosis. In the authors’ series, 10 percent of patients with cauda equina lesions reported normal perianal sensation.32 Electrodiagnostic tests that need to be considered are bilateral needle EMG of the EAS muscle and the bulbocavernosus muscle in subacute situations; and electrophysiological evaluation of the bulbocavernosus reflex33,34 Detection of spontaneous denervation activity by needle EMG (in the bulbocavernosus muscle!) is common from approximately 3 weeks to several months after injury. Later, MUP analysis becomes more important for demonstrating reinnervation. Most of these lesions cause partial denervation; a traumatic lesion to the lumbosacral spine or pelvis is probably the only acquired condition in which complete denervation of the perineal muscles can be observed.35, 36, 37

Following a cauda equina or a conus medullaris lesion, the MUP of pelvic floor and perineal muscles are prolonged and polyphasic, of increased amplitude, area, number of turns.6 Surgical dissections can also affect the innervation of the sphincter and lead to loss of motor units and reinnervation of those surviving.38 After pelvic trauma, gross changes of denervation and reinnervation may be detected in pelvic floor muscles. Abnormalities in polyneuropathy, as for instance diabetic, are usually minor.39

Neuropathic changes can be recorded in sphincter muscles of patients with multiple system atrophy (MSA), a progressive neurodegenerative disease, which can be mistaken for Parkinson's disease (PD). 40 Among 30 patients with a pathological diagnosis of multisystem atrophy, 24 had abnormal, 5 had a borderline, and only 1 had a normal sphincter EMG.41 Sphincter EMG has been ***proposed*** to distinguishing MSA from Parkinson's disease, but is probably not specific in the later stages of parkinsonism, and may not be sensitive enough in the early phase of the disease,42 43 44 Some studies have failed to demonstrate the effectiveness of MUP analysis in sphincter muscles,45, 46 probably because of the exclusion of late components from MUP duration.9 Extensive discussion on the subject can be found elsewhere.47 The changes of chronic reinnervation may also be found in progressive supranuclear palsy,48, 49 and in Machado–Joseph disease,50 in which neuronal loss in Onuf’s nucleus has also been demonstrated histologically.51

In patients with acute idiopathic autonomic neuropathy and lower urinary tract (LUT) dysfunction the EMG of external sphincter muscles was reported as normal.52

2.1.1.5.2 Changes in Primary Muscle Disease

In skeletal muscle, the “typical” features of a myopathy are small, low amplitude polyphasic units recruited at mild effort. There are few reports of pelvic floor muscle EMG in generalised myopathy. In a nulliparous woman with limb-girdle muscular dystrophy, histology revealed involvement of pelvic floor muscles, but concentric needle EMG of the urethral sphincter was normal.53 Myopathic EMG changes were observed in the puborectalis and the EAS in patients with myotonic dystrophy,54 but not in another group of patients with myopathy.55

2.1.1.5.3 Stress Incontinence

Pelvic floor muscle denervation has been implicated in the pathophysiology of ? USI (GSI).56 EMG techniques have been used to identify sphincter injury after childbirth and to evaluate women with USI. SUI and POP were associated with partial denervation of the pelvic floor.57 The changes were most marked in women who were incontinent after delivery, who had a prolonged second stage of labour, and had given birth to heavier babies. In a recent study, nearly all EMG parameters showed significant differences between continent and SUI women consistent with better motor unit recruitment in continent women. Continent women had larger-amplitude, longer-duration MUPs with increased turns and better MUP recruitment during bladder filling ($P < 0.05$).58

Myogenic histological changes in pelvic floor muscles after vaginal delivery were also reported,59 with some EMG support by another group.60 “Myopathic EMG changes” (i.e. short, small MUPs) may, however, be a consequence of deficient reinnervation.35 There were claims urethral sphincter EMG can assist in selecting the type of surgery for patients with intrinsic sphincter deficiency.59

Although CNEMG of the urethral sphincter seems the logical choice in patients with urinary incontinence of possibly neurogenic origin, only a small amount of pathological muscle tissue remains in many incontinent parous women, which makes EMG of the muscle impractical.38 CNEMG findings generally will not affect therapeutic considerations.61

2.1.1.5.4 Idiopathic Faecal Incontinence

“Idiopathic” faecal incontinence refers to patients in whom this symptom is not attributable to an underlying disorder, but it has been often implied that it is a neurogenic condition. Vaginal delivery is proven to cause structural sphincter defects; it may cause outright sphincter denervation in rare cases, but its more widespread implication in causing “idiopathic” incontinence is controversial.

CNEMG may be helpful in selected patients with faecal incontinence if a specific neurogenic condition (e.g., trauma or disease affecting the conus, sacral roots, sacral plexus or pudendal nerves) is suspected on clinical grounds.

External anal sphincter muscle innervation pattern evaluation by multichannel surface EMG has been claimed to offer information to the obstetrician to prevent damaging episiotomies.62

2.1.1.5.5 Idiopathic Urinary Retention in Women

In the external urethral sphincter of young women with urinary retention (or obstructed voiding) complex repetitive discharges (and decelerating bursts) in profuse amounts have been described.63, 64 The abnormality was reported to be a predictor of the long-term success of therapeutic sacral neuromodulation.65 In a group of such women an occult generalised dysautonomia was found.66

It has been known before that repetitive discharges develop in chronically partially denervated sphincters, and that they are present even in a proportion of asymptomatic women. Recently, it has been shown that this activity changes during the menstrual cycle (more commonly found in the luteal phase of the menstrual cycle in asympomatic women). The importance of this »abnormal«EMG activity in the aetiology of urinary retention in young women remains uncertain.67

Currently, the diagnosis of Fowler syndrome remains a clinical one, based on a multimodal assessment of the patient.

2.1.1.5.6 EMG in Urodynamic and Functional Anorectal Studies

In health, voiding is characterised by cessation of motor unit firing in the urethral sphincter prior to detrusor contraction, as can be demonstrated by recording of “kinesiological EMG”. Bladder-sphincter coordination is impaired with lesions between the lower sacral segments and the upper pons. Consequently, sphincter activity is not inhibited, and often increases before detrusor contraction (i.e., 'detrusor-sphincter dyssynergia'). On the basis of the temporal relationship between urethral sphincter and detrusor contractions, three types of dyssynergia have been described.68

There are other clinical situations that mimic detrusor sphincter dyssynergia. Sphincter contraction or at least failure of relaxation during involuntary detrusor contractions can be seen in patients with Parkinson's disease. The pelvic floor muscle contractions of the so-called nonneurogenic voiding dyssynergia may be a learned abnormal behaviour,69 and are a feature of dysfunctional voiding.64 There is insufficient data to determine the nature of the non-relaxation of sphincter activity as demonstrated by EMG signals during micturition (often seen in children and females) by EMG as such. The EMG recording has to be interpreted in the light of the overall clinical picture of the examinee.

The pubococcygeus in the healthy female reveals similar activity patterns to the urethral and anal sphincters at most detection sites: continuous activity at rest, often some increase of activity during bladder

filling, and reflex increases in activity during any activation manoeuvre performed by the subject such as talking, deep breathing, coughing. The pubococcygeus relaxes during voiding; the muscles on either side act in unison.20 In stressincontinent patients, the patterns of activation and the co-ordination between the two sides can be lost.70 A delay in muscle activation on coughing has also been demonstrated, as compared to continent women.21

Little is known about the complex activity patterns of different pelvic floor muscles (the urethral sphincter, urethrovaginal sphincter, anal sphincter muscle, different parts of the levator ani) during different manoeuvres. It is generally assumed that they all act in a co-ordinated fashion functionally as one muscle. However there are demonstrable differences between the intra- and peri-urethral sphincter in healthy females71 and in activation of the levator ani and the urethral sphincter.72 Co-ordinated behaviour is frequently lost in abnormal conditions.

Kinesiological needle EMG analysis of the urethra with the patient at rest and coughing may predict the outcome after certain types of incontinence surgery.73 However, other studies found that preoperative EMG did not predict patients at risk for postoperative voiding dysfunction. (Kirby AC, Nager,CW, Litman,HJ et al. Perineal Surface Electromyography Does Not Typically Demonstrate Expected Relaxation During Normal Voiding Neurourology and Urodynamics 30:1591–1596 (2011)

Indeed, while kinesiological EMG (particularly when combined with other urodynamic tests) promises theoretically relevant data, technical standards are lacking, and findings have been reported in single center studies. Further basic research is necessary to delineate the correlation of EMG signals and their interpretation in terms of clinical significance (the significance of EMG data for defining overall LUT function).

Current concepts suggest that defecation requires increased rectal pressure co-ordinated with relaxation of the anal sphincters and pelvic floor muscles. Pelvic floor relaxation allows opening of the anorectal angle and perineal descent, facilitating faecal expulsion. During defecation puborectalis activity is as a rule inhibited, but was unchanged in 9 % and increased in 25 % of healthy subjects.74 Thus, while “paradoxical” puborectalis contraction during defecation is used to diagnose pelvic floor dyssynergia in patients with typical symptoms, this finding may be a variation of the normal.

Same considerations regarding the lack of controlled studies, technical standards, etc. apply as stated above for kinesiological EMG in studies of LUT function.

2.1.2 Pudendal Nerve Conduction Tests

Measurement of motor conduction velocity is routinely used to evaluate limb nerves, distinguishing between a demyelinating and axonal neuropathy. To make the measurement requires access to the nerve at two well-separated points and measurement of the distance between them, a requirement that cannot be met in the pelvis. Another way to evaluate peripheral motor nerve function is the measurement of the latency of a muscle response, requiring only a single stimulation site. The muscle response is the compound muscle action potential (CMAP) or M-wave. Because in limb nerves the site of stimulation to obtain only the motor latency (without measuring the actual conduction velocity) is as a rule placed distally on the nerve, it is also called the distal (or terminal) latency. For the pudendal nerve the site of stimulation may be more or less “distally”, but the term distal or terminal has – in accordance to general clinical neurophysiology – become generally used. Distal motor latency can be measured by recording with a concentric needle electrode from the bulbocavernosus, the EAS and the EUS muscles in response to bipolar surface stimulation placed in the perianal/perineal region, or with needle electrode stimulation of the pudendal nerve in the perineum. The most widely employed technique to obtain pudendal nerve terminal motor latency (PNTML) relies on stimulation with a special surface electrode assembly fixed on a gloved index finger, known as the St Mark's stimulator.75 It consists of a bipolar stimulating electrode on the tip of the gloved finger with the recording electrode pair placed proximally on the base of the finger. The finger is inserted into the rectum or vagina and stimulation is applied close to the ischial spine. It is assumed that, using this approach, the pudendal nerve is stimulated close to the ischial spine, and that the response recorded is of the EAS muscle. In women, intravaginal stimulation and recording from the bulbocavernosus muscles has also been undertaken, with similar distal latencies.76 However, the latency of such a response is typically only around 2 msec, which seems unusually short compared with the perineal technique and with conduction in the much thicker motor fibers of peripheral nerves in the limbs. It seems unlikely that the PNTML using the St. Mark’s electrode really evaluates conduction along the last 8 cm of the pudendal nerve. Stimulation of the terminal pudendal branches or pelvic floor muscles near their motor points seems more likely, and this is supported by the much longer PNTML (3.7 ± 0.9 msec) obtained with a monopolar intrarectal stimulation electrode.77 If a catheter-mounted electrode is used for recording, EMG responses from the striated muscle of the urethral sphincter can be obtained. Experts differ in their estimation of validity of this test. A prospective evaluation of anorectal physiologic tests in 90 patients with faecal incontinence did not find that PNTML results changed treatment decisions.78 Indeed, the American Gastroenterological Association statement indicated that “PNTML

2.1.3 Anterior Sacral Root (Cauda Equina) Stimulation

Anterior root stimulation has been used to study conduction of the sacral nerve roots. Electrical stimulation with needle electrodes at vertebral laminae Th12-

LI elicits M-waves in the bulbocavernosus and EAS muscle.80

Transcutaneous stimulation of deeply situated nervous tissue became possible with development of special electrical and magnetic stimulators. When applied over the spine, these stimulators activate the roots as they exit the vertebral canal. Needle EMG rather than non-selective surface electrodes should be used to record pelvic floor and particularly sphincter responses to electrical or magnetic stimulation of the cauda equina. These stimuli non-selectively depolarise underlying neural structures, thereby activating several muscles innervated by lumbosacral segments.81 Lumbosacral stimulation often evokes a large stimulus artifact that can be decreased by positioning the ground electrode between the stimulating and recording electrodes.82 Invasive percutaneous stimulation of individual roots in sacral foramina is used to identify patients with lower urinary and anorectal dysfunction who are likely to benefit from long-term stimulation, e.g. with the Interstim (Medtronic, Inc., Minneapolis, USA). Electrical stimulation of nerve roots at the level of the appropriate sacral foramina results in observable muscle contraction in the foot and perineum. These responses can be identified as MEP or reflex responses on the basis of their latency. Selective stimulation of individual sacral roots is possible by appropriate positioning of surface stimulating electrodes.83

In conclusion, demonstrating the presence of a perineal MEP on stimulation over lumbosacral spine may occasionally be helpful in patients without voluntarily activated muscles. It also identifies the particular nerve root before introducing therapeutic electrical stimulation. However, the clinical value of the test has yet to be established and there are no sensitivity and specificity data on test results in individual patients.

2.1.4 Motor Evoked Potentials

Using magnetic or electric stimulation, it is possible to depolarise the motor cortex and record a response from the pelvic floor. Magnetic cortical stimulation is better tolerated than electrical stimulation, which has been abandoned in awake subjects, but may be useful for intraoperative monitoring.

By performing the stimulation at two different sites (brain and spinal roots), it is possible to record three different conduction times: a total conduction time, a peripheral conduction time, and a central conduction time (Fig 51). The total conduction time corresponds to the transit time from brain to target muscle. The peripheral conduction time is the transit time from sacral roots to the muscle. The central conduction time is obtained by subtracting the peripheral conduction time from the total conduction time. The total conduction time can be measured both at rest and during a facilitation procedure. MEPs from the EAS, the urethral sphincter, the bulbocavernosus muscle, and the levator ani muscle have been reported, but normative values have only been obtained (for transcranial magnetic stimulation) for the urethral sphincter and the puborectal muscle in adult women.84 A central conduction time of 15 to 16 msec without and 13 to 14 msec with facilitation is obtained for pelvic floor and sphincter muscles.85, 86, 87 The necessity to use concentric needle EMG for recording has been reconfirmed.88

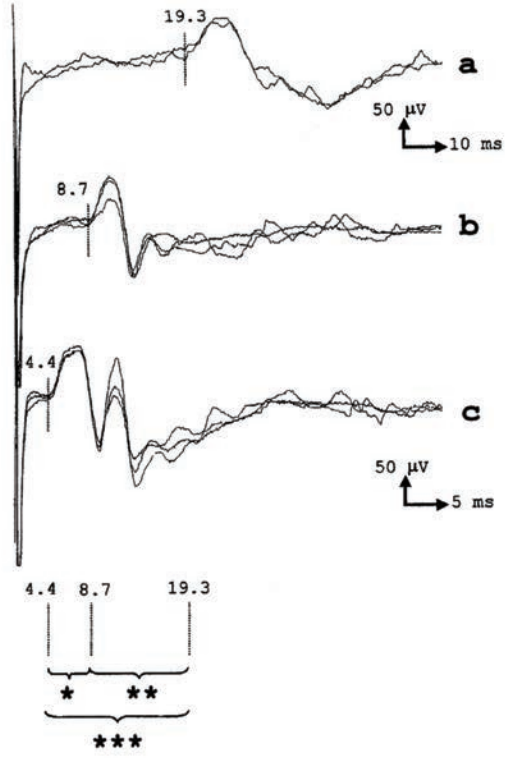

Figure 51: MEPs recorded by concentric needle in the external urethral sphincter of a 51-year-old-woman. Cortical (a), thoracic (b), and sacral (c) stimulation. Central motor conduction time (CMCT) is calculated as cortical - lumbar latency (** = 10.6 ms). Cauda equina motor conduction time is calculated as lumbar - sacral latency (* = 4.3 ms). (From (Brostrom et al., 2003a), with permission).

Substantially longer central conduction times have been found in patients with multiple sclerosis and spinal cord lesions as compared to healthy controls.87, 88, 89 However all patients in this study had clinically recognisable cord disease. Nevertheless, MEPs may be useful in patients with unclear localization of spinal lesions.87

Conceptually, MEP may help to differentiate between involvement of motor and sensory pathways. However, the clinical utility of these measurements is not established. MEP have opened an avenue of research on excitability of motor cortex. It has been demonstrated that in comparison to the motor area for hand muscles the anal sphincter motor cortex has less intracortical inhibition.90

2.2. Sensory System Tests

There are several methods of sensory testing for the perineum, the genitourinary and anorectal tract. Clinical testing includes perineal and external genital skin sensation for light touch and pinprick, and sensation of bladder filling during cystometry. Anorectal sensory testing can be clinically assessed through rating of applied stimuli. More objective sensory testing can be performed with quantitative sensory testing (QST), which assesses sensory perception. For evaluation of the integrity of sensory pathways sensory neurography, and somatosensory evoked potentials (SEP) can be used.

2.2.1 Sensory Measurements During Cystometry

During routine cystometry bladder sensation is assessed by recording first sensation of bladder filling, first desire to void and strong desire to void.

Although not strictly a neurophysiologic test, measurement of electrical thresholds adds clinically non-obtainable information on sensory function of the lower urinary tract.91 Bladder and urethral sensory thresholds have also been measured using electrical stimulation,91 and mechanical traction on the bladder trigone.92 Electrical currents are applied to the bladder, urethra or genital skin using catheter-mounted or surface electrodes. High-frequency stimulation (> 20 Hz), with a stimulus duration of 0.5 or 1 msec is used because it is more easily perceived in the lower urinary tract. Measurement of sensory thresholds with such stimulation is reproducible, and normative data have been published.91 To date it has been used in only a few conditions (e.g., painful bladder syndrome93). There is no established clinical use for any of these tests other than simple reporting of sensation during cystometry.

In addition, palmar SSR and perineal surface EMG recordings can be used for more objectively demonstrating sensations during cystometry. The activity of both appears and increases in parallel with the first sensation of bladder filling, and with the first desire to void, respectively.94 Further studies using these methods are needed to establish their clinical utility.

2.2.2 Assessment of Anorectal Sensation

Rectal sensation is assessed by progressively distending a balloon manually or by a barostat while measuring thresholds for first perception, desire to defaecate, and severe discomfort. The intensity of perception during rectal distension can be recorded by a visual analogue scale during phasic distensions of graded intensity.95 The rate and pattern of distension affect rectal perception and internal sphincter relaxation.96

Anal sensation can be assessed by determining the perception threshold to an electrical stimulus or temperature change in the anal canal. Electrical testing does not activate mucosal receptors. Anal sensitivity to temperature change has been reported reduced in faecal incontinence.97

2.2.3 Quantitative Sensory Testing

Quantitative sensory testing (QST) of the urogenitoanal system should provide more objective and reproducible data than routine clinical testing. QST sensory modalities applied to the evaluation of urogenital function include vibration,98 temperature,99 and electrical current.100 (See also Sensory Measurements During Cystometry). There is no commonly accepted, detailed, standardised test, and the specificity and sensitivity of the tests are not known. The relationship of cutaneous quantitative sensory tests to bladder and urethral sensation and function is unknown. The physiological, psychophysiological and methodological issues and controversies will not be addressed in this chapter.

2.2.4 Sensory Neurography

Nerve conduction velocities of the dorsal nerve of the penis can be calculated by placing a pair of stimulating electrodes across the glans and a pair of recording electrodes across the base of penis. A nerve action potential can be recorded with an amplitude of about 10 μV. It can also be recorded by stimulating the nerve trans-rectally or transperineally. There is no known association between penile sensory neuropathy and bladder/sphincter dysfunction.

A few studies have recorded activity in sacral roots during electrical stimulation. Intraoperatively, when the sacral roots are exposed, compound sensory action potentials on stimulation of dorsal penile and clitoral nerve may be recorded directly.101 This helps to preserve roots mediating perineal sensation in spastic children undergoing dorsal rhizotomy, and reduce the incidence of postoperative voiding dysfunction.102 These tests are limited to their very specific intraoperative indications.

2.2.5 Somatosensory Evoked Potentials (SEP)

Somatosensory evoked potentials are electric waveforms of biological origin elicited by stimulation of a sensory nerve (or a sensory innervated skin area – dermatome). The most commonly performed tests in the urogenitoanal region are pudendal somatosensory evoked potentials (SEP), which assesses conduction in large fibre pathways between the site of nerve stimulation and the parietal sensory cortex. Potentials can also be measured at the spinal level (spinal SEP).

Visceral (thin) fibre pathways are assessed by recording SEPs while stimulating the proximal urethra and bladder, although this is technically not depolarisation of nerves, but a mesh of afferents.

2.2.5.1 Pudendal Somatosensory Evoked Potentials

2.2.5.1.1 Cerebral Pudendal SEP

On electrical stimulation of the dorsal penile/clitoral or perineal nerve, a cerebral SEP can be recorded. (Fig 52) This SEP is as a rule of highest amplitude at the central recording site (Cz - 2 cm : Fz of the International 10-20 EEG System) and is highly reproducible. The first positive peak at about 40 ms (called P40) is usually clearly defined in healthy subjects using a stimulus 2-4 times stronger than the sensory threshold.103 The presence and amplitude of subsequent negative and positive waves are quite variable between subjects. Classically described pudendal SEP techniques stimulate both dorsal penile/clitoral nerves, thus reducing the sensitivity of the test. However, techniques of pudendal SEP that isolate each dorsal penile/clitoral nerve may be more sensitive for identifying pathology.104

Pudendal SEPs have been advocated in patients with neurogenic bladder dysfunction, e.g. in multiple sclerosis.105 However, even in patients with multiple sclerosis and bladder symptoms, the tibial cerebral SEP was more often abnormal than the pudendal SEP. The combination of an abnormal pudendal SEP with a normal tibial SEP suggests isolated conus involvement.106 The pudendal SEP was less useful than neurological examination for identifying neurological disease in patients with uro-genital symptoms.107 Following spinal cord injury, tibial and pudendal SEPs may be of some value for predicting recovery in bladder control.108 Cerebral SEP during penile/clitoral stimulation may be useful for intraoperative monitoring. Pudendal SEP were used to study the mechanism of sacral neuromodulation.109

2.2.5.1.2 Spinal Pudendal SEP

Stimulating the dorsal penile nerve and recording with surface electrodes at the level of the Th12-L2 vertebrae (and the S1, Th6 or iliac spine as reference) reveals the postsynaptic segmental spinal cord activity (the spinal SEP). Unfortunately, this spinal SEP may be difficult to record even in normal (particularly obese) subjects.

2.3. Sacral Reflexes

Clinically, two reflexes are commonly elicited in the lower sacral segments: (1) the penilo- or clitoro-cavernosus (i.e. bulbocavernosus) reflex; and (2) the anal reflex.110

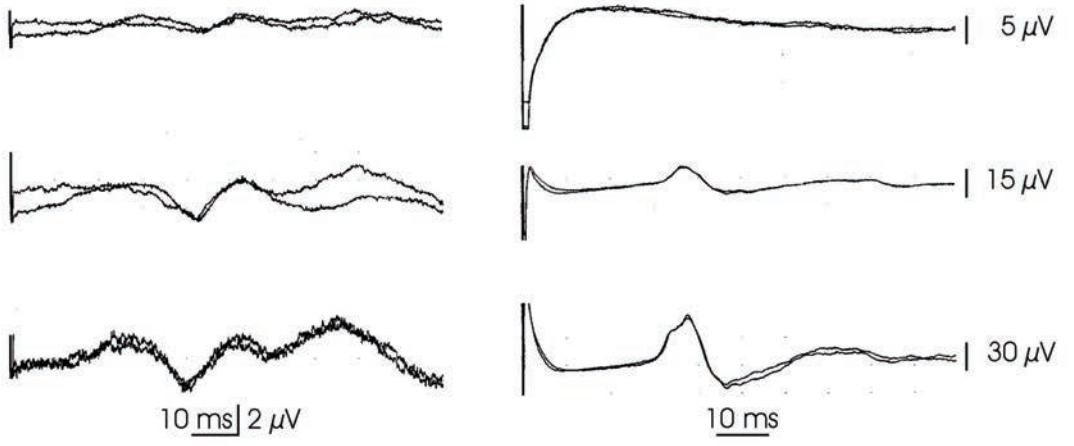

Figure 52: SEPs (traces on the left) and sacral reflexes (traces on the right) in a healthy woman. Cerebral SEPs are recorded from Cz - 2 cm; sacral reflexes from the anal sphincter. The dorsal clitoral nerve is being stimulated with rectangular electrical pulses at 2 Hz. Stimulation and recording is performed with surface electrodes. The cerebral SEP and sacral reflex are recorded simultaneously. In the upper row the stimulation is just above sensory threshold, in the middle row the stimulation is 1.5, and in the lower row at 2-times sensory threshold (pulse duration 0.2 ms; two consecutive averages of 128 responses are superimposed).

To elicit sacral reflexes, electrical,111, 112, 113, 114, 115, 116, 117, 118 mechanical,115,116, 119 or magnetic120 stimulation can be used. Whereas the latter two modalities have only been applied to the penis,117, 118, 119 clitoris, electrical stimuli can be applied to various sites: to the dorsal penile or clitoral nerve; perianally; and, using a catheter-mounted ring electrode, to the bladder neck/proximal urethra.121

2.3.1 Sacral Reflex on Electrical Stimulation

Electrical stimulation of the dorsal penile or clitoral nerve elicits (somato-somatic) sacral reflexes in perineal muscles with a typical latency approx. 33 ms (29.9 ± 5.7 msec in one study in men117), traditionally called the bulbocavernosus reflex (Fig 52). In addition to single-pulse electrical stimulation, two identical electrical pulses separated by a 3-msec interval

can be used (i.e., double-pulse electrical stimulation).117, 118 Double-pulse electrical stimulation is more efficient in eliciting sacral reflexes.117 Stimulation of the perianal skin, bladder neck or proximal urethra elicits sacral reflexes with latencies above 50 ms. This latency is longer compared to responses conveyed by the pudendal nerve, suggesting that the afferent limb for these responses involves visceral afferent fibres accompanying the pelvic nerves, which are thinly myelinated and have a slower conduction velocity than the thicker pudendal afferents. With visceral denervation (e.g. following radical hysterectomy) the viscerosomatic reflexes (from both bladder and urethral stimulation) may be lost while the bulbocavernosus (penilo-/clitoro-cavernosus) reflex is preserved. Loss of bladder-urethral reflex with preservation of bladder-anal reflex has been described with urethral afferent injury after recurrent urethral surgeries.122

The longer latency anal reflex (the contraction of the EAS on stimulation of the perianal region) is quite variable thus limiting its usefulness as a diagnostic tool.

On perianal stimulation, a short latency response can also be recorded, as a result of depolarisation of motor branches to the EAS, possibly involving antidromic travelling of the depolarisation, with “returning” of the depolarisation orthodromically to the sphincter at a branching point of the motor axon.

EMG recording of the sacral reflex has been shown to be more reliable than the clinically assessed response (e.g. observing and palpating the contraction) in males and particularly in females.123 In men, value of 40, 36 and 36 msec have been suggested as the upper limit of normal for the shortest latency obtained on eliciting a series of reflex responses using single, double and mechanical stimulation, respectively.117

In men with cauda equina lesions penilo-cavernosus reflex could not be elicited in 64%, 47% and 47% of patients on single electrical, double electrical, and mechanical stimulation, respectively. Measurement of the reflex latency increased the sensitivity to record abnormalities for 17%, 36%, and 34%, respectively. Furthermore, it has been shown that sacral reflex measurement increase sensitivity of quantitative EMG of the EAS muscles from 73% to 81-83% using the different stimulation techniques mentioned.118

Sacral reflex testing has been studied extensively and is used in many laboratories in everyday practice to demonstrate objectively the integrity of the S2-S4 reflex arc. The sacral reflex evoked on dorsal penile or clitoral nerve stimulation (the bulbocavernosus or penilo-/clitoro-cavernosus reflex) was shown to be a complex response, often forming two components. The first component with a typical latency of about 33 ms, is the response that has been most often called the bulbocavernosus reflex. It is stable, does not habituate, and has other attributes of an oligosynaptic reflex response.112 The second component has latency similar to the sacral reflexes evoked by stimulation perianally or from the proximal urethra, and is not always demonstrable as a discreet response. In those subjects in whom the first reflex component is difficult to elicit, stimulation strength should be increased, but preferably double electrical stimuli should be used. A complete reflex arc lesion should not be inferred by absence of a response if only single pulse is used for stimulation.

During voiding sacral reflexes are un-elicitable but in presence of spinal cord lesions such as myelodysplasia this normal suppression is lost.

Sacral reflex responses recorded with needle or wire electrodes can be analysed separately for each side from the EAS or bulbocavernosus muscle. Using unilateral dorsal penile nerve blocks, the existence of two unilateral BCR arcs has been demonstrated. Thus by detection from the left and right bulbocavernosus (and also the EAS) muscles separate testing of right and left reflex arcs can be performed. Some authors reported that sensitivity of the test can be increased by use of the inter-side latency difference (normative limits: < 3 ms), but finding could not be confirmed by others (normative limits: < 7.2 ms).117 In cases of unilateral (sacral plexopathy, pudendal neuropathy) or asymmetrical lesions (cauda equina), a healthy reflex arc may obscure a pathological one on clinical elicitation, but not on neurophysiologic measurements of the sacral reflexes.

As described above, penilo-cavernosus reflexes were absent in 47-64%, and delayed in additional 17-19% of patients with conus/cauda lesions. Of these patients 47% were incontinent for urine and 47% for faeces. However, a reflex with a normal latency does not exclude the possibility of an axonal lesion in its reflex arc, as demonstrated by pathologic quantitative EMG of the EAS in 79-86% of patients with conus/cauda lesions.118 Furthermore, much delayed sacral reflex responses are compatible with normal bladder and sexual function as found in patients with hereditary motor and sensory demyelinating neuropathy. In a proportion of women with non-neurogenic sacral dysfunction clitoro-cavernosus reflex latencies were found to be much longer compared to those obtained in women with intact sacral function.124

Sacral reflex recording is suggested as a complementary test to CNEMG examination of pelvic floor muscles in patients with suspected peripheral nervous lesions.4

In addition to latency, a number of other parameters can also be measured using electrical, but not mechanical stimulation. These are the sensory threshold (i.e., the stimulus strength (mA) at which subjects feels stimulation), and reflex threshold (i.e., the stimulus strength (mA) at which the reproducible penilo/clitoro-cavernosus reflex appears on the screen). They evaluate lower sacral sensory pathways, and excitation level of the sacral reflex pathway, respectively. Although for men normative data for these parameters is available,117 their utility in clinical situation remains unclear.

Continuous intraoperative recording of sacral reflex responses on penis/clitoris stimulation is feasible if double pulses or a train of stimuli are used.125

2.3.2 Sacral Reflex on Mechanical Stimulation

Mechanical stimulation has been used to elicit BCR in both sexes and found to be a robust technique. Either a standard reflex hammer or a customised electromechanical hammer can be used. Using a reflex hammer, the stimulus is applied to a wooden spatula placed on the glans penis or clitoris.117, 118 Such stimulation is painless and can be used in children.119 The latency of the BCR elicited mechanically is comparable to the electrically elicited reflex in the same patients, but depends on the electromechanical device used.117, 119 .

2.4. Autonomical Function Tests

Most uro-neurophysiological methods discussed so far assess myelinated fibres, but not the autonomic nervous system, especially the parasympathetic component, which is most relevant for pelvic organ functions. Methods for evaluating the autonomic nerves innervating the pelvic viscera are not available. Cystometry indirectly evaluates the parasympathetic innervation to the bladder. However, from a clinical neurophysiological point of view direct electrophysiological testing would be desirable.

2.4.1 Tests in Generalised Autonomic Neuropathy

Cardiovascular autonomic function tests are useful for identifying generalised autonomic dysfunction in patients with bladder or gastrointestinal motility disturbances.

In cases when a general involvement of thin fibres is expected, an indirect way to examine autonomic fibres is to assess thin sensory fibre function. Thin visceral sensory fibres are tested by stimulating the proximal urethra or bladder, and by recording sacral reflex responses or cerebral SEP.

2.4.2 Dartos reflex

In men, another approach to test lumbosacral sympathetic function is by neurophysiologic measurement of the dartos reflex obtained by electrical cutaneous stimulation of the thigh. The dartos muscle is a sympathetically innervated dermal layer within the scrotum, distinct from the somatically innervated cremasteric muscle. A reliable and reproducible dartos reflex (i.e., scrotal skin contraction) with a latency of about 5 seconds has been demonstrated in healthy men.126

Technical problems have so far limited smooth muscle electromyography of the detrusor muscle, and of genital smooth muscle. Recently, successful intrinsic (smooth muscle) anal sphincter muscle EMG recordings on electric autonomic nerve stimulations were reported to spare the autonomic nerve supply during surgery in pigs. 127

2.4.3 Sympathetic Skin Response (SSR)

The sympathetic nervous system mediates sweat gland activity in the skin. Changes in sweat gland activity lead to changes in skin resistance. On noxious stimulation (such as a sudden noise, electrical pulse, etc.) a potential shift can be recorded with surface electrodes from the skin of the palms and the soles, and has been reported to be a useful parameter in assessment of neuropathy involving non-myelinated nerve fibres. The response, known as the SSR, can also be recorded from perineal skin and the penis. Similarly, the SSR can be recorded from the genital region in women. The SSR is a reflex, which consists of myelinated sensory fibres, a complex central integrative mechanism and a sympathetic efferent limb with postganglionic nonmyelinated C fibres. SSR is the only electrophysiological method directly testing sympathetic fibres; recording from the perineal region assesses sympathetic nerve function of thoracolumbar segments. Limited literature exists regarding the relationship between SSR results and bladder dysfunction. A correlation has been shown between the absence of the SSR response in the foot and bladder neck dyssynergia following spinal cord injury.128

Only complete absence of response can be regarded as abnormal. Its utility in evaluating bladder and urethral dysfunction is not established.

3. EVIDENCE BASED USE OF CLINICAL NEUROPHYSIOLOGICAL TESTS

Evidence-based medicine is founded on the assessment of evidence for and against the efficacy of particular types of therapeutic intervention. Clinical neurophysiology testing should thus demonstrate evidence that testing improves outcome (through treatment choice and patient selection). However, testing and therapeutic intervention are different concepts, and neurophysiological testing has another important objective. It is to generate knowledge about the situation to be treated in a given patient, so that the practitioner can formulate rational treatment options based on knowledge rather than do so blindfold; that is, he or she can practice “knowledge-based medicine”.

To judge the importance of this second objective different criteria are needed. Particularly in the referral setting, the physician is confronted with complicated cases in which the underlying pathophysiology is quite uncertain, and what is required is to identify all the factors that may be contributing. Neurophysiology is helpful in assessment of neurogenic dysfunction because it contributes to “knowledge-based medicine”, whether or not there is narrowly-defined “evidence” that it improves outcomes.

Of course, it remains true that we should seek evidence of the conventional kind for and against testing. Any test should be subjected to three questions:

1. Does the test have good technical performance?
2. Does the test have good diagnostic performance, ideally against a "gold standard" measure?
3. Does the test have good therapeutic performance, that is, does the use of the test alter clinical management, does the use of the test improve outcome?

Clinical diagnosis requires that measures obtained in individual patients be compared to population norms with the intent of determining whether they are "normal" or "abnormal". Data can be classified as "abnormal" only with the understanding that they are compared to a sample from the normal population. Predictive statements are made possible by the use of tolerance limits. For most clinical neurophysiological tests, one-tailed tolerance limits are recommended. For any given limit of normality, there is a certain probability of falsely interpreting values (obtaining false-positives or false-negatives). Further confounding these issues is the practice of applying multiple criteria of abnormality. But ultimately, the adequacy of any given normal limit in discriminating between normal and abnormal must be supported by appropriate clinical or clinico-pathological correlations; for uroneurophysiological techniques, such data are scarce.

3.1. Usefulness of Clinical Neurophysiological Tests in Evaluation of Individual Patients

Whenever pathophysiology is uncertain or unpredictable, and especially if irreversible treatment is necessary or contemplated, it seems logical to gather quantitative knowledge of the dysfunction in order to make a rational treatment choice.

In most patient groups with neurogenic incontinence, the pathophysiology is unpredictable and comprehensive urodynamic evaluation is essential in order to practice knowledge-based medicine. In selected patients from these groups, clinical neurophysiological testing will clarify issues related to the neural control of lower urinary tract, relevant for understanding pathophysiology.129

As is generally true for electrophysiological tests, uroneurophysiological examinations are particularly useful for substantiating the clinical diagnosis of a peripheral nerve lesion. The potential usefulness of testing in an individual patient needs to be analysed in the overall clinical setting. The indications for testing are guided primarily by expert opinion, not on definitely established criteria derived from controlled studies.

In the incontinent patient without other signs or symptoms of a neurological condition, as in most patients with stress/urgency, or mixed urinary incontinence electrophysiological testing is as a rule non-contributory.61

Neurophysiological methods may have other uses, as for instance using the EMG signal for correct needle positioning for infiltration of sphincter muscle with botulinum toxin,130 or using tests for intraoperative identification and monitoring of nerves and muscles.126

3.2. Usefulness of Clinical Neurophysiological Tests in Research

As understanding pathophysiology of neural control of lower urinary tract is essential in the application of more sophisticated therapeutic methods, such as electrical stimulation techniques,131,132 there is a continuing place for clinical neurophysiology in research on neurogenic urinary and anorectal dysfunction and their therapy.

There is ongoing research on already described techniques to validate their usefulness in diagnostics133, and in intraoperative monitoring.134

4. CONSENSUS STATEMENT

4.1. Recommendation for Clinical Neurophysiological Testing

The information gained by clinical examination and urodynamic testing may be enhanced by uroneurophysiological tests in selected patient groups with suspected neurogenic urinary incontinence with lesions within the nervous reflex arcs of sacral segments 2 – 5. Concentric needle EMG to diagnose denervation and reinervation of pelvic floor and perineal muscles, and sacral reflex testing to assess the continuity of the sacral reflex arc, are the recommended tests.

Level of evidence: 2b

Level of recommendation: B

Clinical neurophysiological testing should be performed in accredited laboratories, by trained and certified staff, with formal control of the quality of the results. Ideally, the uroneurophysiologist should be in liaison with general clinical neurophysiologists.

It seems optimal to create interdisciplinary teams between urology, urogynecology, proctology, and neurology departments.

4.2. Recommendation for Technical Standards

Even in the more widely used "general" clinical neurophysiology there is no universal standardisation of tests. This is mainly due to different historical backgrounds of testing developed in different countries. The need to standardise methods is, however, recognised.

Proposals for standardisation for external anal sphincter CNEMG4 and the bulbocavernosus

(penilo/clitoro-cavernosus) reflex117 have been made, and seem to be widely adopted.

Level of evidence: 2b

Level of recommendation: B

4.3. Future Research Areas

Clinical neurophysiological methods should be further explored and used to better define the neural control in lower urinary tract function, demonstrating both the nervous system's "hardware" (integrity of anatomy)135 as well as "software" (level of activity, excitation thresholds) for co-ordinated urinary storage and voiding, in physiological and in pathological conditions.136

There is as yet no standardisation of the technical aspects of (kinesiological) EMG within urodynamic (and anorectal) function testing. Furthermore, more research is needed to shed light on the relationship between the EMG signals, pelvic floor muscle function, and overall LUT (anorectal) function (Anding et al. When Should Video and EMG Be Added to Urodynamics in Children With Lower Urinary Tract Dysfunction and Is This Justified by the Evidence? ICI-RS 2014. Neurourology and Urodynamics 35:331–335 (2016) References at end and anorectal function.

There are also challenges to validate the use of the described techniques for intraoperative identification of structures and monitoring nervous function,137 to define neurophysiological changes induced by therapeutic electrostimulation, and to develop tests to assess directly the sacral parasympathetic system.

VI. OTHER INVESTIGATIONS

1. URINALYSIS

"Urinalysis is a fundamental test that should be performed in all urological patients" (1). In patients with urinary incontinence, urinalysis is not a diagnostic test for the condition, but it is rather used to screen for haematuria, glucosuria, pyuria and bacteriuria. Even in the absence of controlled studies, there is general expert consensus that the benefits of urinalysis clearly outweigh the costs involved (2). A positive urinalysis will prompt infection treatment and/or the use of additional tests such as endoscopy and urinary tract imaging. In the evaluation of urinary incontinence in the female, urinalysis is recommended since 60% of women develop urgency symptoms at the time of urinary tract infection (UTI). Pyuria was found to be common among incontinent but otherwise asymptomatic, female patients. Pyuria was not necessarily associated with UTI, the significance of sterile pyuria in the elderly population is still unclear (3).

A Norwegian survey of general practitioners' management of female urinary incontinence suggested that urinalysis is the most frequently performed test (73%) and is far more frequent than gynaecological examination (54%) (4). Another survey suggested that urinalysis is one of the three-part assessment of UI together with patient history and physical examination (5).The same apply, according to Stricker, for patient selection for collagen implant (6). A minority of the reviewed papers suggested that urine culture should be carried out together with urinalysis (3, 7). Urinalysis is also considered of importance in the evaluation of nursing home residents who are incontinent (8), in peri- and postmenopausal women (9), in older women reporting urinary incontinence (10). Belmin et al, suggested than significant urine samples can even be obtained from disposable pads in elderly incontinent women (11, 12). It is recommended that geriatric incontinent patients undergo history, physical examination, tests of lower urinary tract function and urinalysis. The latter test is proposed to rule out the presence of UTI (12). The clinical relevance of asymptomatic bacteriuria in the elderly is controversial. Although DuBeau and Resnick suggest the use of urinalysis in the diagnostic algorithm to identify asymptomatic bacteriuria in incontinent residents of nursing homes (13), others consider that the condition does not require any treatment (11). Urinalysis is less sensitive and specific for urinary tract infection in women who have had radiotherapy but the combination of leucocyte esterase and nitrates still has a positive predictive value of 95% (14). Urinalysis in patients with stents and patients on haemodialysis has not been found to be an effective screening test and routine culture is recommended(15, 16).

1.1. Consensus Statement

- It is considered standard practice to perform a urinalysis either by using a dipstick test or examining the spun sediment. (Level of Evidence 3, Grade of Recommendation C)
- If a dipstick test is used, it is recommended chosing of a "multiproperty" strip that includes testing for haematuria, proteinuria, glucose and ketones, leukocytes esterase (indicating the presence of leukocytes in the urine) and nitrite tests (suggesting bacteriuria). (Level of Evidence 3, Grade of Recommendation C)

1.2. Future Research Areas

- Needed to screen analysis of urinalysis in the diagnosis and treatment of UI, MUI and SUI

2. BLOOD TESTS

The prevalence of renal damage or of biochemical abnormalities in the general population of patients with urinary incontinence is very low, but there are subgroups of patients where the prevalence can be higher (e.g., neurogenic incontinence, overflow incontinence). The routine use of a battery of common chemical and/or haematological tests in patients with

UI appears to be a prudent rule of good clinical practice in the following situations:

- chronic retention with incontinence
- neurogenic LUT dysfunction
- when surgery is contemplated
- when there is a clinical suspicion
- sodium plasma concentration may be reduced in patients on desmopressin.

Special tests such as measurement of anti diuretic hormone (ADH) and atrial natriuretic polypeptide have proven useful in research of enuresis in childhood and nocturia in the elderly (1, 2). Changes in the circadian rhythm of these, and probably also other hormones regulating the renal excretion of water, will in the future contribute to a better understanding of pathophysiology. Synthetic ADH analogues have already come into clinical use for the treatment of nocturnal enuresis. However, the clinical value of these specific tests remains to be established.

3. TISSUE ANALYSIS

Since the last report of the International Consultation on Incontinence in 2012, several papers have been published based on the analysis of sample of tissues coming from patients with SUI and/or pelvic organ prolapse aiming at evaluating the molecular bases of these conditions. The main targets of both preclinical and clinical research have been the pelvic floor-supporting tissues and the role of steroid hormones, with some intriguing linkages between the two lines of research.

Pelvic floor-supporting tissues are composed mainly of connective tissue in which fibrous elements such as collagen and elastic fibres and visco-elastic matrix based on proteoglycans are the predominant components of the so called extracellular matrix. Extracellular matrix is a complex network of numerous macromolecules that fulfill a large number of mechanical, chemical and biological functions (1). While collagens and elastin fibres confer strength and elasticity to tissues, respectively, structural proteoglycans allow tissue cohesiveness. Specifically, collagen is the most prevalent component, with type I fibres usually well organised and associated with ligamentous tissue, while type III collagen is more common in the loose areolar tissue, which makes up the vaginal wall adventitia and surrounds the pelvic organs (2). According to the molecular weight, indeed, proteoglycans are distinguished into large molecules (aggrecan, versican and perlecan) and small molecules, such as decorin, fibromodulin, biglycan, lumican and chondroadherin (3).

The organised structure of the matrix is due to a clear balance between the production of the different constituents and their breakdown. There are many proteolytic enzymes capable of degrading the elements of the extracellular matrix, falling into into three groups: the serine proteases, the cysteine proteases, and matrix metalloproteinases (MMPs) (4).

Several authors evaluated the expression of the different proteins as well as of their precursors and fragments of degradation. With regards to the metabolism of collagen, some studies seem to indicate that women with SUI have a reduced total collagen content in the skin and urogenital tissue (5-7), while other studies reported higher total collagen concentration and higher levels of mRNAs for type I and type III collagen in paraurethral connective tissue (8). Chen et al., evaluating cultures of fibroblasts taken from endopelvic fascia and skin biopsies in 14 patients with stress urinary incontinence and 12 controls, showed that the overall collagen synthesis and the ratio of type III and type I fibres were not significantly different between fibroblasts obtained from women with or without SUI (4), indicating that alteration in the collagen synthesis might not be involved in SUI.

On the other hand, a few studies reported change in the relative percentages of the different fibres, with a decrease in type I and increase in type III ones (9, 10). In women with SUI,Skorupski et al. evaluated the transcription factor Sp1-binding site in the gene encoding a-1 chain of type I collagen, andsuggested that the observed G-T polymorphism is a risk factor for incontinence (11). Again at molecular level, some studies evaluated the cycle regulatory proteins in patients with pelvic organ prolapse, showing controversial results. Some papers reported reduced expression of proteins such as p53 and p21 which normally cause cycle G1 arrest suggesting an increase in proliferation capacities for fibroblasts derived from human cardinal ligaments of patients with prolapse (2).

Other authors evaluated markers of collagen degradation. Specifically, Edwall et al. evaluated markers of collagen synthesis and breakdown such as the carboxy-terminal propeptide of type I procollagen (PICP), the carboxy-terminal telopeptide of type I collagen (ICTP), and the amino-terminal propeptide of procollagen III (PIIINP) in urogenital tissue homogenates and peripheral serum from 71 patients with SUI and 31 healthy control women (12). After adjusting for age, BMI, parity, and hormonal status, the patients with SUI had significantly lower serum concentrations of PICP and significantly lower tissue concentrations of PIIINP and ICTP than the controls, suggesting reducing breakdown in the presence of unchanged synthesis of type I collagen and, regarding type III collagen, a potential reduction in either synthesis or breakdown, the second being considered more probable (12). These data may lead to the hypothesis that SUI might be associated with impaired degradation of collagen, leading to reduced turnover and accumulation of aging collagen, negatively affecting the strength and elasticity of urogenital tissue. Further studies on transforming growth factor-β (TGF-β) identified the molecular basis of such mechanism, suggesting that overexpression of TGF-β might trigger the accumula-

tion of aging collagen, inhibiting the expression of collagenases and increasing the production of the tissue inhibitor metalloproteinase (13-15). Moreover, some genes, such as those of the Homebox A (HOXA) family, encoding transcription factors that regulate mammalian embryonic growth and development of the urogenital tract, have been shown to be underexpressed in patients with pelvic organ prolapse, suggesting a further molecular basis for the alterations in collagens (16).

Some other studies investigated the role of proteinases that may degrade elements of the extracellular matrix. Chen et al., evaluating full-thickness peri-urethral vaginal wall tissues from patients with SUI or prolapsed and matched control women, found significant decrease in mRNA and protein expressions of alpha-1 antitrypsin (ATT), a neutrophil elastase inhibitor in tissues from affected women, while no difference was found in neutrophil elastase and cathepsin K expressions (17). Similarly, Gabriel et al. studied the expression of different MMPs in 17 women with prolapse and 18 control, identifying higher expression of MMP2 in patients with prolapse (18). These studies allowed to hypothesize that altered catabolism of some components of the extracellular matrix might contribute to the connective tissue alterations observed in pelvic floor dysfunction.

Other studies were focused on the expression of small proteoglycans. Wen et al. studied mRNA and protein levels of biglycan, decorin, and fibromodulin in vaginal wall tissue from women with SUI and menstrual-cycle matched continent women (1). Specifically, the authors demonstrated that the mRNA expression of fibromodulin was significantly lower in patients in the proliferative phase compared to controls, while decorin mRNA expression was higher both in the proliferative and secretory phases in the patients with SUI, supporting the hypothesis that the expression of such small proteoglycans was hormonally modulated and may contribute to the altered pelvic floor connective tissues of women with SUI (1).

Oestrogens interact with specific receptors which, when activated by the ligand, have conformational change, dimerisation and recruitment of co-factors, once translocated into the nucleus, these promote the expression of region of oestrogen-responsive genes, called the oestrogen response elements, leading to the synthesis of proteins (19). More recently, selective modulators of oestrogens receptors have been identified, that act modulating the activity of the receptors, working as agonists, partial agonists, or antagonists in a tissue-dependent manner (20). Studies on these molecules supported a new role of oestrogens in SUI and pelvic organ prolapse. Specifically, in a randomised controlled trial testing one of these molecules (levormeloxifene) as osteoporosis treatment, a 3.4-fold increase in the reporting of POP and an almost 5-fold increase in the reporting of UI have been observed (21). To explain such effect, the expression of more than 500 proteins have been studied in the rat model, showing that oestradiol induced the expression of metalloproteinase 7 and 14, reduced the expression of their inhibitors such as TIMP-3, while selective modulators of oestrogens receptors such as raloxifene had minimal effects on metalloproteinase 7, and maintained or restored expression of the mRNA for tissue inhibitor of metalloproteinases-3 (TIMP-3) and other components of the extracellular matrix, such as glypican, and biglycan (19). Although the role of selective oestrogen-receptor modulators (SERMs) in the expression of the component of extracellular matrix has to be further clarified, these findings support the hypothesis that the increased occurrence of urinary incontinence and pelvic organ prolapse observed with oestrogen therapy and SERMs such as levormeloxifene may be related to changes in expression of genes regulating collagen turnover that ultimately weaken the normal structural integrity and support for the genitourinary system (19).

3.1. Consensus Statement

To date, all these tissue analyses are not part of the everyday clinical practice

3.2. Future Research Areas

The relationship between tissue composition and risk of UI and POP

The relationship between tissue composition and treatment outcome in patients with UI and POP

VII. CONCLUSIONS

Clinical research involving diagnostic accuracy and clinical benefit of imaging studies and other diagnostic tests is particularly difficult. Recommendation of a diagnostic test is based upon the evidence that the outcome of it provides valuable information for patient management and this often involves evaluating the outcome of surgery. Implementation of good clinical research in this area remains difficult and sometimes lacks adequate founding. We acknowledge that only a few of the imaging techniques and other investigations we reviewed in the current chapter have been properly evaluated with respect to reproducibility, specificity, sensitivity and predictive value in connection with the diagnosis and management of urinary incontinence. Nevertheless, we acknowledge the great amount of work performed in the last four years and the continuous advancement in this field. The use of imaging and other investigations, described in this chapter, remains mostly based on expert opinion, common sense, availability and local expertise, rather than on evidence based clinical research. The diagnostic tests we considered can be subdivided into safety tests, tests with specific and selected indications, investigational tests.

Safety tests - Intended to protect patients' health, theyare indicated in all patients complaining of urinary incontinence. They include urinalysis and measurement of post-void residual urine. While a consensus is easily achieved for urinalysis, the clinical benefit

and cost-effectiveness of PVR measurement in the primary evaluation of urinary incontinence needs to be confirmed in prospective studies.

Tests with specific and selected indications. Upper urinary tract imaging (as well as renal function assessment) may be indicated in cases of neurogenic urinary incontinence with risk of renal damage, chronic retention with incontinence, incontinence associated with severe genitourinary prolapse and suspicion of extraurethral incontinence. No other imaging technique is recommended in the primary evaluation of uncomplicated urinary incontinence and/or pelvic organ prolapse. Cystourethrography remains a reasonable option only in the preoperative evaluation of complicated and/or recurrent cases. Video urodynamics, is the gold standard in the evaluation of neurogenic incontinence, particularly in the paediatric population, although the clinical benefit of it remains unclear. In female urinary incontinence videourodynamics is not recommended except under specific complex circumstances. MRI remains the gold standard for the diagnosis of urethral diverticula although ultrasonography is a good alternative option. Lumbosacral spine X-rays have specific indications in children with suspect neurogenic incontinence without gluteo-sacral stigmata. Imaging of the CNS should be considered when a neurological disorder is suspected on the basis of clinical, imaging and neurophysiological findings. Urethrocystoscopy is indicated in cases of incontinence with microscopic haematuria, in the evaluation of recurrent or iatrogenic cases, in the evaluation of vesico-vaginal fistula and extra-urethral urinary incontinence.

Endoanal ultrasound and endocoil MRI are the gold standard for the evaluation of anal sphincter disorders, dynamic X-ray imaging remains the standard for evaluating rectal prolapse.

Investigational tests Pelvic floor ultrasound is widely used as an adjunct to physical examination in patients with urinary incontinence and/or pelvic organ prolapse. Although the technique is rapidly evolving and much progress has been made in clinical research in this field, ultrasonography remains optional as evidence of its clinical benefit is not there yet.

MRI of the pelvic floor is rapidly gaining popularity in the evaluation of enteroceles and in the morphological analysis of pelvic floor muscles although evidence of its clinical benefit is still lacking . Both ultrasonography and MRI are the most rapidly evolving techniques and hold promises for potential future clinical applications.

Research in this area is also performed to improve our understanding of the pathophysiology of continence disorders and POP. Functional neuroimaging continues to provide new insight regarding functional anatomy of CNS related to vesicourethral function and dysfunction. The content of the draft reflects the composition of the Committee is made up of clinicians with a particular interest in a specific area of imaging and neurophysiology. The chapter certainly reveals the enthusiasm the authors poured in clinical research into this area but we believe that the methodology implemented by the Consultation is the best guarantee of a balanced opinion and evidence based recommendations. We hope that this chapter will stimulate clinical research in this field and will inspire those involved in the management of continence disorders and POP.

Neurophysiological testing should be part of the armamentarium available in the management of neurogenic incontinence and the establishment of good collaboration with neurophysiologists is recommended.

I. INTRODUCTION

The function of the lower urinary tract (LUT) is to store and periodically release urine, and is dependent on the activity of smooth and striated muscles in the bladder, urethra, and pelvic floor. These structures form a functional unit, which is controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors [Andersson, 1993; de Groat and Yoshimura, 2001; 2015; Andersson and Wein, 2004; see, Andersson and Michel., 2011]. Ma

Ifunction at various levels may result in bladder control disorders, which roughly can be classified as disturbances of filling/storage or disturbances of voiding/emptying. Failure to store urine may lead to various forms of incontinence (mainly urgency and stress incontinence), and failure to empty can lead to urinary retention, which may result in detrusor underactivity (DU) and underactive bladder (UAB). A disturbed filling/storage function can, at least theoretically, be improved by agents decreasing detrusor activity, increasing bladder capacity, and/or increasing outlet resistance [Wein, 2012].

Many drugs have been tried, but the results are often disappointing, partly due to poor treatment efficacy and/or side effects. The development of pharmacologic treatment of the different forms of urinary incontinence has been slow, but several promising targets and drug principles have been identified [Andersson 2007; 2011c; 2015; 2016; Colli et al., 2007; Athanasopoulos and Cruz, 2011; Yeo et al., 2013; Zacche et al 2014; Sacco and Bientinesi, 2015; Bechis et al. 2015].

In this report, we update the recommendations from the 2012 International Consensus meeting [Andersson et al., 2013]. The most relevant information obtained since the last meeting is briefly reviewed and summarised. Agents specifically used for treatment of urinary tract infections and interstitial cystitis, have not been included. Our clinical drug recommendations are based on evaluations made using a modification of the Oxford system (Table 1). The terminology used is that recommended by the International Continence Society (ICS) [Abrams et al., 2002].

1. PUBLICATION SEARCHES

The review undertook a comprehensive search of all major literature databases and the abstract books from several major conferences: American Urological Association, ICS, European Association of Urology, International Urogynaecological Association, International Consultation of Incontinence and Societe Internationale d'Urologie.

Table 1. ICI assessments 2008: Oxford guidelines (modified)

Levels of evidence
Level 1: Systematic reviews, meta-analyses, good quality randomized controlled clinical trials (RCTs) Level 2: RCTs, good quality prospective cohort studies Level 3: Case-control studies, case series Level 4: Expert opinion
Grades of recommendation
Grade A: Based on level 1 evidence (highly recommended) Grade B: Consistent level 2 or 3 evidence (recommended) Grade C: Level 4 studies or " majority evidence" (optional) Grade D: Evidence inconsistent/inconclusive (no recommendation possible) or the evidence indicates that the drug should not be recommended

There were no restrictions on the inclusion of publications by language; publications in languages other than English were translated into English.

2. CENTRAL NERVOUS CONTROL

In the adult individual, the normal micturition reflex is mediated by a spinobulbospinal pathway, which passes through relay centers in the brain (Figures1-4).

In infants, the central pathways seem to be organised as on-off switching circuits, but after the age of four to six years, voiding is initiated voluntarily by the cerebral cortex [de Groat et al., 1999; Beckel and Holstege, 2011]. Studies in humans and animals have identified areas in the brainstem and diencephalon (Figure 5) that are specifically implicated in micturition control, including Barrington's nucleus or the pontine micturition center (PMC) in the dorsomedial pontine tegmentum [Fowler et al., 2008]. These structures directly excite bladder motoneurons and indirectly inhibit urethral sphincter motoneurons via inhibitory interneurons in the medial sacral cord. The periaqueductal grey (PAG) receives bladder filling information, and the pre-optic area of the hypothalamus is probably involved in the initiation of micturition. According to PET-scan and functional imaging studies in humans, these supraspinal regions are active during micturition [Blok et al., 1998; Nour et al., 2000; Athwal et al., 2001; Griffiths et al., 2007; 2008; Hruz et al., 2008; Mehnert et al., 2008; Tadic et al., 2008; Griffiths, 2011; Deruyver et al., 2016].

3. PERIPHERAL NERVOUS CONTROL

Bladder emptying and urine storage involve a complex pattern of efferent and afferent signalling in parasympathetic, sympathetic, somatic, and sensory nerves. These nerves are parts of reflex pathways, which either keep the bladder in a non-contracted state, enabling urine storage at low intravesical pressure, or which initiate micturition by relaxing the outflow region and contracting the bladder smooth muscle. Contraction of the detrusor smooth muscle and relaxation of the outflow region result from activation of *parasympathetic* neurones located in the sacral parasympathetic nucleus (SPN) in the spinal cord at the level of S2-S4 [de Groat et al., 1993; Beckel and Holstege, 2011]. The postganglionic neurones in the pelvic nerve mediate the excitatory input to the human detrusor smooth muscle by releasing acetylcholine (ACh) acting on muscarinic receptors. However, an atropine-resistant component has been demonstrated, particularly in functionally and morphologically altered human bladder tissue (see below). The pelvic nerve also conveys parasympathetic fibres to the outflow region and the urethra. These fibres exert an inhibitory effect and thereby relax the outflow region. This is mediated partly by release of nitric oxide [Andersson and Persson, 1993], although other transmitters might be involved [Bridgewater and Brading, 1993; Hashimoto et al., 1993; Werkström et al., 1995].

Most of the *sympathetic* innervation of the bladder and urethra originates from the intermediolateral nuclei in the thoraco-lumbar region (T10-L2) of the spinal cord [Beckel and Holstege, 2011]. The axons travel either through the inferior mesenteric ganglia and the hypogastric nerve, or pass through the paravertebral chain and enter the pelvic nerve. Thus, sympathetic signals are conveyed in both the hypogastric and pelvic nerves [Lincoln and Burnstock, 1993].

The predominant effects of the sympathetic innervation of the lower urinary tract are inhibition of the parasympathetic pathways at spinal and ganglion levels (demonstrated in animals), and mediation of contraction of the bladder base and the urethra (shown in animals and man, see Andersson, 1993). However, the adrenergic innervation of the bladder body is believed to inactivate the contractile mechanisms in the detrusor directly. Noradrenaline (norepinephrine) is released in response to electrical stimulation of detrusor tissues *in vitro*, and the normal response of detrusor tissues to released noradrenaline is relaxation [Andersson, 1993].

The *somatic* innervation of the urethral rhabdosphincter and of some perineal muscles (for example compressor urethrae and urethrovaginal sphincter), is provided by the pudendal nerve [Beckel and Holstege, 2011]. These fibers originate from sphincter motor neurons located in the ventral horn of the sacral spinal cord (levels S2-S4) in a region called Onuf´s (Onufrowicz's) nucleus).

Most of the *sensory* innervation of the bladder and urethra reaches the spinal cord via the pelvic nerve and dorsal root ganglia (Kanai and Andersson, 2010; De Wachter, 2011). In addition, some afferents travel in the hypogastric nerve. The sensory nerves of the striated muscle in the rhabdosphincter travel in the pudendal nerve to the sacral region of the spinal cord [Lincoln and Burnstock, 1993].

The most important afferents for the micturition process are myelinated Aδ-fibres and unmyelinated C-fibres travelling in the pelvic nerve to the sacral spinal cord, conveying information from receptors in the bladder wall to the spinal cord. The Aδ-fibres respond to passive distension and active contraction, thus conveying information about bladder filling [Janig and Morrison, 1986]. C-fibres have a high mechanical threshold and respond primarily to chemical irritation of the bladder mucosa [Habler et al., 1990] or cold [Fall et al., 1990].

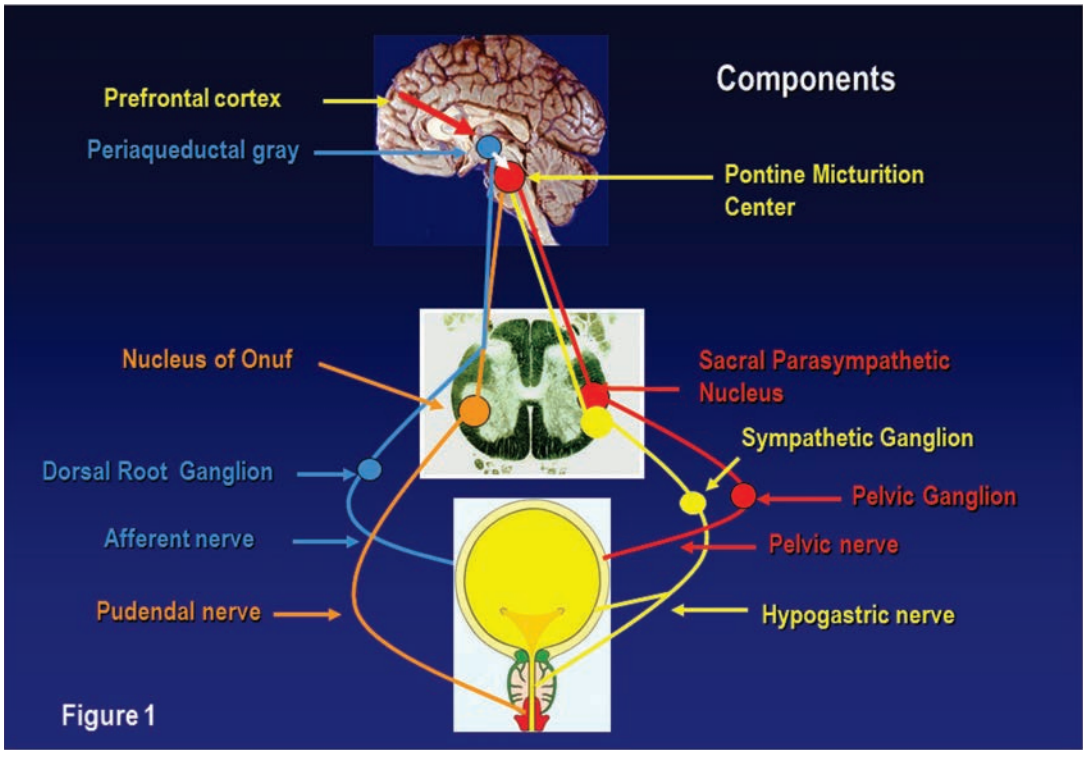

Figure 1: Components of the micturition reflex.

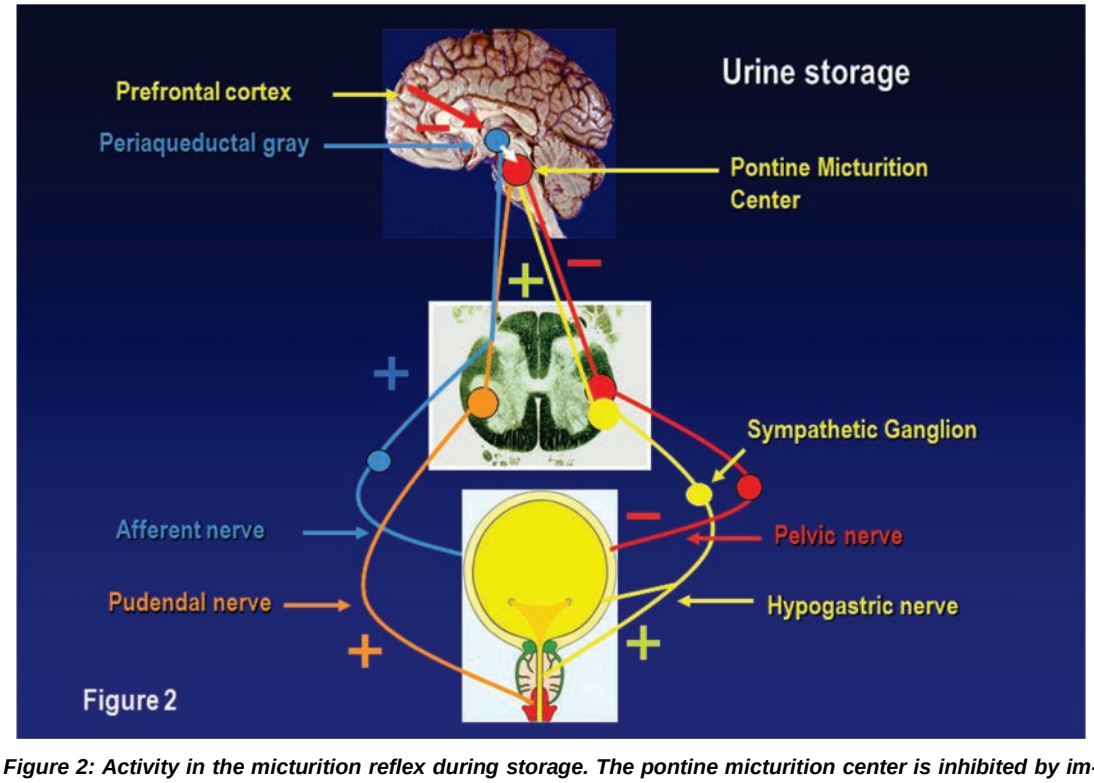

Figure 2: Activity in the micturition reflex during storage. The pontine micturition center is inhibited by impulses from the prefrontal cortex, afferent impulses unable to initiate micturition. Activities in the hypogastric and pudendal nerves keep the bladder relaxed and the outflow region contracted.

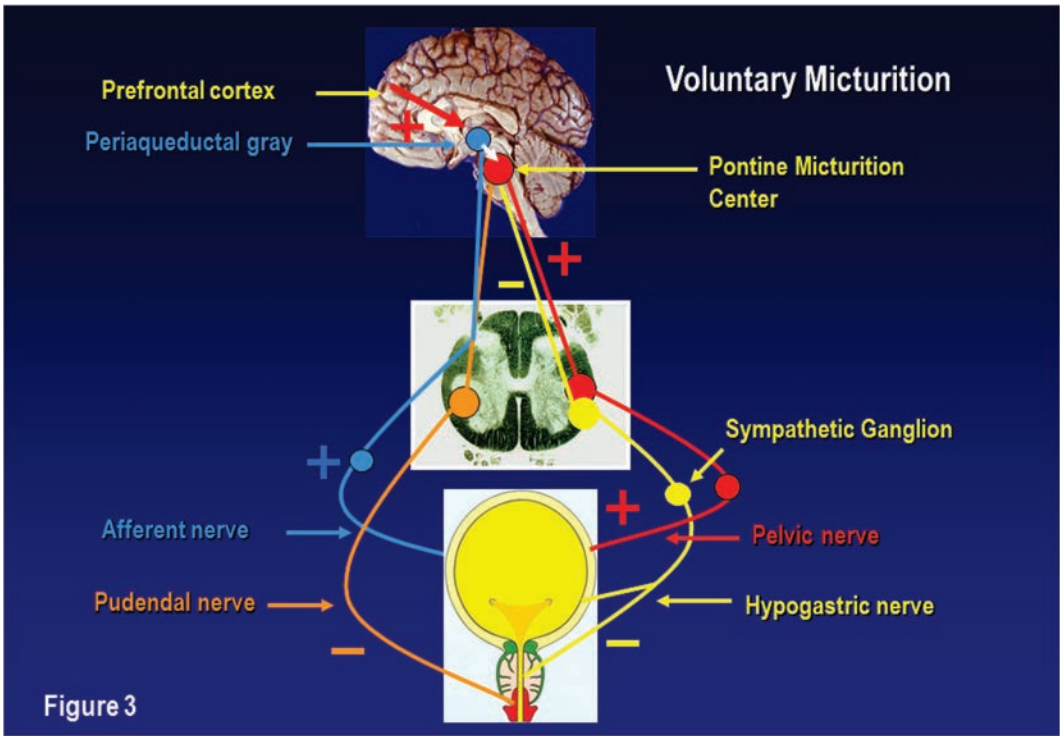

Figure 3: Activity in the micturition reflex during voluntary voiding. The inhibitory impulses from the prefrontal cortex pontine micturition center are removed and afferent impulses are able to initiate micturition. Activities in the hypogastric and pudendal nerves are inhibited, the outflow region is relaxed, and the bladder is contracted by the activity in the pelvic nerve.

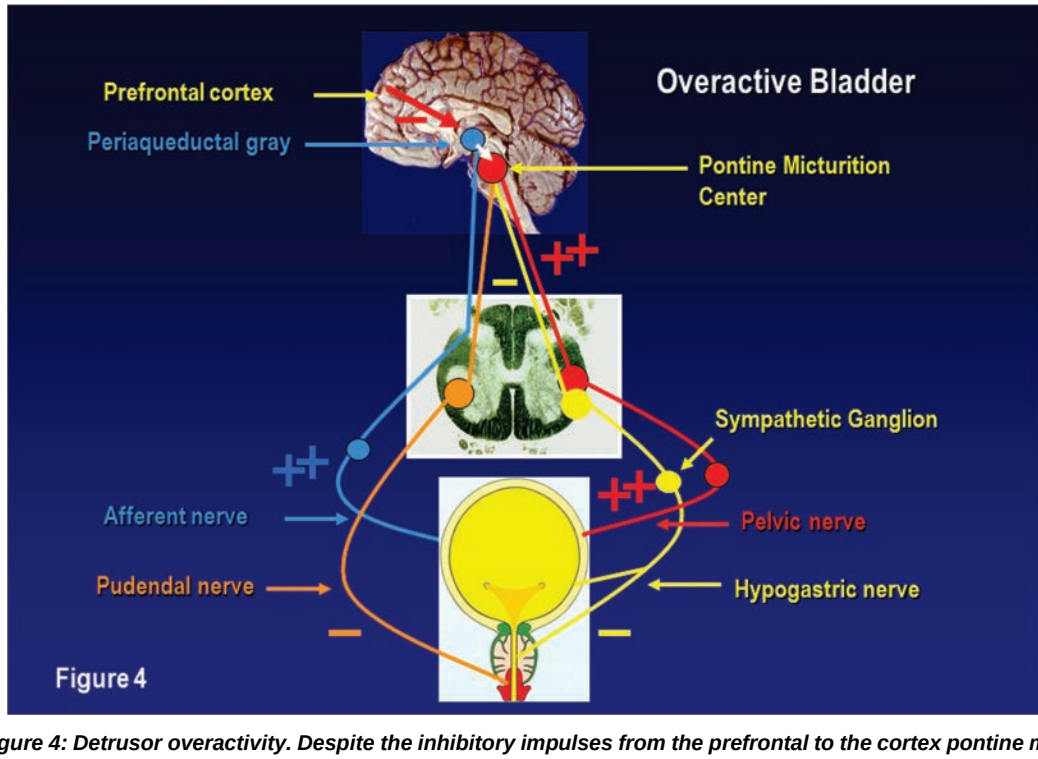

Figure 4: Detrusor overactivity. Despite the inhibitory impulses from the prefrontal to the cortex pontine micturition center the enhanced (?) afferent impulses are able to initiate micturition.

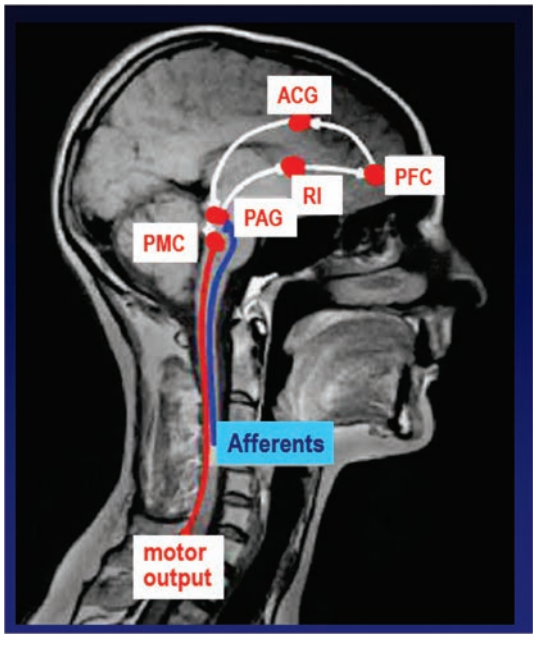

Figure 5: Simplified model of the supraspinal control system of micturition. Secondary bladder afferents synapse in the Periaqueductal Gray (PAG) and are relayed to the Insula (RI), forming the substrate for sensation. Insula representation may have slight right-sided predominance. The Anterior Cingulate Gyrus (ACG) is responsible for monitoring, arousal, and efferent output to the PAG and the Pontine Micturition Center (PMC). The prefrontal cortex (PFC) is involved in voluntary decision about voiding and generates efferent signals to control ACG and ultimately PMC. PMC provides motor output to cause voiding. Modified from Griffiths and Tadic, Neurourol Urodyn, 2008;27:466-474

Following chemical irritation, the C-fibre afferents exhibit spontaneous firing when the bladder is empty and increased firing during bladder distension [Habler et al., 1990]. These fibres are normally inactive and are therefore termed ”silent fibres” [de Groat and Yoshimura, 2001; 2015].

4. PATHOGENESIS OF BLADDER CONTROL DISORDERS

As pointed out previously, bladder control disorders can be divided into two general categories: disorders of filling/storage and disorders of voiding [Wein, 2012]. Storage problems can occur as a result of weakness or anatomical defects in the urethral outlet, causing stress urinary incontinence. Failure to store also occurs if the bladder is overactive, as in the overactive bladder (OAB) syndrome. The prevalence varies with the criteria used for diagnosis, but according to Irwin et al. (2006), using the ICS definition of 2002 [Abrams et al., 2002], the overall prevalence of OAB, based on computer assisted telephone interviews (the EPIC study) was 11.8%; rates were similar in men and women and increased with age [Irwin et al., 2006]. A similar study based on a cross Canada telephone survey found the prevalence of OAB to be 13 % in men and 14.7% in women [Herschorn et al., 2008]. In a Finnish study, taking into account bother, the prevalence of *clinically meaningful OAB,* was was much lower than reported in these studies [Vaughan et al., 2011].

OAB (symptomatic diagnosis) is often assumed to be caused by detrusor overactivity (DO; urodynamic diagnosis), even if this does not always seem to be the case [Hyman et al., 2001; Digesu et al., 2003; Hashim and Abrams, 2004]. DO/OAB can occur as a result of sensitization of afferent nerve terminals in the bladder or outlet region, changes of the bladder smooth muscle secondary to denervation, or consequent upon damage to the central nervous system (CNS) inhibitory pathways, as can be seen in various neurological disorders, such as multiple sclerosis, cerebrovascular disease, Parkinson’s disease, brain tumors, and spinal cord injury [Andersson and Pehrson, 2003; Ouslander, 2004; Banakhar et al., 2012; Meng et al., 2012; Wein and Dmochowski, 2012; Michel and Igawa, 2015]. Urinary retention and overflow incontinence can be observed in patients with urethral outlet obstruction (e.g. prostate enlargement), decreased detrusor contractility, or both), neural injury, and/or diseases that damage nerves (e.g. diabetes mellitus), or in those who are taking drugs that depress the neural control of the bladder or bladder smooth muscle directly [Wein, 2012].

5. BLADDER CONTRACTION

Normal bladder contraction in humans is mediated mainly through stimulation of muscarinic receptors in the detrusor muscle [Andersson and Wein, 2004] (Figure 6). Atropine resistance, i.e. contraction of isolated bladder muscle in response to electrical nerve stimulation after pretreatment with atropine, has been demonstrated in most animal species, but seems to be of little importance in normal human bladder muscle [Andersson, 1993; Bayliss et al., 1999; Rouget et al., 2014]. However, atropine-resistant (non-adrenergic, non-cholinergic: NANC) contractions have been reported in normal human detrusor and may be caused mainly by adenosine triphosphate (ATP) [Andersson, 1993; Bayliss et al., 1999, Andersson and Wein, 2004; Kennedy et al., 2007]. ATP acts on two families of purinergic receptors: an ion channel family (P2X) and a G-protein-coupled receptor family (P2Y). Seven P2X subtypes and eight P2Y subtypes have been identified. In several species (rabbit, cat, rat, and human), various studies suggested that multiple purinergic excitatory receptors are present in the bladder [de Groat and Yoshimura, 2001; Ford and Cockayne, 2011; Burnstock. 2013; Ford and Undem., 2013; North and Jarvis, 2013; Andersson, 2015]]. Immunohistochemical experiments with specific antibodies for different P2X receptors showed that P2X1 receptors are the dominant subtype in membranes of

rat detrusor muscle and vascular smooth muscle in the bladder. Excitatory receptors for ATP are present in parasympathetic ganglia, afferent nerve terminals, and urothelial cells [de Groat and Yoshimura, 2001]. P2X3 receptors, which have been identified in small-diameter afferent neurons in dorsal root ganglia, have also been detected immunohistochemically in the wall of the bladder and ureter in a suburothelial plexus of afferent nerves. In P2X3 knockout mice, afferent activity induced by bladder distension was significantly reduced [Cockayne et al., 2000; Ford et al., 2006; Ruggieri et al., 2006; Ford and Cockeyne, 2011; Burnstock, 2013]. These data indicate that purinergic receptors are involved in mechanosensory signaling in the nonprimate mammalian bladder.

A significant degree of atropine resistance may exist in morphologically and/or functionally changed bladders, and has been reported to occur in hypertrophic bladders [Sjögren et al., 1982], interstitial cystitis [Palea et al., 1993], neurogenic bladders [Wammack et al., 1995], and in the aging bladder [Yoshida et al., 2001]. The importance of the NANC component to detrusor contraction in vivo, normally, and in different micturition disorders, remains to be established [Andersson, 2006Muscarinic Receptors

The neurotransmitter ACh acts on two classes of receptors, the nicotinic and the muscarinic receptors. While the former plays a role in the signal transduction between neurones or between neurones and skeletal muscle (e.g. in the distal urethra), the signal transduction between parasympathetic nerves and smooth muscle of the detrusor involves muscarinic receptors [Abrams and Andersson, 2007]. Importantly, the endogenous muscarinic receptor agonist ACh is not necessarily derived only from parasympathetic nerves in the urinary bladder, but can also be formed and released non-neuronally by the urothelium [Bschleiper et al., 2007; Mansfield et al., 2005; Zarghooni et al., 2007; Andersson, 2011a; Birder and Andersson, 2013]. Five subtypes of muscarinic receptors have been cloned in humans and other mammalian species, which are designated M_{1-5} [Caulfield and Birdsall 1998; Giglio and Tobin, 2009]. Based upon structural criteria and shared preferred signal transduction pathways, the subtypes can be grouped into M1, M3 and M5 on the one hand and the subtypes M2 and M4 on the other. The former prototypically couple via pertussis toxin-insensitive Gq proteins to stimulation of a phospholipase C followed by elevation of intracellular calcium and activation of a protein kinase C, whereas the latter prototypically couple via pertussis toxin-sensitive Gi proteins to inhibition of adenylyl cyclase and modulation of several ion channels [Caulfield and Birdsall 1998]. While sensitive molecular techniques such as reverse transcriptase polymerase chain reaction can detect mRNA for all five subtypes in the mammalian bladder [Abrams et al., 2006; Hegde, 2006], studies at the protein level, e.g. based upon radioligand binding, have typically detected only M2 and M3 receptors, with the former dominating quantitatively [Abrams et

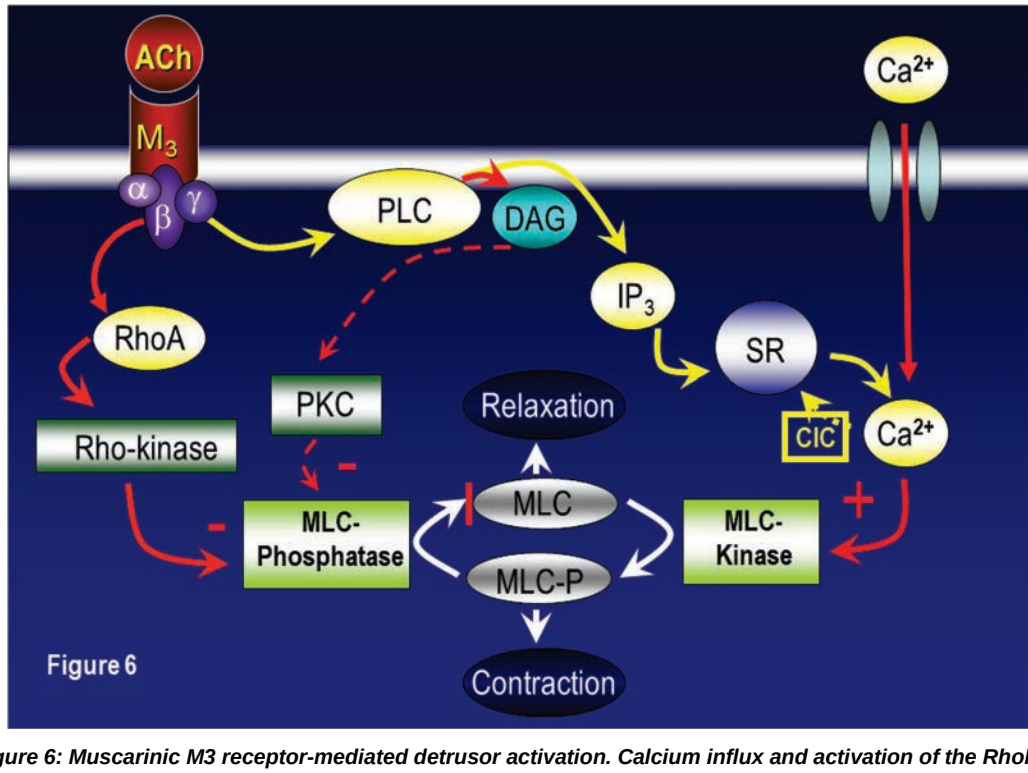

Figure 6: Muscarinic M3 receptor-mediated detrusor activation. Calcium influx and activation of the Rhokinase system are the main pathways mediating activation of the contractile system in the detrusor.

al., 2006: Hegde et al., 1997; Hegde, 2006, Andersson, 2011]. Inhibitory pre-junctional muscarinic receptors have been classified as M2 in the rabbit and rat, and M4 in the guinea-pig, rat and human (d´Agostini et al., 1997; see Andersson, 2011) bladder. These receptors appear to be of the M1 subtype in the rat and rabbit urinary bladder, but have also been detected in human bladders. The muscarinic facilitatory mechanism seems to be upregulated (M3 receptors) in overactive bladders from chronic spinal cord transected rats.

Apparently, most muscarinic receptors in the bladder are found on the smooth muscle cells of the detrusor. While the detrusor expresses far more M_2 than M_3 receptors, it appears that detrusor contraction under physiological conditions is largely if not exclusively mediated by the M_3 receptor [Hegde et al., 1997; Chess-Williams et al., 2001; Fetscher et al., 2002; Kories et al., 2003; Schneider et al., 2004a; b]. Studies in knock-out mice confirm this conclusion [Matsui et al., 2000; 2002; Stengel et al., 2002; Ehlert et al., 2007]. Under physiological conditions M_2 receptor-selective stimulation causes little contraction [Schneider et al., 2005a], but rather appears to act mainly by inhibiting β-adrenoceptor-mediated detrusor relaxation [Hegde et al., 1997; Ehlert et al., 2007; Matsui et al., 2003]. It has been proposed that M_2 receptors can also directly elicit bladder contraction under pathological conditions [Braverman et al., 1998a, b; 2002; 2003; 2006; Pontari et al., 2003] , but such observations have not been confirmed by other investigators using distinct methodological approaches [Schneider et al., 2005a; b].

Based upon the prototypical signalling pathway of M_3 receptors [Cauldfield and Birdsall, 1998] and the presence of phospholipase C stimulation by muscarinic agonists in the bladder [Kories et al., 2003; Schneider et al., 2005a] it had originally been believed that muscarinic receptor-mediated contraction is largely mediated by an activation of phospholipase C [Ouslander, 2004]. While some earlier data had supported this concept, it now appears clear that, at least in rat, mice and humans, muscarinic receptor-mediated bladder contraction occurs largely independent of phospholipase C [Schneider et al., 2004a; b; Wegener et al., 2004; Frazier et al., 2007]. Rather, alternative signalling pathways such as opening of L-type calcium channels and activation of a rho-kinase (Figure 6) appear to contribute to muscarinic receptor-mediated bladder contraction in a major way [Frazier et al., 2008]. More recently, muscarinic receptors have also been identified in the urothelium [Chess-Williams, 2002; Kumar et al., 2005]. Similarly to the findings in bladder smooth muscle, the muscarinic receptors in the urothelium mainly belong to the M_2 and M_3 subtype, with the former dominating quantitatively [Mansfield et al., 2005; Bschleiper et al., 2007]. At present the functional role of muscarinic receptors in the urothelium has largely been studied indirectly, i.e. by investigating the effects of urothelium removal or of administration of pharmacological inhibitors. These data indicate that muscarinic stimulation of the urothelium causes release of an as yet unidentified factor which inhibits detrusor contraction [Hawthorn et al., 2000; Wuest et al., 2005; Sadananda et al., 2008]. Some data indicate that muscarinic receptors in the urothelium may partly act by releasing nitric oxide (NO) [Andersson et al., 2008]. Muscarinic receptor blockade in urothelial cells may also reduce ATP release induced by strech [Young et al., 2012]. Thus, it appears that muscarinic receptors in the urothelium also contribute to the regulation of overall bladder function but their specific roles in health and disease have not been fully established.

Assuming an involvement of muscarinic receptors in physiological *voiding* contractions of the bladder, numerous studies have explored whether an overactivity of the muscarinic system may play a causative role in bladder dysfunction. This could involve, e.g., an enhanced expression of such receptors and/or an increased functional responsiveness. In vitro, an increased sensitivity to muscarinic receptor stimulation was found in both idiopathic and neurogenic overactive human detrusors [Stevens et al. 2006]. However, according to Michel and Barendrecht [2008] the overall balance of available studies suggests that the muscarinic receptor system is not hyperactive under conditions of DO and, if anything, can be even hypoactive [Michel and Barendrecht, 2008b]. This does not exclude a contribution to DO of ACh and muscarinic receptor stimulation during bladder filling (see below). It appears that the contribution of muscarinic mechanisms to the overall regulation of bladder contractility decreases in favour of non-cholinergic mechanisms under pathological conditions [Yoshida et al., 2001; 2008; Rapp et al., 2005]. These observations may help to explain the moderate efficacy of muscarinic receptor antagonists relative to placebo in controlled clinical studies [Herbison et al., 2003; Chapple et al., 2005; 2008; Novara et al., 2008; Shamliyan et al., 2008; Buser et al., 2012].

II. DRUGS USED FOR TREATMENT OF OVERACTIVE BLADDER SYMPTOMS/DETRUSOR OVERACTIVITY

It has been estimated that more than 50 million people in the developed world are affected by urinary incontinence, and an abundance of drugs has been used for treatment (Table 2). Helfand and co-workers showed that in a cohort of 7,244,501 patients over 45 years with an OAB diagnosis, 24.4% of these were treated mainly with antimuscarinic agents; 75.6% went untreated. Only 25.6% of those treated were men. (Helfand et al., 2010). As underlined by several other subcommittees, drugs may be efficacious in some patients, but they do have side effects, and frequently are not continued indefinitely. Hence it would be worth considering them as an adjunct to conservative therapy.

Table 2: Drugs used in the treatment of LUTS/OAB/ DO. Assessments according to the Oxford system (modified)

	Level of Evidence	Grade of Recommendation
Antimuscarinic drugs		
Atropine, hyoscyamine	3	C
Darifenacin	1	A
Fesoterodine	1	A
Imidafenacin	1	A
Propantheline	2	B
Solifenacin	1	A
Tolterodine	1	A

1. ANTIMUSCARINIC (ANTICHOLINERGIC) DRUGS

Mechanism of action. Antimuscarinics block, more or less selectively, muscarinic receptors irrespective of location [Abrams and Andersson, 2007; Andersson, 2011a; Sellers and Chess-Williams, 2012] (Figure 7). The common view is that in OAB/DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the lower urinary tract [Andersson, 2004, 2011b]. Furthermore, antimuscarinics are usually competitive antagonists.

This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, but in the dose range used for beneficial effects in OAB/DO (Figure 8), there is little evidence for a significant reduction of the voiding contraction [Finney et al., 2006]. However, there is good experimental evidence that the drugs act during the storage phase by decreasing the activity in afferent nerves (both C- and Aδ -fibres) from the bladder [De Laet et al., 2006; Ijima et al., 2007] (Figure 9).

As mentioned previously, muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest [Andersson, 2002a; Birder and de Groat, 2007, Birder and Andersson, 2013], but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues [2004; 2006; 2008] found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and, at least partly, generated by the urothelium. There is also indirect clinical evidence for release of ACh during bladder filling. Smith et al. [1974]

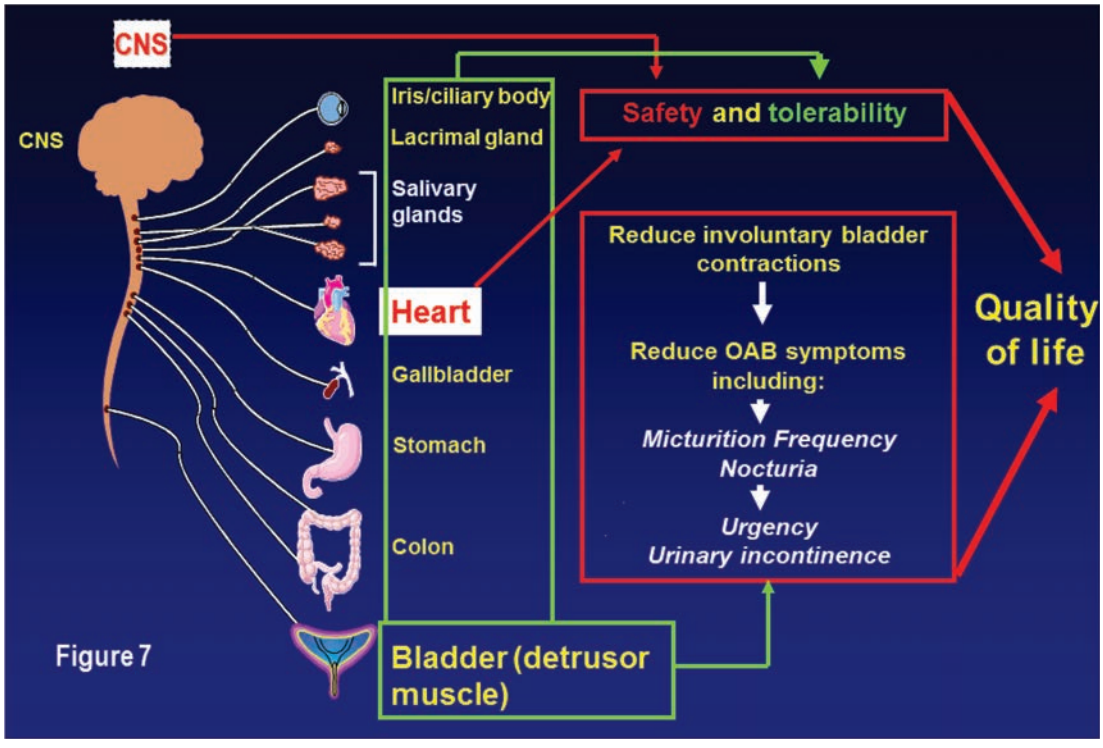

Figure 7: Important sites of action of antimuscarinics.

found that in patients with recent spinal-cord injury, inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch et al. [2001] inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of overactive bladder, but in no patients without specific complaints suggesting DO. Thus, during the storage phase, ACh and ATP may be released from both neuronal and non-neuronal sources (eg, the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB/DO and represent possible targets for antimuscarinic drugs.

Pharmacologic properties. Generally, antimuscarinics can be divided into tertiary and quaternary amines [Guay, 2003; Abrams and Andersson, 2007]. They differ with regards to lipophilicity, molecular charge, and even molecular size, tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the CNS, dependent on their individual physicochemical properties. High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood brain barrier, but in some cases, such as darifenacin, that is compensated by active transport out of the CNS by the product of the MDR1 gene. Quaternary ammonium compounds, like propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects [Guay, 2003]. They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increases in heart rate, and dryness of mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites [Guay, 2003]. The most commonly involved P450 enzymes are CYP2D6, and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration/effect of the antimuscarinic and /or interacting drug. Antimuscarinics secreted by the renal tubules (eg trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism. Some antimuscarinics and their active metabolites are excreted in urine in amounts that may affect the mucosal muscarinic receptors from the luminal side. This has not yet been demonstrated to imply superior clinical efficacy [Andersson et al., 2008b].

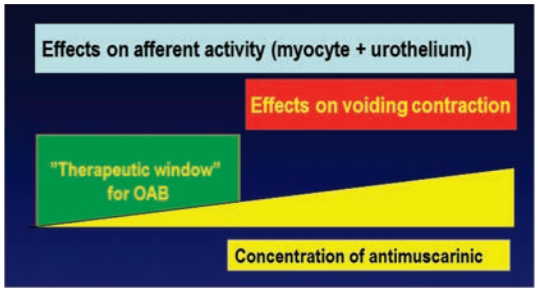

Figure 8: Rationale for use of antimuscarinics for treatment of OAB/DO. Blockade of muscarinic receptors at both detrusor and nondetrusor sites may prevent OAB symptoms and DO without depressing the contraction during voiding. The "Therapeutic window for OAB" can be obtained in most patients with recommended doses of antimuscarinics

Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence [Andersson, 2004, Andersson et al., 2009]. However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects, which limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained, if the subtype(s) mediating bladder contraction, and those producing the main side effects of antimuscarinic drugs, were different. Unfortunately, this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For some of them, documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepronium). Information on these drugs has not been included, but can be found elsewhere [Andersson, 1988; Andersson et al., 1999].

1.1. Antimuscarinics with "Specific" Action

Below data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term "specific"). The amount of information for the individual drugs varies, and so does the degree of details from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse effect profile of each individual drug.

1.1.1 Atropine Sulfate

Atropine (dl-hyoscyamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials [Ekström et al., 1992; Glickman et al., 1995; Deaney et al., 1998; Enskat et al., 2001; Fader et al 2007]. It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO [Fader et al., 2007].

The pharmacologically active antimuscarinic component of atropine is l-hyoscyamine. Although still used, few clinical studies are available to evaluate the antimuscarinic activity of l-hyoscyamine sulfate [Muskat et al., 1996]. For assessment, see Table 2.

1.1.2 Darifenacin Hydrobromide

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the gastrointestinal tract after oral administration, and extensively metablised in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range [Skerjanec, 2006]. UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites of which only UK-148,993 is said to have significant anti-muscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects [Michel and Hegde, 2006]. The metabolism of darifenacin by CYP3A4 suggests that co-administration of a potent inhibitor of this enzyme

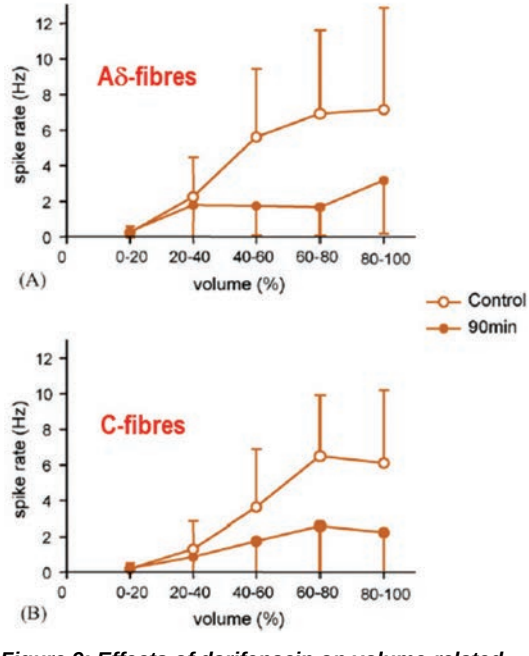

Figure 9: Effects of darifenacin on volume-related nerve activity in Aδ afferents (A) and C afferents (B) in the rat pelvic nerve. From Iijima et al. Eur Urol. 2007 Sep;52(3):842

(e.g. ketoconazole) may lead to an increase in the circulating concentration of darifenacin [Kerbusch et al., 2003].

Darifenacin is a relatively selective muscarinic M_3 receptor antagonist. In vitro, it is selective for human cloned muscarinic M_3 receptors relative to M_1, M_2, M_4 or M_5 receptors. Theoretically, drugs with selectivity for the M_3 receptor can be expected to have clinical efficacy in OAB/DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes [Andersson, 2002b]. However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg per day. The clinical effectiveness of the drug has been documented in several RCTs [Haab et al., 2004; Cardozo and Dixon 2005; Steers et al., 2005; Chapple et al., 2005; Foote et al., 2005; Hill et al., 2006; Haab et al., 2006; Zinner et al., 2006, Chapple et al., 2007; Abrams et al., 2008, Chancellor et al., 2008; Dwyer et al., 2008; for reviews, see Guay, 2005; Zinner, 2007; Novara et al., 2008; Chapple et al., 2008b]. Haab et al. [2004] reported a multicentre, double-blind, placebo-controlled, parallel-group study which enrolled 561 patients (19–88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomised (1:4:2:3) to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n=53), 7.5 mg (n=229) or 15 mg (n=115) or matching placebo (n=164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6 and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg, respectively, was significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg: -1.6; 15 mg: -1.7; placebo -0.8, frequency of urgency per day (-2.0; -2.0; -0.9), and number of incontinence episodes leading to a change in clothing or pads (-4.0; -4.7; -2.0). There was no significant reduction in nocturnal awakenings due to OAB. The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth and discontinuation related to constipation was rare (0.6% placebo versus 0.9% darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well-tolerated [Steers et al., 2005]. A 2-year open label extension study of these investigations [i.e., Haab et al., 2004; Steers et al., 2005], confirmed a favorable efficacy, tolerability and safety profile [Haab et al., 2006].

A review of the pooled darifenacin data from the three phase III, multicentre, double blind clinical trials in patients with OAB was reported by Chapple et al. [2005] After a 4-week washout/run-in period, 1,059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least six months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, –8.8 [–68.4%; placebo -54%, P<004]; 15 mg, –10.6 [–76.8%; placebo 58%, p<0.001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg 0.6% of patients; darifenacin 15 mg 2.1%; placebo 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (≥65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability and safety profile [Foote et al., 2005, Zinner et al., 2005; Hill et al. 2006].

The time-to effect with darifenacin was analysed in a pooled analysis of efficacy and safety data from 1,059 patients participating in three double-blind 12-week studies Khullar et al [2011]. Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin, on the 'warning time' associated with urinary urgency. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks' washout, 2 weeks' medication-free run-in and a 2-week treatment phase [Cardozo and Dixon, 2005]. Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence

and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant ($p<0.004$) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to -1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a ≥30% increase in mean warning time. There were methodological problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centred environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study [Zinner et al., 2006] on 445 OAB patients, darifenacin treatment (15 mg) resulted in numerical increases in warning time, however, these were not significant compared to placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health related quality of life (HRQoL) in patients with OAB [Abrams et al., 2008], and such improvements were sustained as shown in a two-year extension study [Dwyer et al., 2008]. It was shown that neither the positive effects on micturition variables, nor on HRQoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioural modification programme including timed voiding, dietary modifications and Kegel exercises [Chancellor et al., 2008a].

Since darifenacin is a substrate for the P-glycoprotein drug efflux transporter [Miller et al., 2011; Chancellor et al., 2012], which is present both in the blood-brain and blood-ocular barriers, several clinical studies have been devoted to investigate possible effect of darifenacin on cognition. Neither in healthy volunteers (19-44 years) and healthy subjects (≥60 years), nor in volunteers 65 years or older, could any effect of darifenacin (3.75-15mg daily) be demonstrated, compared to placebo [Kay and Wesnes, 2005; Lipton et al., Kay et al., 2006; Kay and Ebinger 2008; Chancellor et al., 2012].

To study whether darifenacin had any effect on QT/QTc intervals [Serra et al., 2005] performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses, alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic T_{max} versus placebo were –0.4 and –2.2 milliseconds in the darifenacin 15mg and 75 mg groups, respectively, compared with +11.6 milliseconds in the moxifloxacin group ($P < .01$). The conclusion was that darifenacin does not prolong the QT/QTc interval.

Darifenacin 15 mg per day given to healthy volunteers did not change heart rate significantly compared to placebo [Olshansky et al., 2008].

The impact of darifenacin on constipation has been assessed in an analysis of the Phase III, IIIb and IV darifenacin published trials [Tack et al., 2012]. The pooled Phase III data, suggested 14.8% (50/337) of patients on darifenacin 7.5 mg/day and 21.3% (71/334) on 15 mg/day experienced constipation. Only 0.6% and 1.2% of patients taking darifenacin 7.5mg/day and 15mg /day, respectively, stopped treatment as a result of constipation. Furthermore, 3.3% [11/337] and 6.6% [22/334], in the darifenacin 7.5 mg/day and 15 mg/day, groups required concomitant laxative medications. At the end of a long-term study (2 years), the incidence of constipation was 20.9% (150/716) and 5.6% (40/716) of patients initiated use of fiber supplements, stool softeners or laxatives [Tack et al. 2012].

Assessment

Darifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and tolerability and safety seems acceptable.

1.1.3 Fesoterodine Fumarate

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by non-specific esterases [Michel, 2008a; Malhotra et al., 2009a]. This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a non-subtype selective muscarinic receptor antagonist [Ney et al., 2008]. All of the effects of fesoterodine in man are thought to be mediated via 5-HMT, since the parent compound remains undetectable upon oral dosing. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Since the renal clearance of 5-HMT is about 250 mL/min, with >15% of the administered fesoterodine dose excreted as unchanged 5-HM, this raises the possibility that 5-HMT also could work from the luminal side of the bladder [Michel, 2008]. The bioavailability of fesoterodine, averaging 52%, was independent of food intake and the drug may be taken with or without a meal [Malhotra et al., 2009b]. Peak plasma concentration of 5-HMT is reached at 5 h following oral administration and has a half-life of 7–9 h [Malhotra et al., 2008]. The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function due to the combination of renal excretion and hepatic metabolism of 5-HMT [Malhotra et al., 2009c; de Mey et al., 2011].

The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs [Chapple et al., 2007; 2008c, Nitti et al., 2007; Dmochowski et al., 2010a; Herschhorn et al., 2010; Kaplan et al., 2011; Nitti et al., 2010; see Dell'Utri et al., 2012]. In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1132 patients were enrolled and received treatment [Chapple et al., 2007]. The trial showed that both the 4 and 8 mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8 mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only one subject from the fesoterodine 8 mg group and one subject from the tolterodine ER group withdrew from the study due to dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs [Khullar et al., 2008]. Fesoterodine 8 mg performed better than the 4 mg dose in improving urgency and UUI as recorded by 3-day bladder diary, offering the possibility of dose titration. Subsequently the Eight Trial, a large randomised double blind placebo controlled trial compared fesoterodine 8 and 4mgs (n=1745; who completed the study) (Chapple et al., 2014). At 12 weeks UUI, urgency, micturition frequency, diary dry rates, PPBC, UPS and OAB-q scores were significantly better with fesoterodine 8mg compared to 4mg or placebo. Dry mouth and constipation rates were 26.1% and 4%, 12.9% and 1.5%, 3.4% and 1.8% in the fesoterdoine 8mg, 4mg and placebo groups, respectively (Chapple et al., 2014).

A head to head placebo controlled trial has been completed comparing fesoterodine 8mg to tolterodine extended release 4mg and placebo [Herschorn et al., 2010]. The study randomized 1,590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, p = 0.015), mean voided volume per void (+32.9 ml vs. +23.5 ml, p = 0.005), and in patients' assessments of bladder related problems as measured by OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (40% vs. 33% with > 2 point improvement, p < 0.001), and Urgency Perception Scale (46% vs. 40% with improvement, p = 0.014) compared with tolterodine. The clinical significance of these statistically significant findings is questionable as there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4 %), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head to head trial comparing two drugs in class supports the use of fesoterodine 8mg for additional benefit over tolterodine ER 4 mg.

Wyndaele et al. [2009] reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centres worldwide and comprised 516 participants (men and women) >18 years who self-reported OAB symptoms for at least 3 months before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence episodes, micturition-related urgency episodes and severe micturition-related urgency episodes per 24 h. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

The largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centres with a total of 2,417 patients enrolled, was performed by Kaplan et al. [2010]. All patients were healthy, >18 years of age and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables) than those receiving either tolterodine ER or placebo; UUI and urgency episodes, micturition frequency and MVV. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving of UUI and urgency episodes and 24-h micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, Dmchowski et al. [2010] reported statistically significant improvements at week 12 in the mean number of micturition per 24 h and in both UUI and urgency episodes. Between groups, difference in nocturnal micturition was not statistically significant.

A subsequent pooled analysis of 2 phase III trials confirmed superiority of fesoterodine 8mg to tolterodine ER 4mg [Ginsberg et al., 2013]. In women fesoterodine 8mg was superior to tolterodine at 12 weeks in UUI, urgency, micturition episodes, diary dry rates, PPBC, UPS and OAB-q scores. In men superiority with fesoterodine 8mg was only demonstrated for severe urgency and the symptom bother domain of the OAB-q. In women, dry mouth rates were 29%, 15%, 6%, constipation rates were 5%, 4%, 2%, urinary retention rates were <1%, <1%, 0% for fesoterdoine 8mg, tolterodine ER 4mg and placebo, respectively. In men, dry mouth rates were 21%, 13%, 5%, constipation rates were 5%, 3%, 1% and urinary retention rates were 2%, <1%, 2% for fesoterdoine 8mg, tolterodine ER 4mg and placebo, respectively [Ginsberg et al., 2013].

Kaplan et al. [2014] assessed fesoterodine 8mg and placebo in patients who had not responded to tolterodine ER 4mg (<50% reduction in UUI). At week 12 UUI and urgency episodes were significantly better in

the fesoterodine group but micturition episodes and diary dry rates were statistically no different compared to placebo. Patients with > 50% and >70% UUI episodes were greater in the fesoterodine 8mg group at 8 weeks. Furthermore, at 12 weeks, improvements in favor of fesoterodine compared to placebo were seen in PPBC, UPDS and OAB-q. Dry mouth and constipation were seen in 16.6 and 3.9% in the fesoterodine group and 4 and 1.3% in the placebo group, respectively [Kaplan et al., 2014].

Little is known on the impact of antimuscarinics on nocturnal urgency. Weiss et al. [2013], explored this is a multi-center randomized double blind placebo controlled 12-week flexible dosing trial in the US. In the fesoterodine group 61% were escalated at the clinicians' discretion to the 8mg dose. Nocturnal urgency episodes (-1.28 vs -1.07), nocturnal micturition episodes, nocturnal frequency-urgency sum (urgency sensations were rated on a 1-5 scale), were significantly better in the fesoterodine group. Interestingly, UUI per 24 hours was not statistically different between fesoterodine and placebo in this trial and the authors acknowledge there is no minimally important difference in nocturnal urgency episodes to ascertain clinical significance definitively. However, in an Asian post-hoc analysis of a double-blind placebo controlled trial of fesoterodine 4 and 8 mg involving 555 patients, fesoterodine was not statistically better than placebo in reducing nocturnal micturition episodes at 12 weeks [Yokoyama et al. 2014]. If patients with a nocturnal polyuris index of > 33% were excluded, fesoterodine 8mg was statistically better than placebo in reducing nocturnal micturition episodes. Undisturbed sleep increased in both fesoterodine arms (4mg – 80 minutes; 8mg – 74 minutes) but was only statistically significant in the 4mg dose compared with placebo (54 minutes). Significant improvements in the sleep / energy domain of the KHQ was seen in both fesoterodine groups compared to placebo.

Nitti et al. [2010] determined whether the presence of DO in patients with OAB and urgency urinary incontinence was a predictor of the response to treatment with fesoterodine in a phase 2 randomized, multicentre, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms, indicating that the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.

Kelleher et al. [2008] evaluated the effect of fesoterodine on HRQoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies [Chapple et al., 2007; Nitti et al., 2007] were analysed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine extended release (tolterodine-ER) 4 mg. By the end of treatment, all active-treatment groups had significantly improved HRQoL compared with those on placebo. In a post hoc analysis of data pooled from these studies, significant improvements in all KHQ domains, ICIQ-SF scores, and bladder related problems were observed at months 12 and 24 compared to open label baseline [Kelleher et al., 2012]. The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

A large post marketing study from Korea has confirmed the efficacy of fesoterodine in OAB [Kim et al. 2016]. The mean duration of symptoms was 165 days but interestingly, 63% had symptom duration of less than a week. Of the patients included, 92.7% (2879/3107), 76.8% (2387/3107), and 37.5% (1164/3107) reported having symptoms of urinary frequency, urgency, and UUI, respectively and mean fesoterodine treatment duration was 83.2 ± 75.3 days. Frequency, urgency and UUI per 24 hours declined from 12.1 to 8.0, 3.7 to 1.3, and 1.1 to 0.3, respectively (all $p < 0.001$). Utilising the PPBC questionnaire the majority of patients reported their bladder condition caused some very minor problems (43.0%, 1265/2939) or no problems at all (22.2%, 651/2939). Adverse events were reported in 8.2%, with dry mouth in 5.4% and constipation in 1.5% [Kim et al. 2016].

Longer term effects were analysed in a pooled analysis of 2 open label extension studies which demonstrated sustained improvement in OAB with fesoterodine [Sand et al. 2012]. Mean duration of exposure was 21 months with 51% of patients receiving fesoterodine for ≥ 24 months. 77% elected to remain on fesoteroding 8mg during the open label extension. Discontinuations were seen in 51% before the 24-month visit with insufficient clinical response, adverse events or withdrawal of consent being the main reasons for stopping treatment. Significant improvements were seen in UUI, urgency and micturition epsiodes over the study period compared to open label baseline. The most common adverse events were dry mouth and constipation. Significant improvements in all KHQ domains (except general health domain), ICIQ-SF and perception of bladder related problems were seen at 12 and 24 months compared to the open label baseline [Kelleher et al. 2012]. During the extension study treatment satisfaction was seen in 96% and 97% at 12 and 24 months, respectively.

A post-hoc analysis of 2 fixed dose trials, stratified by age, suggested fesoterodine 4 and 8 mg doses were efficacious compared to placebo in those < 75 years of age, but only fesoterodine 8mg in those ≥ 75 years of age [Kraus et al. 2010]. As a result, the SOPHIA trial recruited patients ≥ 65 years of age with at least 30% of the population being older than 75 years of age, in this flexible fesoterodine dosing placebo controlled study [Wagg et al., 2013]. At week 4, 52% and 66% opted for dose escalation in the fesoterodine 4mg and placebo groups, respectively. At week 8 de-escalation was allowed and occurred in 4% and 3% in the fesoterodine and placebo groups, respectively. Urgency, severe urgency, micturition and nocturnal micturition episodes, as well as pad use significantly

improved in the fesoterodine group compared to placebo at 12 weeks. However, in the 46% who were OAB wet no significant difference in UUI episodes were demonstrated between the groups. Patient reported outcomes using the TBS, PPBC, UPS, OAB-S were significantly greater in the fesoterodine group compared to placebo. Age stratification ie less than or greater than 75 years of age did not alter the results. Mini mental state examination did not change from baseline to end of study and was not different between groups. Dry mouth and constipation rates were 33.9% vs 5.3% and 8.9% vs 2.5% in the fesoterodine and placebo groups, respectively. Central nervous system adverse events occurred very rarely and 6 patients went into retention (5 in the active arm). The authors concluded that fesoterodine was tolerated well and was efficacious in an elderly population [Wagg et al., 2013; 2015]). Subsequently Wagg et al. [2014], have published on a 12-week open label extension of this trial. Of the original 655 patients in the SOPHIA trial, 581 completed the open label extension with approximately half the population being male. Significant improvements were observed in bladder diary measures as well as patient reported outcome measures in those that originally had placebo who switched to fesoterodine and efficacy was maintained in those that were originally treated with fesoterodine by study end. Treatment withdrawal due to emergent adverse events were 9.1% in those switched to fesoterodine from placebo and 1.3% in those that continued with fesoterodine [Wagg et al. 2014]. Dubeau et al. [2014], looked at the use of fesoterodine with dose escalation/de-escalation design vs placebo in a vulnerable elderly population with complex co-morbidities. Patients had to have moderate bladder problems based on PPBC, UUI 2-15 episodes, daytime frequency ≥ 8, vulnerable elderly score (VES-13) of ≥ 3 and a MMSE ≥ 20. The proportion of patients who completed the study were similar in both groups. Approximately 50% of the population were greater than 75 years of age and both groups had complex patients with functional impairment and polypharmacy. Significant reductions in daytime micturition, daytime and nocturnal urgency, UUI episodes per 24 hours and a reduction for the need of absorbent products was seen with fesoterodine compared to placebo. A greater proportion reported improvements in their bladder condition based on PPBC and OAB-q scores and satisfaction were better in the fesoterodine group compared to placebo. In the fesoterodine group 9.3% vs 5% in the placebo group discontinued treatment due to adverse events. Dry mouth and constipation rates were 23.5% and 11%, respectively, in the fesoterodine group. Urinary retention occurred in 3.2% in those treated with fesoterodine but only 3/9 patients were catheterized. No significant changes in MMSE were observed. No significant changes in blood pressure or heart rate were observed in either group until end of study and there were no deaths [Dubeau et al. 2014].

Malhotra et al. [2010] performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 28 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on Days -1 (baseline), 1, and 3. The primary analysis was the time-averaged changes from baseline for Fridericia's-corrected QT interval (QTcF) on Day 3. Among 261 subjects randomized to fesoterodine 4 mg (n = 64), fesoterodine 28 mg (n = 68), placebo (n = 65), or moxifloxacin 400 mg (n = 64), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment

Fesoterodine has a well-documented beneficial effect in OAB (Table 2) and has been studied in a variety of patient populations, and the adverse event profile seems acceptable.

1.1.4 Imidafenacin

Imidafenacin (KRP-197/ONO-8025,4-(2-methyl-1H-imidazol-1-yl)-2,2-diphenylbutanamide) is an antagonist for the muscarinic ACh receptor with higher affinities for M_3 and M_1 receptors than for the M_2 receptor. Metabolites of imidafenacin (M-2, M-4 and M-9) had low affinities for muscarinic ACh receptor subtypes [Kobayashi et al., 2007a, b]. The drug blocks pre- as well as postjunctional muscarinic receptors and was shown to block both detrusor contractions and acetylcholine release [Murakami et al., 2003]. The receptor binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than submaxillary gland or colon [Yamada et al., 2011], and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect here than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed from the gastrointestinal tract and its absolute bioavailability in human is 57.8% [Ohmori et al. 2007; Ohno et al. 2008]. It is rapidly absorbed with maximum plasma concentration occuring 1-3h after oral administration [Ohno et al. 2008]. Metabolites in the plasma are produced mainly by first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs [Kanayama et al. 2007].

Kitagawa et al. [2011] reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that mean total OABSS decreased gradually during 2 weeks after administration.

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety/tolerability, and dose-response relationship of imidafenacin [Homma et al., 2008a]. Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin/day (99 patients), 0.2 mg of imidafenacin/day (100), 0.5 mg of imidafenacin/day (101), or a placebo (101). After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo was observed ($P < 0.0001$). Compared with the placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency, and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased dose-dependently. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment due to dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

A randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms were conducted by Homma et al. [2009]. They were randomized to imidafenacin 0.1mg twice daily (324), propiverine 20mg once daily (310), or a placebo (147). After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group ($P < 0.0001$). The non-inferiority of imidafenacin compared with propiverine was confirmed for the reduction in using incontinence episodes ($P = 0.0014$, non-inferiority margin: 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine ($P = 0.0101$). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group ($P < 0.0001$). However, there were no clinical arrhythmia and clinical arrhythmic events in any of the treatment groups. Similar results have also been published in A population of OAB patients in Korea [Park et al., 2014]. In this non-inferiority trial comparing imidafenacin (0.1mg twice daily) to propiverine (20 mg once daily), both drugs significantly improved OAB parameters and quality of life measures. Severity of dry mouth was better in the imidafenacin group. The authors concluded that imidafenacin was non-inferior to propiverine with a better adverse event profile [Park et al. 2014]. The long-term safety, tolerability, and efficacy imidafenacin 0.1 mg twice daily was studied in Japanese OAB patients [Homma and Yamaguchi, 2008b], of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being a dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 through week 52. After 52 weeks, imidafenacin produced mean changes from baseline in the number of incontinence episodes (-83.51%), urgency incontinence episodes (-84.21%), voiding frequency (-2.35 micturitions/day), urgency episodes (-70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the King's Health Questionnaire. received the treatment and 376 patients completed the 52-week program. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or post-void residual volume.A 52-week prospective, open randomized comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) was conducted in a total of 41 Japanese patients with untreated OAB [Zaitsu et al., 2011]. They were randomly assigned to imidafenacin and solifenacin groups. There was no difference in OABSS and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group ($P = 0.0092$ and $P = 0.0013$, resp.). An important limitation of this study is the low number of patients. Only 25 patients (17 males 8 females) were available for long-term analysis. Similar results were reported by Yokoyama et al. [2013] in their comparative long term study with equivalent efficacy and better tolerability for imidafenacin compared to solifenacin but high dicontinuation rates in both arms at study end.

Two small open labelled studies and a post-hoc analysis of a large multi-center RCT of imidafenacin have suggested benefits on noctura and/or nocturnal polyuria [Kadekawa et al.,. 2012; Wada et al., 2012; Yokoyama et al., 2013]. Wada et al. [2012] reported improvements in OAB symptoms, Pittsburgh Sleep Quality Index scores, nocturia episodes and nocturnal polyuria in patients older than 75 years with imidafenacin 0.1 mg twice daily. Patients whose main complaint was nocturia were treated with 0.1mg daily and after 4 weeks were allowed a dose escalation to 0.2 mg daily if required. This group showed significant improvements with regards to nocturia as well as other OAB parameters, OAB symptom score and IPSS-QoL index score [Kadekawa et al., 2012]. A stratified analysis of a a large RCT showed that in 46 patients with nocturia and nocturnal polyuria (>33% urine production at night) imidafenacin 0.1mg twice daily after 12 weeks of treatment significantly reduced night-time micturition, nocturnal percentage of 24-hour production, and the interval to the first night-time void was significantly longer compared to placebo [Yokoyama et al., 2013].

In Korea a multi-center a non-inferiority phase IV trial of imidafenacin 0.1mg twice daily versus fesoterdine 4mg was conducted [Lee et al., 2013]. No significant differences were observed between the 2 treatments for OAB symptoms of KHQ scores. Dry mouth rates were 39.4 and 37.3% in the imidafenacin and fesoterodine groups, respectively and no statistically differences were shown for adverse events, blood pressure, pulse or residual volume betwen the groups. In another post marketing surveillance study imidafenacin was shown to be safe with dry rates of 8.5% and no significant deterioration in MMSE at 48 weeks, with an acceptable mild cognitive impairment conversion to dementia rate (3.6%) [Sakakibara et al., 2014].

Assessment

Imidafenacin is effective and has an acceptable tolerability (Table 2). However, the drug is not yet widely available in the Western countries.

1.1.5 Propantheline Bromide

Propantheline is a quaternary ammonium compound, non-selective for muscarinic receptor subtypes, which has a low (5 to 10%) and individually varying biological availability. It is metabolized (metabolites inactive) and has a short halflife (less than 2 h) [Beermann et al., 1972]. It is usually given in a dose of 15 to 30 mg 4 times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher dosages are required. Using this approach in 26 patients with detrusor overactivitycontractions [Blaivas et al., 1980] in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of dosages varied from 7.5 to 60 mg four times daily. In contrast, Thüroff et al. [1991] comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo, in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency and incontinence related to DO (154 patients), found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes et al. [1991] found no differences in efficacy between oxybutynin and propantheline. Controlled randomized trials (n=6) reviewed by Thüroff et al [1998], confirmed a positive, but varying, response to the drug.

Assessment

Although the effect of propantheline on OAB/DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective, and may, in individually titrated doses, be clinically useful (Table 2). No new studies on the use of this drug for treatment of OAB/DO seem to have been performed during the last decade.

1.1.6 Solifenacin Succinate

Solifenacin succinate (YM905) is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45-68 hours [Kuipers et al., 2002; Smulders et al., 2002; 2004]. It undergoes significant hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4). In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) C_{max} and $AUC_{0\text{-}inf}$ were increased by only approximately 40% and 56%, respectively [Swart et al., 2006]. Solifenacin has a modest selectivity for M3 over M2 (and M1) receptors [Abrams and Andersson, 2007]. Supporting an effect on sensory function by solifenacin, 15 women with DO receiving 10 mg/day of the drug showed an increase in the area under the bladder-volume sensation curve [Lowenstein et al., 2012] Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies [Tanaka et al., 2010; Hsiao et al., 2011]

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed [Smith et al., 2002; Chapple et al., 2004a]. The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO [Chapple et al., 2004a]. Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least 8 micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (-2.21), 10 mg (-2.47), and 20 mg (-2.75), but not in patients receiving placebo (-1.03) or tolterodine (-1.79). This effect was rapid with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there was numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. As the 5 mg and 10 mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (USA) [Smith et al., 2002]. This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials and these findings demonstrate efficacy as early as one week. The 5 mg, 10 mg, and 20 mg dosing groups experienced statistically significant increases in volume voided; the 10 mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo [Chapple et al., 2004b]. It should be noted that this study was powered only to compare active treatments to placebo. Compared with placebo (-8%), mean micturitions/24 h were significantly reduced with solifenacin 10 mg (-20%), solifenacin 5 mg (-17%), and tolterodine (-15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo et al. [2004] randomized 911 patients to 12-week once daily treatment with solifenacin 5 mg, solifenacin 10 mg or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia and incontinence episodes per 24 hours, and mean volume voided per micturition. Compared with changes obtained with placebo (-1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (-2.37) and 10 mg (-2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: -1.63, 61%; 10 mg: -1.57, 52%), but not with placebo (-1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs 2.3% with placebo). A 40-week follow up of these studies [i.e., Chapple et al., 2004b and Cardozo et al., 2004a] demonstrated that the favourable profile, both in terms of efficacy and tolerability was maintained over the study period [Haab et al., 2005].

The STAR trial [Chapple et al., 2005; 2007] was a prospective, double blind, double-dummy, two-arm, parallel-group, 12-week study was conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLT-ER 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment patients had the option to request a dose increase, but were dummied throughout as approved product labelling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was "non-inferior" to tolterodine concerning the primary effect variable, micturition freqency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (-2.85 vs -2.42), incontinence (-1.60 vs -.83), urgency incontinence (-1.42 vs -0.83), and pad usage (-1.72 vs -1.19). More solifenacin treated patients became continent by study endpoint (59 vs 49%) and reported improvements in perception of bladder condition (-1.51 vs -1.33) assessments. However, this was accompanied by an adverse event incidence which was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30 and 6.4%, tolterodine 23 and 2.5%). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9 and 7.3%) in both groups. In the SUNRISE trial solifenacin 5/10mg was significantly effective in reducing urgency and urgency bother when compared to placebo with changes noticeable as early as day 3 [Cardozo et al. 2008]. In this flexible dosing trial, 591 patients received solifenacin 5mg at 8 weeks, and 46.5% requested a dose increase to 10mg and were further randomized for 8 weeks into solifenacin 5 or 10 mgs [Cardozo et al. 2013]. Those that requested dose escalation had a greater severity of OAB at baseline. Solifenacin 10 mg at end of study compared to week 8 was statistically better than solifenacin 5mg for maximum urgency intensity, total urgency score and micturition frequency. PPBC and treatment satisfaction were not statistically different between the groups. Adverse events were generally low and dry mouth rates were 0.7 and 5.7% for solifenacin 5 and 10 mg, respectively [Cardozo et al. 2013].

Luo et al. [2012] performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and safety of the drug. Their results which largely confirmed what could be deduced from previously published information, indicated that solifenacin could significantly decrease the number of urgency episodes per 24 h, micturitions per 24 h, incontinence episodes per 24 h, nighttime micturitions per 24 h, and UUI episodes per 24 h, and improve volume voided per micturitions compared with the placebo or tolterodine treatment.

A number of studies and reviews have further documented the effects of solifenacin [Cardozo et al., 2006; Chapple et al., 2006; 2007; Maniscalco et al., 2006, see also Chapple et al., 2005; Novara et al., 2008; Toglia et al., 2009; Vardy et al., 2009; Bolduc et al., 2010; Serels et al., 2010; Luo et al., 2012], including men with OAB without bladder outlet obstruction [Kaplan et al., 2010;] In a pooled analysis of four RCTs, Abrams and Swift [2005] demonstrated positive effects on urgency, frequency and nocturia symptoms in OAB dry patients. In an analysis of four phase III clinical trials, Brubaker and FitzGerald [2007] confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: -0.6, p<0.025; with 10 mg: -0.6, p<0.001vs placebo: -0,4) but without nocturnal polyuria. A positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin has also been reported in other studies [Takao et al., 2011; Yokoyama et al., 2011; Kelleher et al. [2006] and Staskin and Te [2006] presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (≥ 65 years) patients, and also showed a high level of persistence in a 40 -week extension trial [Wagg et al., 2006]. Post-hoc analysis of two 12-week, open label, flexible-dosing studies on 2645 patients over 65 years of age with OAB, revealed that solifenacin was associated with improvements in measures assessing patients' perception of their bladder problems, symptom bother, and aspects of health-related quality of life [Capo et al., 2011]. Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients [Herschorn et al., 20011b]. An exploratory pilot study with single doses of solifenacin 10 mg to 12 elderly volunteers suggested no clear propensity to impair cognitive functions [Wesnes et al., 2009]. In the SENIOR study 26 patients with mild cognitive impairment were assessed with 3 treatments of 21 days each (solifenacin 5 mg, oxybutynin 5 mg twice daily and placebo) with suitable washout periods between treatments [Wagg et al,. 2013]. Neither solifenacin nor oxybutynin was associated with significant changes from baseline in power of attention, continuity of attention, quality of working memory, quality of episodic memory, and speed of memory. However, in a post-hoc secondary analysis, oxybutynin was associated with significant decreases in power and continuity of attention versus placebo at 1-2h post-dose.

Improvement of QoL by solifenacin treatment has been documented in several studies [Kelleher et al., 2005; Garely et al., 2006]. In 30 patients with mutiple sclerosis, van Rey and Heesakkers [2011] improved OAB symptoms as well as neurogenic disease-specific QoL measures.

Recently the SONIC trial assessed efficacy and tolerability of solifenacin in patients with multiple sclerosis (MS) and spinal cord injury (SCI) in a prospective randomized phase IIIb/IV parallel group study [Amarenco et al., 2015]. Approximately a quarter of the patients were taking muscle relaxants to help with spasticity. Patients were randomized to solifenacin 5mg, solifenacin 10mg, oxybutynin 5mgs three times daily or placebo for 4 weeks after a placebo run-in. The primary analysis was solifenacin 10mg vs placebo. The majority of MS patients were female and the majority of SCI patients were male. The primary endpoint of maximum cystometric capacity was significantly increased with solifenacin 10mg (134 mL) compared with placebo (5 mL). Furthermore, significant improvements were also observed with regards to bladder volume at first contraction and at first leak as well as detrusor pressure at first leak. PPBC and I-QoL sub scales significantly improved in favor of solifeancin 10mg compared to placebo. Significant improvements were also seen for oxybutynin compared to placebo but the trial was not designed to compare outcomes of the different active treatments [Amarenco et al. 2015]. The overall incidenece of adverse events were low and dry mouth rates were 2.3%, 4.2%, 7.8% and 17% for placebo, solifenacin 5 mg, solifenacin 10mg and oxybutynin 5 mgs three times daily, respectively.

Persistence with solifenacin use has recently been assessed in a 12-month multi-center observational study involving 1018 OAB patients from Korea [Kim et al. 2016]. At the final study follow-up at 52 weeks only 22.1% of patients were still using solifenacin. Persistence rates were 72.4%, 45.8% and 31.1% at 12, 24 and 36 weeks. Reasons for discontinuation included symptom improvement in 30.4%, lack of efficacy in 13.4% and switch to another antimuscarinic in 10.8%. Older patients and females were more likely to persist with the treatment and nocturia episodes was negatively associated with persistence [Kim et al. 2016].

A non-interventional observational study in men alone (n=799) was conducted in multiple centers in Germany in a real life practice setting [Burger et al. 2014]. In this 12 week study the majority were taking solifenacin 5mg at study end (71%) and only 1.9% discontinued the treatment. Significant improvement in OAB symptoms were observed. In a subgroup of men with mild to moderate dementia, MMSE did not change significantly over the 12 weeks. Unusually dry mouth was only reported in 1.1% and mean PVR did not change. In 80% PVR did not change and in only 2.2% was the change ≥ 50 mL. No retention of urine was observed [Burger et al., 2014].

A recent trial assessed the use of solifenacin 5mg in patients with de novo OAB symptoms after an obturator mid urethral synthetic sling and compared this to a group who was stress incontinence treatment naïve [Serati et al., 2014]. Women with a pre-existing diagnosis of DO or who had OAB symptoms were excluded as were patients with significant voiding dysfunction or persistent stress incontinence. At 3-month follow-up, interestingly, the reduction in all OAB symptoms, PGI-I and OAB-q SF scores were

significantly better in the stress incontinent naïve group compared with the de novo OAB group [Serati et al., 2014].

Information on solifenacin treatment in children is scarce. Chart review of 138 children with therapy resistant OAB, treated with solifenacin, increased mean voided volume and improved continence [Hoebeke et al., 2009]. Recently an open labelled study utilizing solifenacin doses 1.25-10mg in children with refractory incontinence was reported [Nadeau et al., 2014]. In total 112 girls and 132 boys were included (191 had IDO and 53 NDO) with mean age of 9.2 years at start of treatment. Significant improvements were seen in urodynamic parameters, PPBC, UI episodes with the dry rate being 36%. Treatment outcomes were more successful for IDO than NDO. The majority of patients reported no side effects (n=175).

In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multi-dose, randomized, double-blind, placebo and positive-controlled (moxifloxacin 400 mg) trial [Product monograph, Vesicare]. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4, 13: 90%CI) compared to the 10 mg (2 msec, -3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel et al. [2008] studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that “in real-life conditions, i.e. with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comedications, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure”.

Assessment

Solifenacin has a well-documented beneficial effect in OAB/DO (Table 2), and the adverse event profile seems acceptable.

1.1.7 Tolterodine Tartrate

Tolterodine is is a tertiary amine, rapidly absorbed and extensive metabolized by the cytochrome P450 system (CYP 2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacological profile as the mother compound [Nilvebrant et al., 1997a], and significantly contributes to the therapeutic effect of tolterodine [Brynne et al., 1997; Brynne et al., 1998]. Both tolterodine and 5-HMT have plasma half-lifes of 2-3 h, but the effects on the bladder seem to be more long-lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for <1-2.4 % of the dose; 5 – 14% of 5-HMT is eliminated in the urine (Brynne et al., 1997). Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. [2006] and Chuang et al. [2008], do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT, implies limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP 2D6 [Diefenbach et al., 2008].

Tolterodine has no selectivity for muscarinic receptor subtypes, but is claimed to have functional selectivity for the bladder over the salivary glands [Stahl et al., 1995; Nilvebrant et al. 1997b]. In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug [Stahl et al., 1995]. However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder [Andersson, 2011b]. Confirming data in humans were found by Vijaya et al. [2012]. In a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO in comparison to placebo by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 (described as urgency) and 250 Hz upon both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz (P-value <0.05).

Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability [Van Kerrebroeck et al. 2001].

Several randomised, double blind, placebo-controlled studies on patients with OAB/DO (both idiopathic and neurogenic DO), have documented a significant reduction in micturition frequency and number of incontinence episodes [Hills et al., 1998; Clemett et al., 2001; Salvatore et al., 2008]. Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment), and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily

[Appell et al., 2001] in a 12-week randomized, double blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see also below: oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of central nervous system and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study [Diokno et al., 2003], OXY-ER at 10 mg/d or TOLT-ER at 4 mg/d were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence episodes (primary end point), total (urgency and non-urgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8 and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n=391) or TOLT-ER (n=399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable, including adverse events involving the central nervous system.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) [Sussman and Garely, 2002] study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4 mg group (12%) than either the OXY-ER 5 mg (19%) or OXY-ER 10 mg groups (21%). More patients in the OXY-ER 10 mg group than the TOLT-ER 4 mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4 mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2 mg group, 59% in the OXY-ER 5 mg group and 60% in the OXY-ER 10 mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; p=0.05). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the open label design of the study.

Zinner et al. [2002] evaluated the efficacy, safety, and tolerability of TOLT-ER in older (> or =65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability endpoints were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; > or =65: ER 24.3%, placebo 7.2%). A few patients (< 2%) experienced severe dry mouth. No central nervous system (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (<65: 5.5%; > or =65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. [2003] presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n=398) or placebo (n=374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine upon experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo (P<.001).

In the IMprovement in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study [Elinoff et al., 2005], the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open label, primary care setting. Patients with OAB symptoms for $\geq$3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes,

nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs [Abrams et al., 2006; Dmochowski et al., 2007a; b; Bharucha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Kaplan et al., 2008a; Rogers et al., 2008; Rovner et al., 2008a; b see further: Novara et al, 2008; Chapple et al., 2008]. Importantly, the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo was performed. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 ms absolute QTc or 60ms change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval [Malhotra et al., 2007].

Olshansky et al. [2008] compared the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean heart rate per 24 hours. The proportion of subjects with an increase >5 beats/min was significantly greater in those receiving TOLT-ER (25% than with darifenacin (8.9%).

Hsiao et al. [2011] compared the urodynamic effects, therapeutic efficacy and safety of solifenacin [5 mg] versus tolterodine ER [4 mg] treatment inwomen with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy and adverse events, however, tolterodine had a greater effect in increasing heart rate than solifenacin.

In a prospective, open study, Song et al. [2006] compared the effects of bladder training and/or tolterodine as first line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training (BT), tolterodine (2 mg twice daily) or both for 12 weeks. All treatments were efficacious, however, combination therapy was the most effective. Mattiasson et al. [2003] compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training (BT) with tolterodine alone in patients with OAB in a multicenter single blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine + BT than with tolterodine alone (33% vs. 25%; p<0.001), while the median percentage increase in volume voided per void was 31% with tolterodine + BT and 20% with tolterodine alone (p<0.001). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine + BT (-87%). It was concluded that the effectiveness of tolterodine 2mg twice daily can be augmented by a simplified BT regimen. However, Millard et al. [2004] investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence, however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open label study tolterodine extended release plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics [Klutke et al., 2009]. More recently the combination of intravaginal oestradiol and tolterodine has been assessed to ascertain its impact on OAB [Ellington et al., 2016]. After 12 weeks of monotherapy with either tolterodine ER 4mg or oestradiol no significant differences in OAB symptom score or bladder diary was seen between the groups although within group changes were observed. In the extension study the addition of tolterodine ER to intravgainal oestrodiol significantly improved OAB symptom bother score when compared to oestradiol alone [Ellington et al., 2016].

A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women aged ≥ 18 years that were diagnosed with OAB and reported ≥ 8 micturitions/24 hr and ≥ 4 urgency episodes/week on 5-day bladder diary at baseline [Marencak et al. [2011]. Subjects were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg twice daily [BID]/4 mg once daily [QD], n=102), pregabalin alone (150 mg BID, n=105), tolterodine ER alone (4 mg QD, n=104), low-dose pregabalin/tolterodine ER (75 mg BID/2 mg QD, n=105), and placebo (n=103). Subjects completed 5-day diaries at the end of treatment and washout periods. The primary endpoint was change from baseline to week 4 in mean voided volume (MVV) per micturition. Baseline-adjusted changes in MVV were significantly greater after treatment with standard-dose pregabalin/tolterodine ER (39.5 ml) versus tolterodine ER alone (15.5 ml; P<0.0001), and with pregabalin alone (27.4 ml) versus tolterodine ER alone (P=0.005) and placebo (11.9 ml; P=0.0006). Treatments were generally well tolerated; discontinuation rates due to adverse events were 4%, 2%, 5%, 0%, and 1% with standard- and low-dose pregabalin/tolterodine ER, pregabalin, tolterodine ER, and placebo, respectively. See further section on Combinations].

Dmochowski et al. [2014] have recently assessed a new formulation of IR tolterodine 2mg with delayed release pilocarpine 9mg slow release twice daily. In this double-blind crossover trial with open label extension, combination of tolterodine and pilocarpine and

tolterodine alone were better than placebo at improving daily incontinence and micturition episodes, however were no different compared to each other. Dry mouth as assessed by VAS (0-100) were 20.9, 28.7 and 40.4 for placebo, tolterodine / pilocarpine and tolterodine alone, respectively. Other parameters such as general discomfort around the mouth and difficulty swallowing / chewing showed similar trends. The incidence of dry mouth in tolterodine / pilocarpine was similar to placebo (3.9% vs 5.3%). In the extension study patients were randomized to toltrodine 3mg and pilocarpine 13.5 mg twice daily or tolterodine ER 4mg once daily. Incidence of dry mouth were similar in the 2 groups despite the tolterodine / pilocarpine combination having 50% more tolterodine [Dmochowski et al. 2014].

Assessment

Both the IR and ER forms of tolterodine have a well-documented effect in OAB/DO (Table 2), and are well tolerated.

1.1.8 Trospium Chloride

Trospium is a quaternary ammonium compound with a biological availability less than 10% [Fusgen and Hauri, 2000; Doroshyenko et al., 2005]. The drug has a plasma half-life of approximately 20 h, and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model [Kim et al., 2005]. Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system [Beckmann-Knopp et al., 1999; Doroshyenko et al., 2005]. It is expected to cross the blood-brain to a limited extent since it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain [Geyer et al., 2009]. This was demonstrated by Staskin et al. [2010], showing that trospium chloride levels in CSF samples were undetectable on Day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects [Fusgen and Hauri, 2000; Todorova et al., 2001; Wiedemann et al., 2002; Staskin et al., 2010; Chancellor et al., 2012].

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions [Uckert et al., 2000].

Several RCTs have documented positive effects of trospium both in neurogenic [Stöhrer, et al., 1991; Madersbacher et al., 1995; Menarini et al., 2006] and non-neurogenic DO [Allousi et al., 1998; Cardozo et al., 2000; Junemann et al., 2000; Halaska et al., 2003; Zinner et al., 2004a; Rudy et al., 2006; Staskin et al., 2007; Dmochowski et al., 2008]. In a placebo-controlled, double blind study on patients with with neurogenic DO [Stöhrer et al, 1991], the drug was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximal detrusor pressure and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equieffective; however, trospium seemed to have fewer side effects [Madersbacher et al., 1995].

The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi et al. [1998] compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3-weeks duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. [2000] investigated 208 patients with DO, who were treated with trospium 20 mg twice daily for two weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 ml; placebo 254 to 255 ml) and in maximum bladder capacity (from 329 to 356 ml; placebo 345 to 335 ml) in the trospium treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann et al. [2000] compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary endpoint, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7 and 9%, respectively).

Halaska et al. [2003] studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomisation in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning, and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 ml after 26 weeks and 115 ml after 52 weeks (P=0.001). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the mouth. An overall assessment for each of the drugs

revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability.

Zinner et al. [2004a] treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinent episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action and change in Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (-2.37) and urgency incontinent episodes 59% compared to placebo (-1.29; 44%). It significantly increased average volume per void (32 ml; placebo: 7.7) ml, and decreased average urgency severity and daytime frequency. All effects occurred by week 1 and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (-0.43; placebo: 0.17) - and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%) and headache (6.5%; placebo 4.6%). In a large US multicenter trial with the same design, and including 658 patients with OAB, Rudy et al. [2006] confirmed the data by Zinner et al [2004a], both with respect to efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomised, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence received trospium chloride 15 mg TID (n = 828) or 2.5 mg oxybutynin hydrochloride TID (n = 830). After four weeks, daily doses were doubled and not readjusted in 29.2% (242/828) of patients in the trospium group, and in 23.3% (193/830) in the oxybuytnin group, until the end of treatment. At study end, there were no relevant differences between the "dose adjustment" subgroups and the respective "no dose adjustment" subgroups (trospium: P = 0.249; oxybutynin: P = 0.349). After dose escalation, worsening of dry mouth was higher in both dose adjusted subgroups compared to the respective "no dose adjustment" subgroups (P < 0.001). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups [Bödeker et al., 2010].

An extended release formulation of trospium allowing once daily dosing, has been introduced [Silver et al., 2010], and and its effects tested in controlled trials [Dmochowski et al., 2008; Staskin et al., 2009; Chancellor et al., 2010; MacDiarmid et al., 2011; Sand et al., 2011a; b; Zinner et al., 2011]. These studies demonstrated similar efficacy as found with previous formulations, but include experiences in e.g., elderly patients (>75 years), obese patients, and in patients who use multiple concomitant medications. In the pooled analysis of 2 large phase III trials (n=1027), trospium chloride extended release 60 mg once daily significantly improved micturition and UUI epsidoes per 24 hours compared to placebo [Staskin et al. 2009]. Furthermore, trospium was superior to placebo in OAB symptom composite score, urgency episodes and mean voided volume. Dry mouth and constipation were the 2 commonest adverse events being 10.7% and 8.5% with trospium compared to 3.7% and 1.5% with placebo. The pooled analysis of the long-term extension study (n=667) with extended release once daily trospium chloride 60 mg daily also showed benefit in managing OAB [Zinner et al. 2011]. Significant improvements were seen in the placebo to trospium group and efficacy maintained in the trospium to trospium group by end of study. Approximately 85% of the population felt their symptoms were improved with trospium chloride treatment. Furthermore, significant improvements in quality of life were demonstrated when using the KHQ.

Intravesical application of trospium may be an interesting alternative. Frölich et al. [1998] performed a randomised, single-blind, placebo-controlled, monocentre clinical trial in 84 patients with urgency or urgency incontinence. Compared to placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed [Walter et al., 1999], thus offering an opportunity for treatment with minimal systemic antimuscuscarinic effects.

Assessment

Trospium has a well-documented effect in OAB/DO, and tolerability and safety seems acceptable (Table 2).

1.2. Antimuscarinics with "Mixed" Action

Some drugs used for treatment of the OAB syndrome/DO have been shown to have more than one mechanism of action. They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined "direct" action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage operated Ca^{2+} channels. Most probably, the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsade de pointes) in some patients [Connolly et al., 1991; Stewart et al., 1992].

1.2.1 Oxybutynin Chloride

Oxybutynin is a tertiary amine that is well absorbed, and undergoes extensive upper gastrointestinal and

first-pass hepatic metabolism via the cytochrome P-450 system (CYP3A4) into multiple metabolites. The primary metabolite, N-desethyloxybutynin (DEO) has pharmacological properties similar to the parent compound [Waldeck et al., 1997], but occurs in much higher concentrations after oral administration [Hughes et al., 1992]. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander et al. [1988]. The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation [Hughes et al., 1992; Douchamps et al, 1988].

Oxybutynin has several pharmacological effects *in vitro*, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically, but probably plays no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent [Kachur et al., 1988]. Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions [Waldeck et al., 1997; Nilvebrant et al., 1988]. The drug was shown to have slightly higher affinity for muscarinic M_1 and M_3 receptors than for M_2 receptors [Nilvebrant et al., 1986; Norhona-Blob et al., 1991], but the clinical significance of this is unclear.

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy and most of the newer anti-muscarinic agents have been compared to it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other anti-muscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosing schedules and side-effect profile [Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002]. An extended release oxybutynin (OXY-ER) once daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability. Some of the available formulations of oybutynin were overviewed by McCrery and Appell [2006].

1.2.1.1 Immediate-Release Oxybutynin (OXY-IR)

Several controlled studies have have shown that OXY-IR is effective in controlling DO, including neurogenic DO [Yarker et al., 1995; Andersson and Chapple, 2001]. The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. [1998] summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52% and the mean reduction in frequency per 24 h was 33% (data on placebo not presented). The overall " subjective improvement" rate was reported as 74 % (range 61% - 100%). The mean percent of patients reporting an adverse effect was 70 (range 17% - 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved quality of life of patients suffering from overactive bladder in a large open multicenter trial. In this study, patients´ compliance was 97% and side effects, mainly dry mouth, were reported by only 8% of the patients [Amarenco et al., 1998]. In nursing home residents (n=75), Ouslander et al. [1995] found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double blind, cross-over trial. On the other hand, in another controlled trial in elderly subjects (n=57), oxybutynin with bladder training was found to be superior to bladder training alone [Szonyi et al., 1995].

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit [Szollar et al., 1996; Kim et al., 1996].

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose-limiting [Baigrie et al., 1988; Jonville et al., 1992]. The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence [Hussain et al., 1998]; no changes were found. It cannot be excluded that the commonly recommended dose 5 mg x 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg x 2 with following dose-titration would reduce the number of adverse effects [Amarenco et al., 1998].

1.2.1.2 Extended Release Oxybutynin (OXY-ER)

This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy [see Arisco et al., 2009]. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared to OXY-IR. DEO is still formed through the hepatic cytochrome P-450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR [Appell et al.,

2003]. Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day [Chancellor et al., 2001].

The effects of OXY-ER have been well documented [Siddiqui et al., 2004]. In the OBJECT study [Appell et al., 2001], the efficacy and tolerability of 10 mg OXY-ER was compared to a twice daily 2 mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6 to 6.1%; TOLT-IR 24.1 to 7.8), total incontinence (OXY-ER from 28.6 to 7.1%; TOLT-IR 27.0 to 9.3), and frequency (OXY-ER from 91.8 to 67.1%; TOLT-IR 91.6 to 71.5) and both medications were equally well tolerated. The basic study was repeated as the OPERA study [Diokno et al., 2003] with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg) and the results were quite different. In this study there was no significant difference in efficacy for the primary endpoint of urgency incontinence, however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In a 1999 study [Anderson et al., 1999], 105 patients with urgency or mixed incontinence were randomized to receive 5-30 mg OXY-ER once daily or 5 mg of OXY-IR 1-4 times/day. Dose titrations began at 5 mg and the dose was increased every 4-7 days until one of three endpoints was achieved. These were 1) the patient reported no urgency incontinence during the final two days of the dosing period; 2) the maximum tolerable dose was reached; the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR but dry mouth was reported statistically more often with OXY-IR. In the 2000 study [Versi et al., 2000], 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily. As in the 1999 study, OXY-ER again achieved a >80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naïve patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naïve population [Gleason et al., 1999].

In an RCT comparing different daily doses of oxybutynin (5, 10 and 15 mg), Corcos et al. [2006] found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

In a multicentre, prospective, observational, flexible-dosing Korean study, Yoo et al. [2012] investigate the prescription pattern and dose distribution of OXY-ER in patients the OAB syndrome in actual clinical practice. The dosage of for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12-week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered, the patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5–10 mg ⁄ day oxybutynin ER as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment and 89.3% were satisfied.

1.2.1.3 Transdermal Oxybutynin (OXY-TDS)

Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study [Davila et al., 2001] comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinent episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study [Dmochowski et al., 2002] the 3.9-mg daily dose patch significantly (vs placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 ml; placebo from 175 to 182 ml). Furthermore, dry mouth rate was similar to placebo (7% vs 8.3%). In a third study [Dmochowski et al., 2003a] OXY-TDS was compared not only to placebo but to TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. The primary adverse event for OXY-TDS was application site reaction pruritis in 14% and erythema in 8.3% with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, 2-way crossover study [Appell et al., 2003]. Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism

to DEO compared to OXY-ER which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. [2005] analyzing the combined results of two RCTs concluded that transdermal oxybutynin was shown to be efficacious and well tolerated. The most common sytemic side effect was dry mouth (7.0 % vs placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1 %. Also Cartwright and Cardozo [2006], reviewing published and presented data concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower that with oral antimuscarinics – however, this benefit was offset by the rate of local skin reaction. The reviews of Sahai et al. [2008] and Staskin and Salvatore [2010] largely confirmed these conclusions, which also have been supported by further studies [Cartwright et al., 2011].

In a Japanese population of OAB an alternative daily 73.5mg transdermal oxybutynin patch was assessed against propiverine 20mg daily and placebo [Yamaguchi et al., 2014]. Aproximately 570 patients were in the active arms and 380 in placebo. At 12 weeks, the oxybutynin patch was significantly superior than placebo and non-inferior to propiverine for daily micturition episodes. Urgency and voided volume was better compared to placebo for transdermal oxybutynin, however urgency incontinence episodes and nocturia were no different. Furthermore 8 out of 9 domains assessed utilising the KHQ were better for transdermal oxybutynin compared to placebo suggesting better quality of life in this group. Dry mouth and constipation were seen in 6.5% and 0.7%, 13.2% and 5%, and 1.8% and 1% in the transdermal oxybutynin, propiverine and placebo groups, respectively. In the transdermal oxybutynin group application site dermatitits was seen in 31.8%, with site erythema in 5.6%.

Recently the transdermal patch (3.9mg/day) has been shown to be subjectively effective in a small paediatric population but with 35% skin site irritation and 20% discontinuation rate [Gleason et al., 2014].

1.2.1.4 Oxybutynin Topical Gel

Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. oxybutynin topical gel (OTG) was approved by the US FDA in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area [Staskin et al., 2009]. The 1g application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentrations and a "favorable" N-desethyloxybutynin metabolite: oxybutynin ratio believed to minimizing antimuscarinic side effects [Staskin and Robinson, 2009]. In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks [Staskin et al., 2009]. The mean number of urgeny episodes, as recorded by 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm (P <0.0001). Urinary frequency decreased by 2.7 episodes per day and voided volume increased by 21 mL (versus 2.0 episodes [P = 0.0017] and 3.8 mL [P = 0.0018], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly upon application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site [Dmochowski et al., 2011]. The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand et al. [2012] showing that in 704 women with OAB OTG significantly reduced the number (mean ± standard deviation) of daily incontinence episodes (OTG, -3.0 ± 2.8 episodes; placebo, -2.5 ± 3.0 episodes), reduced urinary frequency, increased voided volume, and improved select health-related quality-of-life domains vs placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

Anewer 3% topical oxybutynin gel has been assessed in a phase III randomised placebo controlled trial (randomised n=626) [Goldfischer et al. 2015]. This product is administered via a metered dose pump dispenser and was hypothesised to have less adverse events. Furthermore, it is made with propylene glycol to help with skin permeation. Two doses of 84mg/day and 56 mg/day of the 3% topical oxybutynin were assessed against placebo gel in this population of patients with urgency and / or urge predominant mixed incontinence. The 84 mg / day dose was statistically better than placebo after 12 weeks in improving weekly UI episodes (primary endpoint) and also daily urinary frequency and urine voided volumes. The lower dose of 56mg / day was not statistically better than placebo. Dry mouth and application site erythema was seen in 12.1% and 3.3% in the 84 mg / day group compared to 5% and 0.5% in the placebo arm.

1.2.1.5 Other Administration Forms

Rectal administration [Collas and Malone-Lee, 1997] was reported to have fewer adverse effects than the conventional tablets.

Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults [Lose and Norgaard, 2001; Fader et al., 2007; George et al., 2007; Guerra et al., 2008], although adverse effects may occur [Kasabian et al., 1994; Palmer et al., 1997]. More recently a phase II exploratory randomized placebo controlled trial (n=323) of intra-vaginal oxybutynin

ring was conducted based on the premise that there is a shared lymphovascular network between the vagina and bladder [Gittelman et al. 2014]. Approximately one quarter of the patients had an accidental fallout of the ring. Both formulations of 4 and 6 mg were better than placebo at reducing weekly UI episodes when compared to placebo. Dry rates, frequency and UUI episodes were also statistically better in the 6mg intravgainal oxybutynin group compared to placebo. UTI, dry mouth and vaginal discharge were the commonest adverse events. UTI and dry mouth rates were 11.6% and 10.2% in the 6mg oxybutynin group, 9.1% and 4.9% in the 4mg oxybutynin group and 4.5% and 2.6% in the placebo groups.

1.2.1.6 Effects on Cognition

Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population [see section on "Condiderations in the Elderly"], but also in adults and inchildren [see, e.g., Kay et al., 2006; Klausner and Steers, 2007; Kay and Ebinger, 2008]. This factor should be taken into consideration when prescribing the drug.

Assessment

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (Table 2). Despite the adverse effect profile, it is still an established therapeutic option.

1.2.2 Propiverine Hydrochloride

Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine were reviewed by Madersbacher and Murz [2001]. The drug is rapidly absorbed (t_{max} 2 h), but has a high first pass metabolism, and its biological availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100-times above the therapeutic doses in man [Walter et al., 2003]. Several active metabolites are formed which quantitatively and qualitatively differ from the mother compound [Haustein et al., 1988; Muller et al., 1993; Wuest et al., 2006; Zhu et al., 2008; Sugiyama et al., 2008]. Most probable these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified [Michel and Hegde, 2006]. The half-life of propiverine itself is about 11-14 h. An extended release preparation was shown to be effective [Junemann et al., 2006; May et al., 2008]. Oral absorption of propiverine is site dependent and influenced by dosage form and circadiantime–dependent elimination processes [May et al., 2008].

Propiverine has combined antimuscarinic and calcium antagonistic actions [Haruno, 1992; Tokuno et al., 1993]. The importance of the calcium antagonistic component for the drug´s clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes. The effects of propiverine on cardiac ion channels and action potentials were investigated by Christ et al. [2008]. Propiverine blocked in a concentration-dependent manner HERG channels expressed in HEK293 cells, as well as native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea-pig and human ventricular tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al [1998] collected 9 randomized studies on a total of 230 patients, and found a 17% reduction in micturitions per 24 hours, a 64 ml increase in bladder capacity, and a 77% (range 33-80%) subjective improvement. Side effects were found in 14 % (range 8-42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine´s superiority over placebo [Stöhrer et al., 1999]. Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate and placebo [Wehnert et al., 1989], and propiverine, oxybutynin and placebo [Wehnert et al., 1992; Madersbacher et al., 1999], have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared [Stöhrer et al., 2007]. The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin. Recently the once daily extended release formulation of propiverines was compared to immediate release propiverine in a trial with 66 patients suffering with NDO [Stohrer et al. 2013]. The primary endpoint was change in reflex volume which was improved and comparable between the two formulations. However, continence rates were statistically better in the ER group compared to IR. Adverse events were similar with dry mouth rates 27% and 24% for ER and IR formulations, respectively.

Also in children and adolescents with neurogenic DO, propiverine was found to be effective [Schulte-Baukloh et al., 2006; Grigoleit et al., 2006], with a low incidence rate of adverse events: <1.5% [Grigoleit et al., 2006]. A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5–10 yr was performed by Marschall-Kehrel et al. [2009]. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary endpoints included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well-tolerated: 23% of side-effects were reported for propiverine and 20% for placebo.

In a randomised, double-blind, multicentre clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days [Junemann et al., 2005]. The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary endpoint. Secondary endpoints were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, post void residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly ($p < 0.01$) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups.

Madersbacher et al. [1999] compared the tolerability and efficacy of propiverine (15 mg three times daily) oxybutynin (5 mg twice daily) and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner et al. [2000] investigated in a double-blind, multicentre, placebo-controlled, randomized study, the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years), suffering from urgency, urgency incontinence or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine – 2 out of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes. The cardiac safety of propiverine was further studied by Donath et al. [2011] in two comprehensively designed monocentric ECG studies (including 24 healthy females, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathological Pardee-Q-wave in the ECG). Both studies were placebo-controlled and compared the effects of single (30 mg s.i.d.) and multiple dosing (15 mg t.i.d.) of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively., They were performed to investigate the influence of propiverine hydrochloride and its main metabolite propiverine-N-oxide on cardiac function with regard to QTc prolongation, QTc dispersion and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams et al. [2006] compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring parameters, safety, and tolerability in OAB patients. Patients (n=77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi et al. [2007] performed a multicentre, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at endpoint in number of voids/24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume voided/void, restoration of continence and quality of life (QoL) were examined. It was found that at endpoint, there were greater reductions in mean (SD) voids/24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL vs placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided vs propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada et al. [2011] performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks then solifenacin (5 mg) for 8 weeks or solifenacin for 8 weeks then propiverine for 8 weeks. At baseline, 8th week and 16th week, symptoms were assessed using overactive bladder symptom score (OABSS). Of the 121 patients enrolled 83 were analysed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicenter, prospective, parallel, double blind, placebo-controlled trial, Lee et al. [2010] studied the effects of 30 mg propiverine/day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with >75 compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing 'much benefit', compared with 15 % in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable.

Recently the extended release formulation of propiverine was compared to the extended release formulation of tolterodine in a non-inferiority trial with approximately 150 patients in each study arm [Leng et al., 2016]. Statistically more significant reductions were seen for propiverine ER compared with tolterodine ER. Discontinuation rates because of adverse events were more in the tolterodine ER group compared to propiverine ER (7.4% vs 3.1%). Based on

the way the study was designed and powered the authors concluded that ER propiverine was non-inferior to ER tolterodine [Leng et al., 2016].

Masumori et al. [2011] examined prospectively the efficacy and safety of propiverine 20mg / day in patients withOAB symptoms who poorly responded to previous treatment with solifenacin, tolterodine or imidafenacin. Of 73 patients enrolled (29 malesand 44 females, median age 71 years), 52 completed the protocol treatment. The OABSS was significantly improved by propiverine treatment. The scores of OAB symptoms (nighttime frequency, urgency and urge incontinence) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event wasdry mouth (13.7%), followed by constipation (6.8%).

In a non-controlled study in patients with wet OAB the efficacy of propiverine on symptoms and quality of life was confirmed [Komatsu et al. [2009].

Assessment

Propiverine has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

1.2.3 Flavoxate Hydrochloride

Flavoxate is often discussed as a drug with mixed actions, however, its main mechanism of action may not be antimuscarinic. Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% [Guay, 2003]. The drug is extensively metabolized and plasma half-life was found to be 3.5 h [Sheu et al., 2001]. Its main metabolite (3-methylflavone-8-carboxylic acid, MFCA) has been shown to have low pharmacological activity [Cazzulani et al., 1988; Caine et al., 1991]. The main mechanism of flavoxate's effect on smooth muscle has not been established. The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase, and to have local anesthetic properties; no antimuscarinic effect was found [Guarneri et al., 1994]. Uckert et al. [2000], on the other hand, found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable, It has been suggested that pertussis toxin-sensitive G-proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhytmic bladder contractions in anesthetized rats [Oka et al., 1996].

The clinical effects of flavoxate in patients with DO and frequency, urgency and incontinence have been studied in both open and controlled investigations, but with varying rates of success [Ruffman, 1988]. Stanton [1973] compared emepronium bromide and flavoxate in a double-blind, cross-over study of patients with detrusor overactivity and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered as 200 mg 3 times daily. In another double-blind, cross-over study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency, and utilising both clinical and urodynamic criteria, Milani et al. [1993] found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects of flavoxate with those of placebo, have not been able to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily [Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995]. In general, few side effects have been reported during treatment with flavoxate. On the other hand, its efficacy, compared to other therapeutic alternatives, is not well documented (Table 2).

Assessment

No RCTs seem to have been performed with flavoxate during the last decade. The scarcity of documented clinical efficacy should be considered before using the drug.

1.3. Clinical Use of Antimuscarinics

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herbison et al. [2003] stated in a widely discussed article: “Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo. *The benefits are, however, of limited clinical significance*” Large meta-analyses of studies performed with the currently most widely used drugs [Chapple et al., 2005; 2008; Novara et al., 2008], clearly show that antimuscarinics are of significant clinical benefit. Novara et al. [2008] reviewed 50 RCTs and 3 pooled analyses, which they considered of good methodological quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references, Chapple et al. [2008], based their conclusions (“antimuscarinics are efficacious, safe, and well tolerated treatments”) on 73 RCTs selected for their meta-analysis. It was recommended that since the profiles of each drug (see below) and dosage differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known and the relapse rate of symptoms after discontinuation of treatment has not been systematically studies. In 173 women with OAB symptoms for >6 months, Lee et al. [2011a] studied in a prospective, randomized, open-label, trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6-months. The relapse rate was 62%, and the request for treatment was 65 %, indiretly suggesting an efficacy of treatment. None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenacin, oxybutynin, propiverine, solifenacin, tolterodine or trospium) is ideal as

a first-line treatment for *all* OAB/DO patients. Optimal treatment should be individualized, implying that the patient´s co-morbidities and concomitant medications, and the pharmacological profiles of the different drugs, should be taken into consideration [Chapple et al., 2008].

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. [2012] analysed 86 trials, 70 with parallel and 16 with crossover designs (31,249 adults). They concluded that when the prescribing choice is between oral immediate release oxybutynin or tolterodine, tolterodine might be preferred for reduced risk of dry mouth. ER preparations of oxybutynin or tolterodine might be preferred to immediate release preparations because there is less risk of dry mouth. Comparing solifenacin and immediate release tolterodine, solifenacin might be preferred for better efficacy and less risk of dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy, but has higher risk of withdrawal due to adverse events and higher risk of dry mouth.

Several studies have documented that the persistence with prescribed antimuscarinic therapy for overactive bladder is low [Kelleher et al., 2005; Basra et al.,2008; Sears et al., 2010; Wagg et al., 2012]. The most common causes seem to be lack of efficacy and adverse effects. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. [2012] analysed prescription data for patients receiving antimuscarinics for treatment of the OAB syndrome over a 12-month period. At 12 months, they found that the proportions of patients still on their original treatment were: solifenacin 35%, tolterodine ER 28%, propiverine 27%, oxybutynin ER 26%, trospium 26%, tolterodine IR 24%, oxybutynin IR 22%, darifenacin 17%, and flavoxate 14%. The longest mean persistence was reported for solifenacin (187 days versus 77 − 157 days for the other treatments). Similar trends in other healthcare systems have been reported [Mauseth et al., 2013; Kalder et al. 2014]. Gomes et al. [2012] compared the persistence of oxybutynin or tolterodine therapy among older patients newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians aged 66 years and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients newly treated with oxybutynin and 24,855 newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, $p < 0.0001$). The median time to discontinuation of oxybutynin and tolterodine was 68 and 128 days, respectively. Kessler et al. [2011] analysed 69 trials enrolling 26'229 patients with OAB with the aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first choice drugs to start the treatment of OAB, except for oral oxybutynin dosages of ≥ 10 mg/day, which may have more unfavorable adverse event profiles. Another systematic review concluded that persistence rates regardless of antimuscarinic was generally poor, with median rates 12-39.4% at 12 months and 6-12% at 24 months [Veenboer and Bosch, 2014]. Risk factors for discontinuation included younger age group, use of IR formulations and oxybutynin.

Even if the use of antimuscarinics is associated with many adverse effects, they are generally considered to be 'safe' drugs. However, among the more serious concerns related to their use is the risk of cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsade de pointes), and increases in heart rate (HR) [Andersson and Olshansky, 2007; Andersson et al., 2011].

QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart.

However, the experiences with terodiline, an antimuscarinic drug that caused torsade de pointes in patients [Connolly et al., 1991; Stewart et al., 1992], have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart (Figure 10) oppose the excitatory actions of the sympathetic nervous system, and slows the heart rate (Figure 11). An elevated resting HR has been linked to overall increased morbidity and mortality, particularly in patients with cardiovascular diseases. The prevalence of CV comorbidities was found to be significantly higher in patients with than without OAB [Andersson et al., 2010]. Since mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk of cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences between drugs cannot be excluded, but risk assessments based on available evidence are not possible.

Antimuscarinics are recommended in treating OAB when lifestyle interventions have failed. However, many guidelines would recommend when one antimuscarinic fails due to lack of efficacy or poor tolerability that a second and even third should be tried. A recent retrospective medicine and pharmacy claims analysis in the US linked to a one-time patient survey of members with OAB-wet was recently reported with the specific aim of assessing antimuscarinic treatment patterns and outcomes [Chancellor et al., 2016]. A total of 620 patients were finally included after ex-

clusions. Patients cycled through 1-6 unique antimuscarinics. In general adherence to the medication was poor and 35% of the population used ≥ 2 antimuscarinics. Moreover, UI episodes and burden was fairly-consistent despite antimuscarinic cycling and whether patients continued or discontinued their medication. Discontinuation rates were high being 71% of the whole population at study end. Approximately 89% of patients continued to be bothered by their bladder symptoms and requested additional help, whether or not they remained on antimuscarinics. The study suggests that antimuscarinic cycling does not have a positive impact on patients in terms of UI. As a result, alternative therapies should be sought for patients who have failed 1-2 antimuscarinics.It seems logical that if there is inadequate efficacy with 1 antimuscarinic that the maximum dose should be trialled in those with a flexible dosing option especially if the lower dose had an acceptable adverse event profile.

In those where tolerability is an issue switching to an alternative muscarinic is also reasonable. However, thereafter treatment should be escalated to include non antimusacrinic options.

The use of antimuscarinics to treat the storage component of lower urinary tract symptoms in combination with other classes of drugs is increasing. Furthermore, the evidence base to support this is also expanding. Details of the use of antimuscarinics in combination with β_3-AR agonist agents to treat refractory OAB, in combination with alpha blockers and 5 alpha reductase inhibitors to combat lower urinary tract symptoms attributable to benign prostatic enlargement are covered in later sections of this chapter (see section on Combinations).

2. β-ADRENOCEPTOR AGONISTS

In isolated human bladder, non-subtype selective β-AR agonists like isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in man [Andersson, 1993]. However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β_1-, nor β_2- ARs, since they could be blocked by propranolol, but not by practolol or metoprolol (β_1) or butoxamine (β_2) [Nergard et al., 1977; Larsen, 1979].

On the other hand, early receptor binding studies using subtype selective ligands, suggested that the β-ARs of the human detrusor are primarily of β_2 subtype [Andersson, 1993], and favourable effects on DO were reported in open studies with selective β_2-AR agonists such as terbutaline [Lindholm and Lose, 1986]. In a double-blind investigation clenbuterol 0.01 mg 3 times daily was shown to have a good therapeutic effect in 15 of 20 women with DO [Gruneberger, 1984]. Other investigators, however, have not been able to show that non-subtype selective β-ARs agonists represent an effective therapeutic principle in elderly patients with DO [Castleden and Morgan, 1980], or in young patients with myelodysplasia and DO [Naglo et al., 1981].

However, three subtypes (β_1, β_2, and β_3) have been identified in the detrusor of most species, including humans [Andersson and Arner, 2004; Michel and Vrydag, 2006]. Also the human urothelium contains all three receptor subtypes [Otsuka et al., 2008]. Studies, using real-time RT-PCR, have revealed a predominant expression of β_3-AR mRNA in human detrusor muscle [Nomiya and Yamaguchi, 2003; Michel and Vrydag, 2006; Igawa et al., 2010] and the functional evidence for an important role in both normal and neurogenic bladders is convincing [Fujumura et al., 1999; Igawa et al., 1999; Takeda et al., 1999; Morita et al., 2000; Igawa et al., 2001; 2010; Biers et al., 2006; Michel and Vrydag, 2006; Badawi et al., 2007; Leon et al., 2008].

The human detrusor also contains β_2-ARs, and most probably both receptors are involved in the physiological effects (relaxation) of noradrenaline in this structure [Andersson and Arner 2004; Michel and Vrydag, 2006; Igawa et al., 2010].

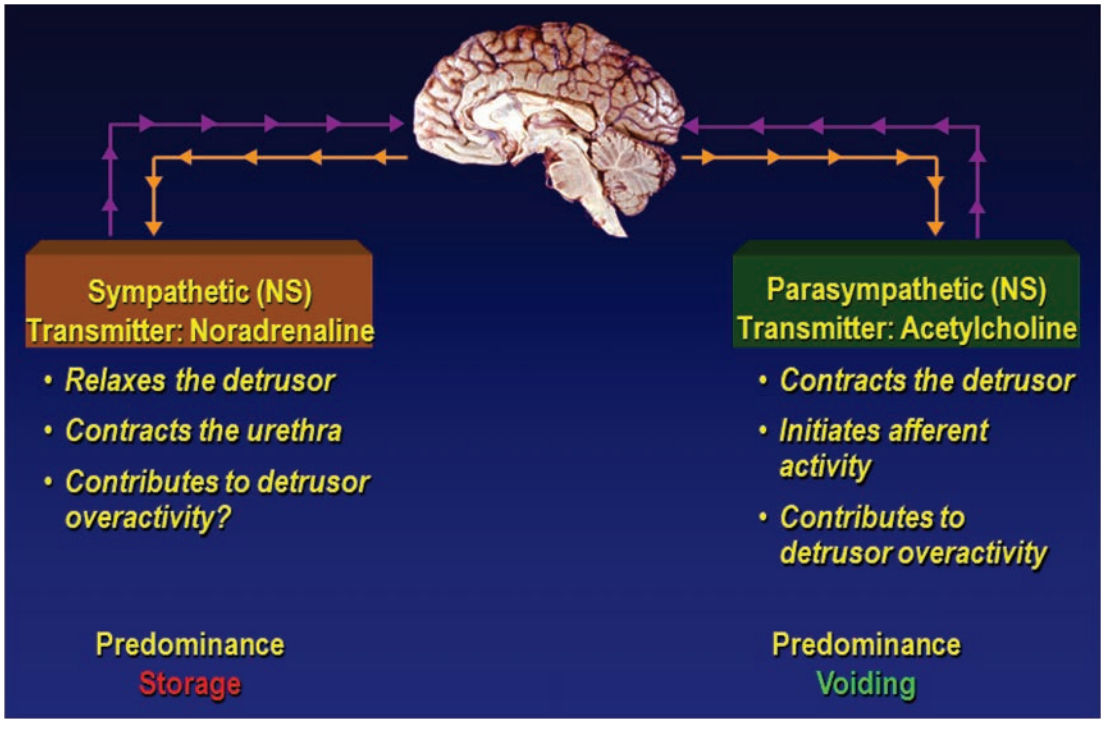

Figure 10: Cardiac control via the autonomic nervous system. Acetylcholine, released from parasympathetic nerve terminals activate muscarinic receptors that mediate decrease in heart rate, decrease in force of contraction, and decrease in conduction velocity

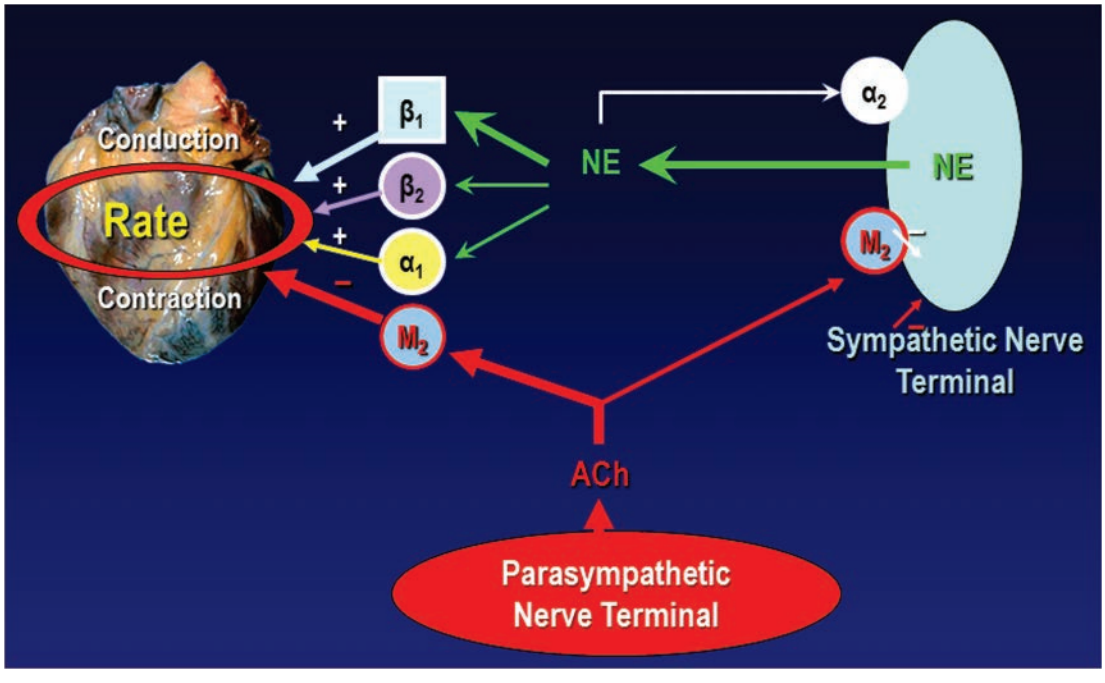

Figure 11: Autonomic receptors controlling heart rate. Acetylcholine, released form parasympathetic nerve terminals, activate muscarinic M_2 receptors that mediate a decrease in heart rate. Inhibition of these receptors by antimuscarinics may increase heart rate.

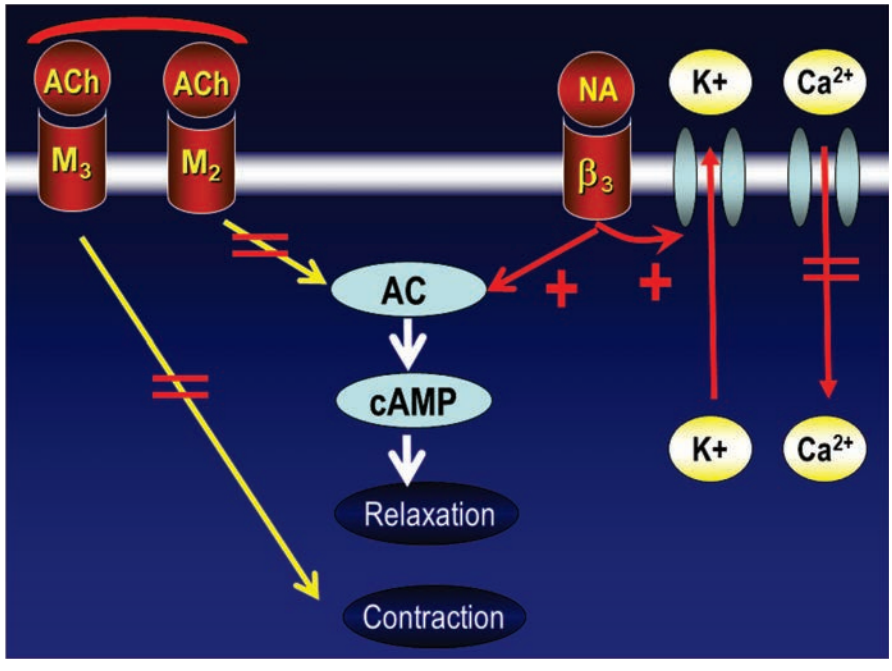

Figure 12: During bladder filling, there is normally no parasympathetic nervous outflow to the bladder and no release of acetylcholine (ACh). The sympathetic nervous system is active and releases noradrenaline (NA) that via β3 adrenoceptors stimulates adenylyl cyclase (AC) and generation of cyclic AMP (cAMP) which mediates relaxation of the bladder. In addition, β3-adrenoceptor stimulation activate K+ channels, stimulating outflow of K+, which causes hyperpolarisation and inhibition of Ca2+ inflow.

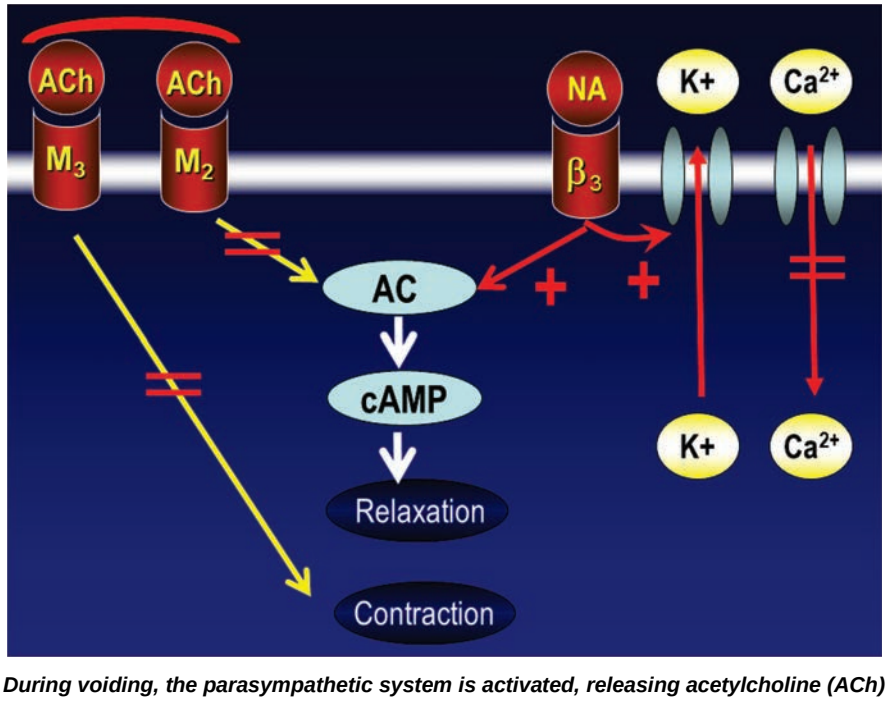

Figure 13: During voiding, the parasympathetic system is activated, releasing acetylcholine (ACh) which causes bladder contraction, directly via muscarinic M_3 receptor stimulation, and indirectly by inhibition of adenylyl cyclase (AC) via stimulation of muscarinic M_2 receptors. The sympathetic nerve activity is turned off. In vivo exogenous stimulation of the β_3-adrenoceptors by β_3-adrenoceptor agonists is not sufficient to inhibit the muscarinic receptor mediated activation, which implies that the voiding contraction is not compromised.

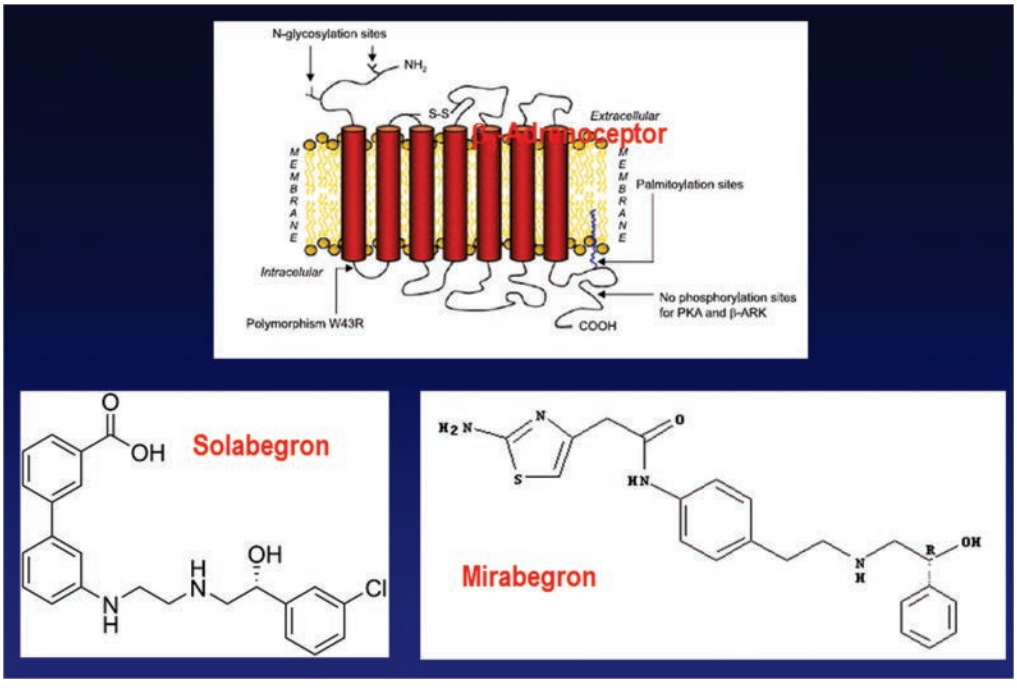

Figure 14: The β 3-adrenoceptor is the predominating β -adrenoceptor subtype in different structures of the bladder (mucosa, detrusor smooth muscle) and they can be stimulated by highly selective β 3-adrenoceptor agonists like mirabegron and solabegron.

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species, is activation of adenylyl cyclase with the subsequent formation of cAMP (Figures 12 and 13).

However, there is evidence suggesting that in the bladder K+ channels, particularly BK_{Ca} channels, may be more important in β-AR mediated relaxation than cAMP [Hudman et al., 2000; Frazier et al., 2005; Uchida et al., 2005; Frazier et al., 2008]. β_3- AR agonists have generally been considered to relieve OAB symptoms by relaxing detrusor muscle, inhibiting spontaneous contractile activity in the detrusor (*in vitro:* microcontractions*; in vivo*: non-voiding contractions), and reducing bladder afferent activity (Figure 14) [Biers et al., 2006; Takasu et al., 2007; Aizawa et al., 2012; Gillespie et al., 2012; Hatanaka et al., 2013; Igawa and Michel, 2013].

However, Gillespie and colleagues have questioned the accepted view on the mode and site of action of β_3-AR agonists [Eastham and Gillespie, 2013; Gillespie et al., 2015a; 2015b; Granato et al., 2015], and suggested that effects on neither spontaneous microcontractions, nor on non-voiding contractions in e.g., obstructed rats, can fully explain the effects of mirabegron. Assuming that acetylcholine (ACh) release from cholinergic terminals during bladder filling contributes to OAB symptoms, the finding that activation of pre-junctional β_3-ARs may down-regulate ACh release resulting in an inhibitory control of parasympathetic activity, may be of importance [Rouget et al., 2014; D'Agostino et al., 2015].

Since β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated [Murakami et al., 2007; Otsuka et al., 2008]. Murakami et al. [2007] found that the relaxation responses of the detrusor were not influenced by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka et al. [2008]. However, to what extent a urothelial signaling pathway contributes *in vitro* and *in vivo* to the relaxant effects of β-AR agonists in general, and β_3-AR agonists specifically, remains to be elucidated.

The in vivo effects of β_3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics), β_3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume [Fujimura et al., 1999; Woods et al., 2001; Takeda et al., 2002; Kaidoh et al., 2002; Igawa et al., 2010]. For example, Hicks et al. [2007] studied the effects of the selective β_3-AR agonist, GW427353, in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid evoked bladder hyperactivity, without affecting voiding.

A number of β_3-AR selective agonists are currently being evaluated as potential treatment for OAB (Fig-

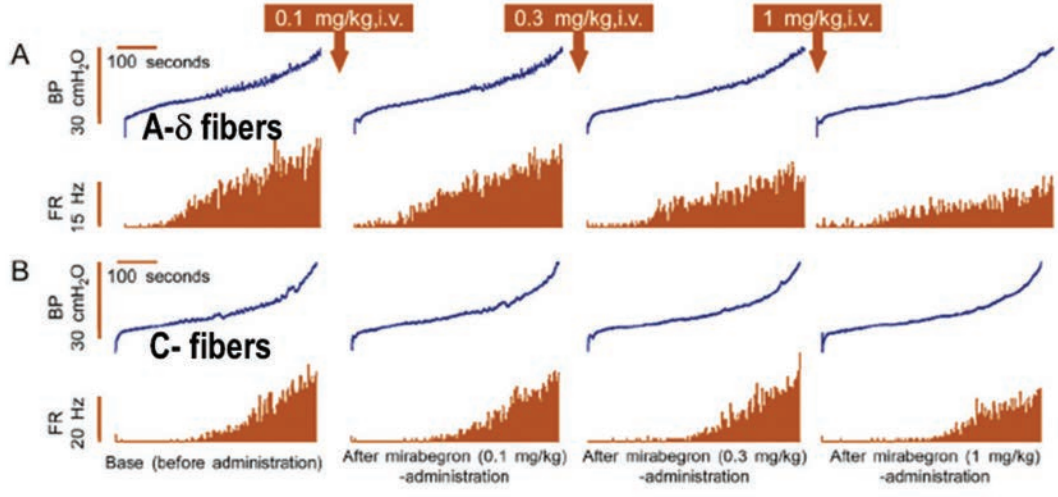

Figure 15: Stimulation by highly selective β_3-adrenoceptor agonists like mirabegron may inhibit bladder afferent activity in both Aδ- and C-fibres. From Aizawa et al., Eur Urol. 2012 Dec;62(6):1165-73

ure 15) but so far the only drug approved for treatment in humans is mirabegron. The effects of mirabegron in men and women with OAB have been summarised in several recent reviews [Chapple et al., 2014; Cui et al., 2014; Rossanese et al., 2015], and also in men with both voiding and OAB symptoms [Suarez et al. 2013; Otsuki et al, 2013].

2.1. Mirabegron

Takusagawa et al. [2012] found that mirabegron was rapidly absorbed after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites. Of the administered dose, 55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces, almost entirely as the unchanged form. Mirabegron is highly lipophilic and is metabolised in the liver via multiple pathways, mainly by cytochrome P450 3A4 and 2D6 (CYP2D6) [van Gelderen et al., 2009]. In a Phase I pharmacokinetic study, sixteen healthy volunteers, phenotyped as either poor or extensive metabolisers of CYP2D6 were enrolled. They received a 160-mg single oral dose after overnight fasting. Poor metabolisers excreted a slightly higher urinary fraction of mirabegron (15.4±4.2%) than extensive metabolisers (11.7±3.0%). T_{max} in both extensive and poor metabolizers was about 2 hours and the terminal elimination half-life (t1/2) approximately 23-25 hours.

Chapple et al. [2008] reported the results of a phase IIA trial of mirabegron in patients with OAB. The Blossom trial, conducted in several European countries, was a proof of concept study. It enrolled 314 patients with OAB symptoms - 262 patients were randomly assigned to 4 groups: placebo, mirabegron 100 mg bid, mirabegron 150 mg bid, and tolterodine 4 mg qd for a 4-week treatment period. The primary endpoint was efficacy, and the primary efficacy variable was the change in the mean number of micturitions per 24 hours as recorded on a frequency/volume chart. In both mirabegron groups significant improvements in the mean number of micturitions per 24 hours were found compared with the placebo group (−2.19 and −2.21 vs. −1.18, respectively). Mean volume voided was dose-dependently increased in the mirabegron groups, and the change reach significance in the mirabegron 150 mg group. Urgency episodes per 24 hours decreased significantly in both mirabegron groups compared with the placebo group. No severe adverse events were reported and treatment was generally well tolerated. A small, mean increase in pulse rate with mirabegron 150 mg (5 beats per minute) was demonstrated, but this was not associated with a clinically significant increase in adverse events such as tachycardia and palpitations. This successful phase IIA trial was followed by a phase IIB trial in OAB patients carried out in Europe [Chapple et al., 2010]. This trial was a dose-ranging study of once-daily mirabegron (an extended release formula of mirabegron) with multiple arms (placebo, mirabegron 25 mg, 100 mg, 150 mg, and 200 mg qd, for a 12-week treatment period), and the primary endpoint was to evaluate the dose-response relationship on efficacy.

The mean number of micturitions per 24 hours decreased dose-dependently, and the decreases were statistically significant with mirabegron 50 mg, 150, and 200 mg compared with placebo. The mean volume voided per micturition increased dose-dependently, and the increases were significant with mirabegron 50 mg and more. Adverse events were experienced by 45.2% of the patients - the incidence of adverse events was similar among all treatment groups (placebo 43.2% vs. mirabegron 43.8-47.9%). The overall discontinuation rate owing to adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4-5.3%). The most commonly reported adverse events considered treatment-related was gastrointestinal

disorders, including constipation, dry mouth, dyspepsia, and nausea. There was no patient-reported acute retention. No significant difference in ECG parameters between the groups was demonstrated. However, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 200 mg (1.6 and 4.1 beats per minute, respectively), although this was not in associated with an increase in cardiovascular adverse events.

Nitti et al. [2011] reported on a phase III multicentre, randomized, double-blind, parallel-group, placebo-controlled trial of mirabegron in North America. They enrolled 1328 patients ≥18 years with OAB symptoms for ≥3 months. Patients who completed a 2-week, single-blind, placebo run-in and had ≥8 micturitions/24 h and ≥3 urgency episodes/72 h (with or without incontinence) during a 3-day micturition diary period, were randomized to receive placebo, or mirabegron 50 or 100 mg once daily for 12 weeks. Co-primary endpoints were change from baseline to final visit (study end) in the mean number of incontinence episodes/24 h and micturitions/24 h. Efficacy was assessed according to patient micturition diaries and safety assessments included adverse event (AE) reporting. Patients were randomized and received study drug (placebo: n=453; mirabegron 50 mg: n=442; mirabegron 100 mg: n=433). Mean age was 60.1 years, 74.3% were female, 29.7% had urgency incontinence, 38.1% had mixed stress/urgency incontinence with urgency predominant and 32.2%had frequency without incontinence. At the final visit, mirabegron 50 and 100 mg showed statistically significant improvements in the co-primary efficacy endpoints and mean volume voided/micturition compared with placebo. Statistically significant benefits were achieved at the first-measured time point of Week 4. The incidence of AEs was similar across the placebo and mirabegron 50 and 100 mg groups (50.1, 51.6 and 46.9%, respectively). The most common (≥3%) AEs in any treatment group were hypertension (6.6, 6.1 and 4.9%, respectively), urinary tract infection (1.8, 2.7 and 3.7%), headache (2.0, 3.2 and 3.0%) and nasopharyngitis (2.9, 3.4 and 2.5%).

Khullar et al. [2011] performed a similarly designed study i Europe and Australia, enrolling 1978 patients, which included a fourth arm in which tolterodine SR 4 mg was used as a comparator. Like the American study, Khullar et al. [2011] found that mirabegron caused a statistically significant improvement from baseline compared with placebo in the number of urgency incontinence episodes and number of micturions per 24 hours. Mirabegrom 50 and 100 mg was numerically superior to tolterodine in these two key OAB symptoms, but the study was not powered for further analysis. Mirabegrom 50 and 100 mg was well tolerated, no differences being found between the placebo arm and the two mirabegron arms. In particular the incidence of hypertension or UTI were identical. In contrast with tolterodine, no increased dry mouth incidence was observed with mirabegron.

Otsuki et al. [2013] reported on the efficacy and safety of mirabegron in a predominantly male population of OAB patients. In this prospective, non-randomized, controlled study, patients with at least one episode of urgency per week and scoring at least 2 for urinary urgency in the Overactive Bladder Symptom Score (OABSS) were enrolled. Fifty-two patients (36 men) with newly diagnosed OAB received mirabegron 50 mg once daily, and 45 (36 men) with OAB refractory to antimuscarinics switched to mirabegron, and another 27 patients (18 men) with newly diagnosed OAB received antimuscarinics and served as controls. Patients on a stable α_1-AR blocker dose for treatment of LUTS were allowed in the study, but those with a PVR greater than 100 ml were excluded. Mirabegron achieved significant improvements in all efficacy outcomes (OABSS: Overactive Bladder Symptom Score and IPSS: International Prostate Symptom Score). In patients with newly diagnosed OAB, improvements were not significantly different to those achieved by antimuscarinics. Mirabegron was well tolerated and did not significantly change PVRs. However, these encouraging results for mirabegron in treating male OAB should be interpreted with caution in view of the limitations of the study, which included small patient numbers, lack of randomization, and a suboptimal treatment period for the indication.

In a study by Chapple et al. [2013] assessing the 12-months safety and efficacy of mirabegron, tolterodine was used as active control. There were no significant differences in efficacy between drugs. However, whether mirabegron has similar efficacy to antimuscarinics awaits direct comparison studies. Mirabegron seems to have definite advantages over the antimuscarinics with respect to adverse events. Dry mouth and constipation are essentially non-existent in comparison to placebo [Chapple et al., 2013; 2014; Cui et al., 2014; Rossanese et al., 2015].

Mirabegron 50 mg and solifenacin 5 mg were recently compared in OAB patients dissatisfied with previous antimuscarinic treatment. The Beyond study [Batista et al., 2015] was a randomized, double-blind, phase IIIb, noninferiority study that enrolled male and female patients aged ⩾18 years old, with symptoms of OAB for ⩾3 months, who were dissatisfied with their previous antimuscarinic drug due to lack of efficacy

Assessment

Mirabegron has a documented beneficial effect in the treatment of OAB/DO (Table 2), and seems to have an acceptable side effect profile.

2.2. New Developments

Thiagamoorthy et al. [2015] reviewed "novel and putative" β_3-AR agonists for management of OAB, including CL-316243, TRK-380, AJ-9677, BRL37344. Another agent, vibegron, was claimed to have an overall superior preclinical profile compared to MK-0634, which was discontinued due to unacceptable

structure-based toxicity in preclinical species [Edmonson et al., 2016]. Even if these agents have been reported as being in development, no clinical data have been published, and it may be questioned whether any of them can be regarded as "novel and putative". Phase II and III randomised, double blind, placebo controlled studies of ritobegron in patients with OAB has been initiated and completed, but the results have not been published and it seems that that the primary efficacy endpoint of the studies was not met. No new clinical trials with ritobegron seem to have been initiated.

Efficacy and safety of solabegron (GW427353) have been reported in a phase II multicenter, randomized, proof-of-concept trial in 258 women with wet OAB. The drug produced a statistically significant difference in percent change from baseline to week 8 in incontinence episodes over 24 h (primary outcome) when compared with placebo (p=0.025) and was well tolerated [Ohlstein et al., 2012].

There seems to be a number of β_3-AR agonists in the pipeline some of which are under development. However, it is uncertain which, if any, will come to market and be available for the management of OAB.

3. DRUGS ACTING ON MEMBRANE CHANNELS

3.1. Calcium Antagonists.

Calcium channels play an important role in the regulation of free intracellular calcium concentrations and thereby contribute to the regulation of smooth muscle tone [Berridge, 2008] Two major groups of calcium channels include the voltage-gated [Caterall et al., 2003] and the store-operated channels [Leung et al., 2008]. While both can contribute to the maintenance of smooth tone in general, store-operated calcium channels apparently contribute only to a limited if any extent to the regulation of bladder smooth muscle tone [Schneider et al., 2004 a; b]. On the other hand, various types of voltage-operated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type [Frew and Lundy, 1995] and L-type channels [Wuest et al., 2007]. The latter appears to be of particular importance as inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans [Frazier et al., 2008]. However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species [Wuest et al., 2007]. In confirmation of the role of L-type calcium channels, it has been shown that knock-out mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility [Wegener et al., 2004].

While these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical installation of the calcium channel inhibitor verapamil, the muscarinic receptor antagonists oxybutynin and trospium and placebo to patients with urgency or urgency incontinence. While the two muscarinic receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function [Fröhlich et al., 1998]. In a clinical study of limited size the calcium channel inhibitor nimodipine (30 mg per day) did not significantly improve the number of incontinence episodes as compared to placebo [Naglie et al., 2002]. Larger studies with clinical endpoints related to effects of calcium channel inhibitors have not been reported in incontinent patients (based upon a Medline search using the MeSH terms "calcium channel blockers" and "urinary incontinence"). Moreover, it should be noted that despite a long-standing and wide-spread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro and the lack of clinical data are not fully clear, but it may relate to pharmacokinetic properties of the currently used drugs which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses.

At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction (Table 2). No new information has been added since the assessment in 2008 [Andersson et al., 2009; 2013].

3.2. Potassium Channel Openers

In a similar fashion to calcium channels, potassium channels also contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist [Gutman et al., 2003; Petkov et al., 2012; 2014]. With regard to bladder function, ATP-dependent (K_{ATP}) and big calcium-activated (BK_{Ca}) channels have been studied most intensively. The BK_{Ca} channels also appear to be important physiologically as their activation can cause hyperpolarization of bladder smooth muscle cells and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, e.g., β-adrenoceptor agonists [Frazier et al., 2008]. Openers of both K_{ATP} [Howe et al., 1995; Hu et al., 1997; Martin et al., 1997] and BK_{Ca} channels [Hu et al., 1997; Sheldon et al., 1997; Petkov et al., 2012; 2014] have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly between species. Some potassium channel openers have also been shown to suppress non-voiding detrusor contractions in vivo in animal models of DO [Howe et al., 1995; Martin et al., 1997; Tanaka et al., 2003] and this also includes activators of the KCNQ type of potassium channels [Streng et al., 2004]. Although potassium

channel openers are believed to mainly act directly on smooth muscle cells [Gopalakrishnan and Shieh, 2004; Petkov et al., 2012; 2014], they may also at least in part affect bladder function by modulating the activity of afferent neurones [Tanaka et al., 2003].

While the above data demonstrate the potential of potassium channel openers to inhibit non-voiding detrusor contractions, these channels are expressed not only in bladder, but also e.g. in vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure [Howe et al., 1995; Shieh et al., 2007]. While some compounds of this class have a certain degree of selectivity for the bladder as compared to the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the K_{ATP} opener ZD0947 has been reported [Chapple et al., 2006]. While ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one due to a lack of selectivity for bladder over cardiovascular tissues (Table 2).

Another way to use potassium channels to normalize bladder function was suggested by Christ et al. [2001] in a rat model of detrusor hyperactivity. They injected "naked" hSlo/pcDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. As to whether this principle can be therapeutically useful in man is currently under investigation.

4. α-ADRENOCEPTOR (AR) ANTAGONISTS

It is well documented that α_1-AR antagonists can ameliorate lower urinary tract symptoms in men, and currently used α_1-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of BPH [Andersson, 2002; McVary et al., 2011; Oelke et al., 201l; Lepor et al., 2012; Fonseca and Martins da Silva., 2015]. However, in a study where tamsulosin was given alone, or together with tolterodine, to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective [Kaplan et al., 2006]. In an RCT from Korea, doxazosin monotherapy resulted in only minimal effects in IPSS storage subscore, urgency episodes and no improvement in the patient perception of bladder condition (PPBC) [Lee et al., 2011b]. Thus, there is no convincing evidence that α-AR antagonists, given as monotherapy, are effective in patients with storage symptoms only.

A pivotal question is if better efficacy and/or tolerability can be obtained by highly subtype selective drugs than with the commonly used alternatives. α_1-ARs include three receptor subtypes, α_{1A}, α_{1B}, and α_{1D}, that are structurally and pharmacologically distinct and have different tissue distributions [Andersson and Gratzke, 2007]. α_{1A}-ARs are the predominant subtype in the human prostate, where they mediate smooth muscle contraction. A fourth subtype, α_{1L}, also present in human prostate, is derived from the same gene as α_{1A}, but α_{1L}- and α_{1A}-receptors have different pharmacologic properties and bind some α-AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated.

Selectivity for α_{1B}-AR has been considered disadvantageous from a cardiovascular point of view [Schwinn et al., 2004; Schwinn and Roehrborn, 2008]. Kojima et al. [2008)] studied the expression of α_1-AR in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin presumed to block α_{1A}-ARs and naftopidil presumed to block α_{1D}-ARs. However, the selectivity of naftopidil for α_{1D}- vs α_{1A}-ARs is modest [Take et al., 1998] and its use as a tool to separate between α_1-AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as α_{1A}-AR dominant (22 and 12 patients) and α_{1D}-AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the α_1-AR subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the α_{1A}-AR subtype, whereas naftopidil was more effective in those with dominant expression of the α_{1D}-AR subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of α_1-AR subtype mRNA and severity of LUTS or bladder outlet obstruction [Kojima et al., 2010]. They found no direct correlation between the expression of α_1-AR subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima et al. [2010] concluded that the expression level of α_1-AR subtype mRNA in the prostate could be a predictor of the efficacy of subtype selective α_1-AR antagonists in patients with BPH, and suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for α_{1A}-ARs [Tatemichi et al., 2006a; b; Lepor and Hill, 2010; Yoshida et al., 2011], had clinically good effects on both voiding and storage symptoms in men with BPH [Kawabe et al., 2005; Yoshida et al., 2007; Marks et al., 2009a;b; Chapple et al., 2010; Morganroth et al., 2010; Yoshida et al., 2011; Novara et al., 2014; Montorsi et al., 2016]. Chapple et al. [2010] conducted a multicenter double-blind,

placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men ≥50 yr of age with an International Prostate Symptom Score (IPSS) ≥13 and a urine maximum flow rate (Q_{max}) >4 and ≤15ml/s were selected at 72 sites in 11 European countries. The patients were entered into a 2-wk wash-out and a 4-wk placebo run-in period. A total of 955 patients were randomized (2:2:1) to silodosin 8 mg (n=381), tamsulosin 0.4 mg (n=384), or placebo (n=190) once daily for 12 wk. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference between the two α_1-AR antagonists and the placebo in terms of Q_{max}. There was also no difference between the two α-AR antagonists for the QoL parameter, whereas both were better than the placebo. Active treatments were well tolerated, and discontinuation rates due to adverse events were low in all groups (2.1%,1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). The most frequent adverse event with silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α_{1A}-AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment due to this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, bladder outlet obstruction index and Schafer´s obstruction class significantly [Yamanishi et al., 2009]. In a different open, nonblinded prospective study silodosin 8 mg lead to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase mean detrusor pressure at maximum flow significantly decreased, mean bladder outlet obstruction index decreased significantly and obstruction grade as assessed by the Schaefer nomogram improved significantly [Matsukawa et al., 2009].

It thus seems that selective blockade of α_{1A}-ARs is a clinically effective approach (Table 2), and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focussed on the α_1-ARs (α_{1D}), specifically in the bladder [Schwinn et al., 2004; Schwinn and Roehrborn, 2008], assuming that these receptors were responsible for storage symptoms. However, the inter-relationship between the α_{1D}-ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear. Naftopidil was shown to significantly improve the OAB symptom score [Sakai et al., 2011] and urgency episodes [Yokoyama et al., 2009]. Ikemoto et al. [2003] gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the I-PSS for storage symptoms, tamsulosin monotherapy decreased the I-PSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α_1-AR subtypes between the drugs) could not be reproduced in a randomized head to head comparison between the drugs [Gotoh et al, 2005]. Based on available evidence, it therefore cannot be concluded that the α_{1D}-ARs on the detrusor smooth muscle are the main therapeutic target. However, α_{1D}-ARs may have effects on different locations in the bladder beside the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia [Andersson and Gratzke, 2007]. The importance and functional role of this observation remain to be established.

In females, treatment with OAB, α_1-AR antagonists seem to be ineffective. In an RCT, comprising 364 women with OAB, no effect of tamsulosin vs placebo could be demonstrated [Robinson et al., 2007]. On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were treated (with modest success) with an α_1-AR antagonist [Kessler et al., 2006, Low et al., 2008]. It should be remembered that in women, these drugs may produce stress incontinence [Dwyer and Teele, 1992].

In patients with neurogenic DO, treatment with α_1-AR antagonists was moderately successful [Abrams et al., 2003].

5. PHOSPHODIESTERASE (PDE) INHIBITORS

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor [Andersson, 1999; Andersson and Wein, 2004]. It is also well established that drugs acting through the NO/cGMP system can relax the smooth muscle of the bladder outflow region [Andersson and Arner, 2004]. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach (Andersson et al., 1997; 2007; 2011). There are presently 11 families of PDEs, some of which preferentially hydrolyse either cAMP or cGMP [Uckert et al., 2006].

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. [2006] investigated human bladder tissue, revealing messenger RNA for PDEs 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDEs preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside, and to agents acting via the cGMP system [Truss et al., 2000]. However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE 1), and forskolin (stimulating the generation of cAMP), suggest-

ing that the cAMP pathway and PDE 1 may be important in regulation of detrusor smooth muscle tone [Truss et al., 2001]. Significant dose-dependent relaxations were also induced by human cAMP analogs [Truss et al., 2001]. With these studies as a background, Truss et al. presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders, and not responding to standard antimuscarinic therapy (Truss et al., 2000). This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter [Truss et al., 2001]. Studies with other PDE 1 inhibitors than vinpocetin (which may not be an optimal drug for elucidation the principle) do not seem to have been performed.

PDE 4 (which also preferably hydrolyses cAMP) has been implicated in the control of bladder smooth muscle tone. PDE 4 inhibitors reduced the in vitro contractile response of guinea pig [Longhurst et al., 1997] and rat [Kaiho et al., 2008] bladder strips, and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder [Gillespie and Drake, 2004; Nishiguchi et al., 2007]. Xin et al. [2014] found that that selective pharmacological inhibition of PDE4 increases the frequency of Ca^{2+} sparks and their functionally coupled BK channels, which lead to the attenuation of DSM excitability and contractility and suggested that PDE4 isoforms might be valuable therapeutic targets for the treatment of overactive bladder. However, previous experiences with selective PDE 4 inhibitors showed emesis to be a dose - limiting effect [Giembycz, 2005]. If this side action can be avoided, PDE 4 inhibition seems to be a promising approach.

Oger and co-workers showed that PDE5-inhibitor sildenafil-induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K(+) channel-dependent signalling pathways, with a minor contribution from NO [Oger et al., 2010]. In combination with the alpha-blocker doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle and their combination provided a significant benefit when targeting relaxation of both tissues [Oger et al., 2008].

In-vivo, several studies have indicated a role for PDE5-inhibitors in the regulation of micturition function. Systemic vardenafil reduced both non-voiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord injury rats, indicating potential mechanisms by which PDE5-Is improve storage symptoms in SCI patients [Behr-Roussel et al., 2010]. The effect of vardenafil on OAB-symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (SHR) [Morelli et al., 2009a; Morelli et al., 2009b]. Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment [Morelli et al., 2009b]. Thus, besides relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalfil was shown to increase prostate tissue oxygenation in SHR and human vesicular-deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results suggest another possible mechanism through which PDE5i exert beneficial effects on LUT symptoms [Morelli et al., 2011; Cellek et al., 2014].

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra and its relaxant effect is associated with increased levels of cyclic GMP [Andersson and Arner, 2004]. However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita et al. examined the effects of isoproterenol, prostaglandin E_1 and E_2, and SNP on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra [Morita et al., 1994]. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström et al.[2006] characterized the distribution of PDE 5, cGMP and PKG1 in female pig and human urethra, and evaluated the effect of pharmacological inhibition of PDE-5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity (IR) in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE-5 IR could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP-IR. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE-5 inhibitors at high concentrations. Fibbi et al. [2009] confirmed that the highest expression and biological activity of PDE5 was found in bladder. However, a consistent PDE5 expression and activity was also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fibre afferent activation, it was shown that the NO/cGMP signalling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather on the motor component of the micturition reflex [Caremel et al., 2010].

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS, has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS [Sairam et al., 2002], this observation has been confirmed in several well designed and conducted RCTs.

A number of RCTs are available comparing the effect of PDE5 inhibitors alone to placebo and the combination of α-AR antagonists and PDE5 inhibitors vs α-AR antagonists alone [Bechara et al., 2008; Gacci et al., 2011; Kaplan et al., 2007; Liguori et al., 2009; McVary et al., 2007a; b; Porst et al., 2009; 2011; Roehrborn et al., 2008; Stief et al., 2008; Tamimi et al., 2010; Tuncel et al., 2010; see Gacci et al., 2016]. In these studies, different PDE5 inhibitors and different doses were administered. PDE5-inhibitors significantly improve IPSS and IIEF scores, but not Qmax when compared to placebo. According to a meta-analysis by Gacci and co-workers, differences in IPSS score were significantly lower in older and obese patients [Gacci et al., 2011]. The combination of PDE5-inhibitors and α-AR-blockers lead to significant improvements of the IPSS and IIEF score as well as Qmax when compared to the use of α-AR-blockers alone. Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pressure at maximum urinary flow rate or such as maximum detrusor pressure and bladder outlet obstruction index while improving IPSS [Dmochowski et al., 2010b]. PDE5-inhibitors were generally shown to be safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. There is *in vitro* evidence that PDE5 inhibition might relax the smooth muscle of the prostate, bladder, and urethra, dilate the pelvic vasculature (including the microvasculature), and modulate sensory bladder functions [Andersson et al., 2011; Giuliano et al., 2013; Cellek et al., 2014]. Improvement of bladder blood flow to the LUT has been suggested [Cellek et al., 2014], and this has been supported by studies in animals with chronic bladder ischemia [Nomiya et al., 2013]. However, Pinggera et al. [2014], using transrectal ultrasonography, compared the effects of tadalafil 5 mg/day and placebo given for 8 weeks to men with moderate to severe LUTS/BPH. They found no differences between the treatments, but did not exclude that changes in blood flow may have occured which for several reasons could not be detected. Previously, Pinggera et al. [2008], using the same methodology, quite convincingly showed that tamsulosin could increase perfusion to the LUT.

Currently, tadalafil is the only FDA approved PDE-5 inhibitor for treatment of male LUTS even of e.g, sildenafil and and vardenafil have been shown to be effective. However, there are several other drugs belonging to the same class that are used for treating erectile dysfunction, including avanafil, udenafil, microdenafil, gisadenafil [Gacci et al., 2014], and there are no reasons to believe that they should not be effective in relieving male LUTS. To what extent new molecules with ability to inhibit PDE-5 [Sawant et al., 2015] will be developed for future clinical application remains to be seen.

6. ANTIDEPRESSANTS

Several antidepressants have been reported to have beneficial effects in patients with DO [Lose et al., 1989; Martin and Schiff, 1984]. However, the use of antidepressants was shown to be an independent risk factor for LUTS suggestive of benign prostatic hyperplasia in a community based population of healthy aging men (Krimpen Study) [Kok et al., 2009]. In a prospective trial, and in total, 205 consecutive female (113 patient taking antidepressants for various disorders and 92 healthy controls), Albayrak et al. [2015] found that the prevalence of OAB was significantly higher in antidepressant users (64 %) than in the control group (33 %) ($p = 0.003$). They suggested that since each SSRI and SNRI has a unique pharmacological profile, this could explain the opposing reports in the literature.

6.1. Imipramine

Imipramine is the only drug that has been widely used clinically to treat this disorder. Imipramine has complex pharmacological effects, including marked systemic antimuscarinic actions [Baldessarini, 1985] and blockade of the reuptake of serotonin and noradrenaline [Maggi et al., 1989], but its mode of action in DO has not been established [Hunsballe and Djurhuus, 2001]. Even if it is generally considered that imipramine is a useful drug in the treatment of DO, no good quality RCTs that can document this have been retrieved. It has been known for a long time that imipramine can have favourable effects in the treatment of nocturnal enuresis in children with a success rate of 10-70 % in controlled trials [Glazener et al., 2003; Hunsballe and Djurhuus, 2001]. It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine [Bigger et al., 1977; Giardina et al., 1979]. Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants [Baldessarini, 1985]. The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the last decade [Hunsballe and Djurhuus, 2001; Natalin et al., 2009]. No good quality RCTs have documented that the drug is effective in the treatment DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study the impact of the "three-drug therapy" (antimuscarinic, alpha-blocker and tricyclic antidepressants) on the treatment of refractory detrusor overactivity (DO) showed a significant increase on bladder capacity and decreases on urgency, urge-incontinence and frequency. Objective urodynamic data as well as symptom score improved significantly with triple therapy [Natalin et al., 2009].

Selective serotonin-reuptake-inhibitors (SSRIs) have been tested with regard to their effects on OAB symptoms. Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor (SNRI), or paroxetine hydrochloride, a selective serotonin reuptake inhibitor, were analysed in a prospective open trial in neurogenic OAB-patients. Milnacipran reduced daytime urinary frequency, improved the quality of life index and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the lower urinary tract symptoms questionnaire or urodynamic studies, or in the paroxetine group [Sakakibara et al., 2008].

In a retrospectively Hillelsohn et al [2014] evaluated 43 patients who were treated with desipramine for OAB refractory to antimuscarinic therapy. Twelve patients (28%) discontinued desipramine, 9 due to perceived lack of efficacy. Still, the authors concluded that desipramine is a potential useful treatment for patients with OABsymptoms, e.g., those with pain. To confirm any useful effect of desipramine, RCTs are needed.

6.2. Duloxetine

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Katofiasc et al., 2002; Thor and Katofiasc, 1995]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser and Chancellor, 2003]. In a placebo-controlled study, the drug showed efficacy in patients with OAB [Steers et al., 2007]. The number of micturition episodes, the primary outcome, was reduced by 2 in the duloxetine arm and by 0.5 in the placebo arm. Episodes of urgency incontinence were also significantly reduced by duloxetine. These data have not been reproduced so far in another trial. However, the high withdrawal rate observed across all studies in which the drug was evaluated fou SUI, affecting 20-40% of the patients at short-term and up to 90% in long-term studies, do not predict clinical utility of duloxetine in OAB.

7. CYCLOOXYGENASE (COX) INHIBITORS

Prostanoids (prostaglandins and thromboxanes) are synthesized by cyclooxygenase (COX) from a common precursor, arachidonic acid. Prostanoids may be involved in the control of bladder function under normal and pathological conditions, including DO and OAB. Human bladder mucosa has the ability to synthesize eicosanoids [Jeremy et al., 1987], and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma [Downie and Karmazyn, 1984; Leslie et al., 1984]. Even if prostaglandins cause contraction of human bladder muscle, it is still unclear whether prostaglandins contribute to the pathogenesis of unstable detrusor contractions. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling. Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, clinical evidence for this is scarce.

Cardozo et al. performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg 3 times daily [Cardozo et al., 1980a]. The drug was shown to have favourable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms. Palmer studied the effects of flurbiprofen 50 mg x 4 versus placebo in a double-blind, cross-over trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial) [Palmer, 1983]. Active treatment significantly increased maximum contractile pressure, decreased the number of voids and decreased the number of urgent voids compared to baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, cross-over study [Cardozo and Stanton, 1980b]. The incidence of side effects was high, occurring in 19 of 32 patients.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication mainly due to side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.

No recent clinical studies on the use of COX-inhibitors for treatment of LUTS/OAB seem to have been published.

8. TOXINS

Intravesical pharmacological therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacological agents can be given to the bladder tissue producing enhanced local effects. Second, drugs inappropriate for systemic administration due to off target effects can be safely used. Attractive as it may be, intravesical pharmacological therapy should still be considered as a second line treatment in patients refractory to oral therapy or that do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if

patients subgroups will benefit of intravesical therapy as first line is clearly necessary.

8.1. Botulinum Toxin

Mechanism of action. Botulinum toxin (BoNT) is a neurotoxin produced by *Clostridium botulinum*, Of the seven subtypes of BoNT, sub-type A (BoNT/A) has the longest duration of action, making it is the most relevant clinically. BoNT/A is available in different commercial forms, with the proprietary names of Botox®, Dysport®, Xeomin®, and Prosigne. Although the toxin is the same, it is wrapped by different proteins which modify the relative potency of each brand. This was the basis for the introduction of the non-proprietary names onabotulinum toxin A (onabotA), abobotulinum toxin A (abobotA) and incobotulinum toxin A (incobotA) for Botox®, Dysport® and Xeomin®, respectively. Prosigne is the proprietary name of a BoNT/A produced in China, which currently does not have a known non-proprietary name.

The current approved method to estimate the potency of a BoNT/A brand is the mouse LD50 (lethal dose 50%); that is, the mass of toxin (expressed in ng/kg of body weight) that kills 50% of mice. More recently, a cell-based potency assay was approved specifically for onabotulinum toxin assay which uses differentiated human neuroblastoma SiMa cells and replicates all steps in BoNT/A mechanism of action. The assay measures the BoNT/A-dependent intracellular increase of cleaved SNAP-25. The EC50, that is, the concentration of toxin required to provoke a response halfway between the baseline and maximum response for OnabotA, is about 1–0.4 U per well [Fernandez-Salas et al., 2012].

Although potency of each toxin brand is expressed in units (U) the doses are not inter-changeable and conversion ratios between the different brands do not exist. Estimates from studies carried in the skeletal muscle suggest that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless, these equivalences should be approached with caution. Comprehensive reviews have been produced during the last few years. The interested reader is also invited to read [Chapple and Patel., 2006; Nitti, 2006; Patel et al., 2006; Karsenty et al., 2008; Apostolidis et al., 2009; Silva and Cruz, 2009b; Dowson et al., 2010; Duthie et al., 2011; Mangera et al., 2011].

In a recent experimental study in the mice the capacity of 1 U of onabotA and 1 U of abobotA to cleave SNAP25 were compared after one single injection in the bladder wall. The average number of cleaved SNAP-25 positive fibers was higher after onabotA, than after abobotA, the difference suggesting that when injected in the bladder wall, in the same unit amount and same volume, the conversion ratio between onabotA and abobotA should be around 1:1.6 [Oliveira et al., 2015].

Most of the information available about intravesical application of BoNT/A derives from the use of onabotA (Botox®). However, in addition to sub-type A, some studies have investigated the effect of detrusor injection sub-type B, rimabotulinumtoxinB (proprietary names being Miobloc™ or Neurobloc™ depending on country). For further details, see below.

8.1.1 BoNT/A

BoNT consists of a heavy and a light chain linked by a disulphide bond. As the BoNT/A gene may differ in nucleotides, four A subtypes have been classified based on up to 15% variation in the amino acid composition. The amino acid sequence of the BoNT/A light chain constitutes a catalytic Zn-dependent endopeptidase domain. The heavy chain is subdivided into three portions (HN, HCN, and HCC), but only two have clear functions. The HCC is associated both with the recognition of neuronal-specific areas and toxin internalization. The HN is responsible for translocation of the light chainfrom synaptic vesicles into the neuronal cytoplasm. In the synaptic cleft BonT/A binds predominately to the isoform C of the synaptic vesicle protein or SV2 (SV2C) [Dong et al., 2006, Dolly et al., 2014], or to the FGF Receptor 3 [Jacky et al., 2013] by the heavy chain. The importance of the latter toxin acceptor is still unclear.

The most well studied process involves SV2 binding before being internalized by the nerve terminal during the recycling process of synaptic vesicles (Figure 16). The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimide-sensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein - VAMP) and syntaxin. BonT/A cleaves SNAP 25 rendering the SNARE complex inactive (Figure 17) [Humeau et al., 2000; Chancellor et al., 2008b]. Subtype B, acts preferentially through the inactivation of VAMP [Humeau et al., 2000]. Interestingly, BonT/A cleaves SNAP 25 always in the same position, cutting the 9 terminal amino-acids of the C terminal of the protein [Dolly et al., 2014]

BonT/A application was extensively evaluated in striated muscle. In this tissue paralysis occurs by prevention of acetycholine (ACh) release from cholinergic motor nerve endings [Humeau et al., 2000]. Accumulation of neurotransmitter containing synaptic vesicles is followed by terminal axonal degeneration. Striate muscle paralysis recovers within 2 to 4-months time. During this time axons develop lateral

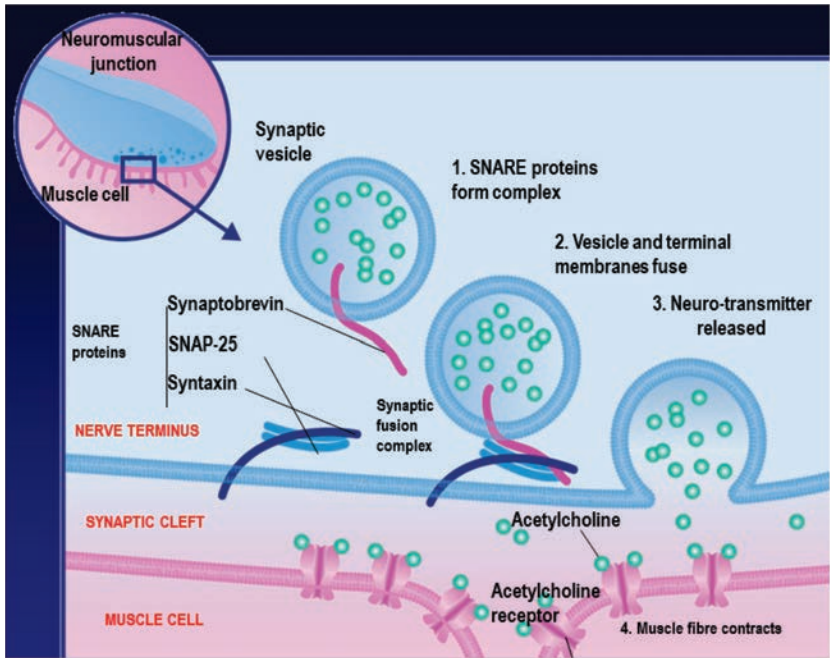

Figure 16: Mechanism of action of botulinum toxin (BoNT). BoNT consists of a heavy and a light chain linked by a disulphide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles. The two chains are then cleaved and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmatic membrane necessary for neurotransmitter release. Attachment protein (SNARE or soluble N-ethylmaleimidesensitive fusion attachment protein receptor) include synaptosome associated protein 25 kD (SNAP 25), synaptobrevin (vesicle associated membrane protein -VAMP) and syntaxin.

sprouts and eventually regenerate completely [de Paiva et al., 1999].

In the human bladder SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic and sensory fibers [Coelho et al., 2010; 2012a; b]. Almost all parasympathetic nerves express the two proteins [Coelho et al., 2012b]. As these nerves play a fundamental role for detrusor contraction during voiding, the blockade of ACh release is believed to play an essential role in detrusor hypo- or a contractility that follows BoNT/A injection in the bladder. In accordance with this view it was shown that in normal or SCI animals BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions [Ikeda et al., 2012]. However cholinergic axon sprouting concomitant with clinical remission could not been documented in the detrusor [Haferkamp et al., 2004].

Bladder sensory impairment is also expected to play an important role in the final effect of BoNT/A bladder injection (Figure 18). About half of the peptidergic sensory fibers express SV2 and SNAP25 [Coelho et al., 2010]. BoNT/A inhibits the spinal cord release of glutamate, substance P (SP) and CGRP from sensory nerves [Purkiss et al., 2000; Aoki et al., 2005; Meng et al., 2007] as well as the release of neuropeptides at the peripheral extremities [Rapp et al., 2006; Lucioni et al., 2008]. BoNT/A has also been shown to reduce the suburothelium immunoreactivity for TRPV1 or P2X3 [Apostolidis et al., 2005]. BonT/A also impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, as this process is also dependent on SNARE proteins [Morenilla Palao et al., 2004; Shimizu et al., 2012]. All these mechanisms may contribute to the recent observation that BoNT/A reduces afferent firing from bladder afferents and antidromic release of neuropeptides [Ikeda et al., 2012].

In the human bladder SV2 and SNAP-25 expression by immunohistochemistry could not be demonstrated [Coelho et al., 2010]. In another study using immunoblot analysis the existence of SV2 in isolated human urothelial cells also was not demonstrate although SV2 was present in the human bladder mucosa (which contains sub-urothelal connective layer). SNAP 25 was present in both isolated human urothelial cells and human bladder mucosa [Hanna-Mitchell et al., 2013]. Another SNARE protein, SNAP 23 was identified in the human urothelial cells and may contribute to the activity of BonT/A in the urothelium [Hanna-Mitchell et al.,2013; Cruz, 2014]. As a matter of fact urothelial function seems also compromised after BoNT/A administration. BonT/A has been shown to inhibit ATP release from urothelium in animal models of spinal cord injury [Khera et al.,2004; Smith et

al., 2008]. Therefore, it is not surprising that administration of BoNT/A to inflamed rat bladders reduces spinal *c-fos* counts at the L6 and S1 spinal cord segments [Vemulakonda et al., 2005].

Cleaved, inactive SNAP-25 appears rapidly after BoNT/A injection. In the guinea-pig a robust expression of cleaved SNAP 25 could be detected already at 12 hours and maximum intensity could be detected at 24 hours with little changes afterwards. In guinea-pigs cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic and postganglionic were affected while less than half of the senory fibers express the cleaved protein [Coelho et al., 2012a; b]. In the human urinary bladder cleaved SNAP 25 could be detected in NDO patients up to 11 months after BoNT/A injection. [Schulte-Baukloh et al., 2007].

BoNT/A has a unique long lasting effect. The structural basis for this remarkable persistence remains poor explained. The enzymatic capacity of the light chain is long lasting apparently due to presence of two leucines near the C terminus of the protease light chain of A toxin [Wang et al., 2011b]. The duration of effect of BoNT/A in the detrusor smooth muscle, longer than in striated muscles, has currently no firm explanation. However, the longer persistence of the inactive form of SNAP-25 plus the involvement of pre and post-ganglionicparasympathetic neurons may contribute to persistence of the BoNT/A effect in the bladder.

Myofibroblasts form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that myofibroblasts act as modulators of bladder behaviour [Wiseman et al., 2003; Apostolidis et al., 2006]. However, the expression of connexin 43 is not altered by BoNT/A [Roosen et al., 2009]. Hence, currently a firm evidence for the action of BoNT/A on myofibroblasts is scant.

BonT/A may decrease the levels of neurotrophic agents in the bladder tissue. Levels of Nerve Growth Factor (NGF) [Giannantoni et al., 2006; Liu et al., 2009] and Brain-derived Neurotrophic Factor (BDNF) [Pinto et al., 2010] have been shown to decrease in the bladder and/or urine following BoNT/A injections. As both neurotrophins have paramount roles for growth, maintenance and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BonT/A acts upon the bladder.

8.1.1.1 BoNT/A Effects on Bladder Histology

There is no evidence that repeated injections of nnabotA into the detrusor muscle cause inflammatory infiltrates, fibrotic activity or apoptosis within the bladder wall [Comperat et al., 2006; Apostolidis et al., 2008; Kessler et al., 2010]. Rather the reverse, one study demonstrated that NDO patients treated with BonT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. The presence of eosinophilic infiltrate

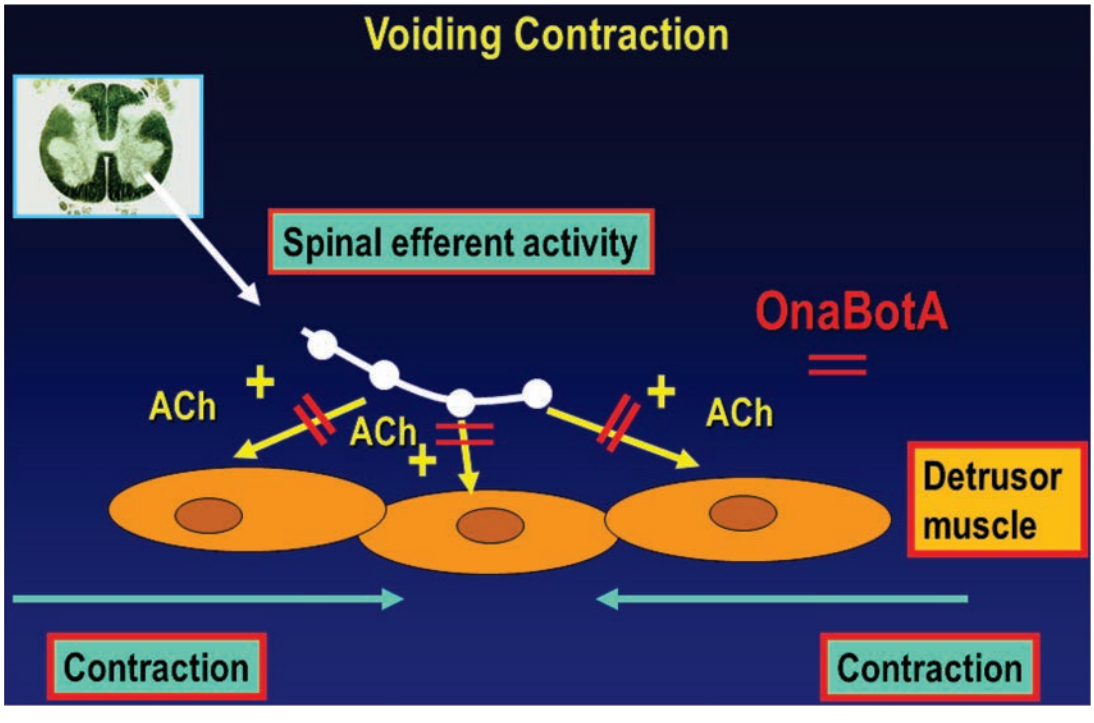

Figure 17: Onabotulinum toxin A inhibition of acetylcholine (ACh) release decreases detrusor smooth muscle contraction.

was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

BoNT/A injection protocol in the bladder wall. When the treatment was first described in 1999 for NDO patients, onabotA was diluted in normal saline in order to obtain a concentration of 10 units/ml [Schurch et al., 2000a; b]. Under visual control through a rigid cystoscope and a flexible 6 Fr injection needle, 30 injections of 1 ml (10 units of botulinum-A toxin) were done in 30 different bladder wall locations above the trigone to prevent vesico-urethral reflux. Additional refinements have been added to this technique along the following years, including the use of a local anaesthetic agent (4% lidocaine) and a flexible cystoscope [Harper et al., 2003].

The pivotal studies [Cruz et al, 2011; Ginsberg et al., 2012] which included more than 700 NDO patients led to the approval of a dose of onabotA 200 U applied in 30 injections sites above the trigone (1ml saline each 6.66 U/ml). The studies showed that 300 U produced the same results and had the same duration of effect but caused more adverse events than the 200 U dose [Cruz et al., 2011; Ginsberg et al., 2012). When considering OAB/IDO two large pivotal studies have been published after enrolling more than 1000 patients. The protocol was first investigated in a dose finding study which led to the conclusion that 100 U was the ideal dose [Dmochowski et al., 2010c]. The toxin was administered via cystoscopy as 20 intradetrusor injections of 0.5 ml, evenly spaced but avoiding the trigone [Chapple et al., 2013; Nitti et al., 2013). Following the approval of 100 U of onabotA for the treatment of refractory incontinence in OAB patients, this protocol should be considered standard while those reviewed in previous systematic reviews for OAB/IDO should be considered off-label. This includes the use of 200 U or abobotA 500 U [see Mangera et al., 2011; Karsenty et al., 2014 for review of other protocols].

Despite the existence of an approved protocol for onabotA injection in the bladder wall, in NDO and OAB/IDO, several variations have been investigated.

One variable at stake is the trigone injection, the rationale for the injection being the dense sensory innervation of this part of the bladder. The suggested risks of ureteral reflux after injecting bladder trigone were never demonstrated, whether onabotA or abobotA was used [Karsenty et al., 2007; Citeri et al., 2008; Mascarenhas et al., 2008; Pinto et al., 2010). A few studies have, therefore, compared trigonal vesus trigonal sparing protocols in IDO patients. A recent trial randomised 22 IDO patients to receive abobotA 500 U administration in 20 injections (1ml each) sparing the trigone against 15 off the trigone plus 5 injections in the trigone [Manecksha et al., 2012]. Mean

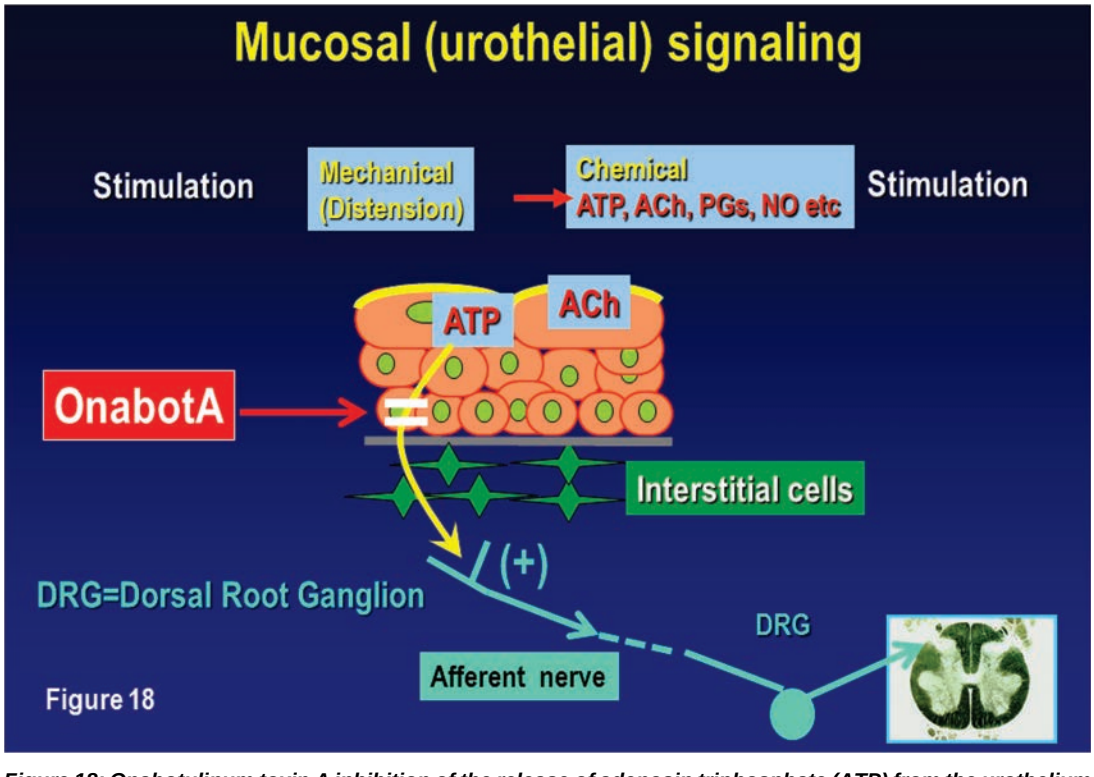

Figure 18: Onabotulinum toxin A inhibition of the release of adenosin triphosphate (ATP) from the urothelium decreases bladder afferent activity.

postvoid residual volumes and clean intermittent self-catheterisation rates between the two groups were similar. However, the change from baseline of the OABSS score was greater in the trigone injected group.

One study compared 10 trigonal injections versus 40 injections into the detrusor or suburothelium of 100 U of OnabotA in IDO patients [Kuo, 2007a]. The most effective protocol was the 40 detrusor injections because it brought more robust symptomatic improvement which lasted longer. The trigone injection only protocol was the less effective and durable of the three, although the risk of urinary retention was null [Kuo, 2007a]. The suburothelial protocol brought intermediate results, worse than the detrusor but better than the trigone only technique [Kuo, 2007a]. Pinto et al. [2010] injected 100 U distributed by 10 sites only in the trigone in 26 women with BPS/IC: No cases of voiding dysfunction were observed. PVR remained normal and bladder contractility index was not changed by OnabotA.

In patients with BPS/IC, pilot studies used onabotA 100 U injected in 10 sites in the trigone to treat bladder pain in patients with and without Hunner's lesions. This protocol was not associated with urinary retention or clinically relevant increase of PVR (Pinto et al., 2010; Pinto et al., 2013).

Another variable under investigation is the reduction of injection sites while increasing the dose in each site. One study randomized NDO patients to receive 300 U either in 10 or 30 sites [Karsenty et al., 2005]. The authors reported that 10 site injection was quicker and less painful and that no differences in efficacy between the two procedures could be detected up to 24 weeks. In another study, it was found that patients receiving 300 U of onabotA distributed over 30 injection sites (30 ml of fluid in total) or the same dose of toxin distributed over 10 injection sites (10 ml of fluid in total) had a similar distribution of the fluid, as determined by MRI. About 1/3 to 1/4 of the total detrusor volume was covered by the two protocols, respectively [Mehnert et al., 2009].

More recently forty-five patients (22 IDO, 23 NDO) were treated with 100–300U of onabotA injected on 1 or 3 injection sites in the posterior bladder wall. ICIQ-SF score improvement of >5 points was achieved in 73% of them (IDO 55%, NDO 91%) and the subjective success rate was 69% (50% IDO, 87%NDO). Full continence was achieved in 52% of NDO patients. Increase of PVR was modest and urinary retentions were not reported. Urinary tract infection occurred in 11.1%. Mean duration of effect was 31 weeks. It is unclear if this protocol has already been applied in other centers.

Another variable in the injection protocol is the volume of the saline used to reconstitute the toxin. Most studies used 1.0 mL per injection, although a few used 0.5 mL [Grosse et al., 2005; Schulte-Baukloh et al., 2005], 0.2 mL [Kuo et al., 2004], 0.25 ml [Grise et al., 2010] or even 0.1 mL per injection site [Rapp et al., 2004]. In a recent experimental study, the amount of cleaved SNAP-25 induced by a fixed amount of OnabotA was directly related with the volume of the injection [Coelho et al., 2012a]. Thus, more controlled studies designed to compare different number and locals of injection and the volume of each injection are necessary.

BoNT/A does not cross the rat urothelium if instilled in the bladder [Coelho et al., 2012a]. Onabot/A instillation in the bladder encapsulated in liposomes may however overcome the urothelial barrier and induced distinctive bladder effects [Chuang et al., 2009].

Recently the lipossome encapsulation technology to deliver onabotA was tested in humans. The study used the change of total urinary frequency per 3-day bladder diary at 1 mo after treatment as the primary end-point. A small group of 24 patients were randomized to intravesical instillation of Lipotoxin containing 80 mg liposomes and 200 U BoNT-A or normal saline. Patients were retreated with Lipotoxin 1 month later if they failed the first treatment. At 1 month after treatment, the change of urinary frequency per 3d was significantly improved in the Lipotoxin group. Urgency episodes also showed a significant decrease in the Lipotoxin group. Although no adverse events were reported, the duration of the effect was unfortuntely short lasting [Kuo et al., 2014].

Electromotive administration may also help to carry the large botulinum toxin molecule across the urothelium. In 15 children with NDO due to myelomeningocele, a 10F indwelling catheter containing a silver spiral electrode was placed in the bladder, after providing a local transurethral anaesthesia with 2% lidocaine. The bladder was filled with saline and 10 U/kg of abobotA was added. A maximal current of 10 mA (100 mA increment/s) for 15 minutes was applied using abdominal pads [Kajbafzadeh et al., 2010]. The urodynamic and symptomatic results were excellent. Skin erythema and burning sensation were de only side effects reported with this method. If this technique can be applied to adults it is not known. However, it would certainly simplify BoNT/A administration.

AbobotA administration remains off-label. Nevertheless, in larger cohorts coming from several institutions aboboatA was applied in the bladder wall by similar technique albeit the number of injections was only 20 [del Popolo et al., 2008; Grise et al., 2010]. A total of 500-1000 U of abobotA are injected [del Popolo et al., 2008]. The volume of saline at each injection site is commonly 1 ml but volumes so low as 0.25 ml per site were also used [Grise et al., 2010].

In the pivotal RCT with NDO some type of antibiotic prophylaxis was allowed for onabotulinum toxin injection in the bladder wall on the presumption that bacteriuria reduced the efficacy of the toxin [Cruz et al., 2011; Ginsberg et al., 2012). However, many of injected SCI patients relied on some type of bladder catheterisation and presented therefore chronic bacteriuria. Thus, the relevance of antibiotic prophylaxix

before botulinum toxin injection in SCI patients was investigated in 154 SCI patients undergoing a total of 273 treatments with onabotA for refractory NDO. Patients with no clinical signs of UTI underwent injections without antibiotic prophylaxis. Bacteriuria was found in 73% (200/273) of all patients pre-treatment. Following treatment, symptomatic UTI occurred in 7% (5/73) of cases with sterile urine culture and in 5% (9/200) with bacteriuria. These results suggest that routine antibiotic prophylaxis is not required prior to botulinum toxin injection in assymptomatic SCI patients [Leitner et al., 2016]. Is patients non-catheterizing at treatment, however, the high risk of UTI recommends that antibiotic prophylaxis should be maintaained together with a careful exclusion of active UTI at the moment of injection. TI screening after each BoNT/A bladder treatment remains justifiable until further study.

Effect of BoNT/A on NDO adult patients. OnabotA 200 U is the only dose approved by FDA and by European Authorities to treat NDO in SCI and MS patients. This was in part the consequence of the findings of two large pivotal phase 3 studies where efficacy and safety of onabot A in about 700 patients with NDO was compared against placebo in patients with NDO and incontinence caused by multiple sclerosis (EDSS ≤ 6.5) or spinal cord injury below T1 [Cruz et al., 2011; Ginsberg et al., 2012]. Thesestudies were preceded by small exploratory RCT (Schurch et al., 2005; Schurch et al., 2007]. Two doses, 200 and 300 U of onabotA were compared against placebo. Primary outcome measure was the change from baseline in week episodes of urinary incontinence at week 6 after treatment. Secondary outcome measures included the change from baseline in maximum cystometric capacity, maximum detrusor pressure during first involuntary detrusor contraction and quality of life using the I-QOL total score. Both studies yielded similar findings, and indicated that 200 and 300 U provided the same effect and had the same duration of action. In the first study [Cruz et al., 2011] onabotA significantly reduced UI and improved QOL in both MS and SCI patients, with no clinically relevant differences between the two doses. At week 6 mean change from baseline in weekly incontinence episodes was -21.8 in onabotA 200U, -19.4 with 300U and -13.2 with placebo ($p < 0.01$). At the same time point 7.6%, 38.0%, and 39.6% of patients in the placebo, 200U, and 300U onabotA groups, respectively, were fully continent. The proportion of patients without IDC was around 60% after onabotA 200 and 300 groups but only 17.4% after placebo. In the second study [Ginsberg et al., 2012], onabotA resulted in a 23.0%, 26,7% and 27.4% change from baseline in the incontinence episodes in the placebo, and 200 and 300 groups, respectively. Furthermore, 36% and 41% of patients in the 200 and 300 U groups, respectively, achieved dry status, contrasting with 10% in the placebo arm. In both studies, detrusor pressure and cystometric capacity increased significantly with the two onabotA doses, without clinically relevant differences between them [Cruz et al., 2011; Ginsberg et al., 2012]. Patients could request a retreatment 12 weeks after initial treatment. Median time for saline treated patients was about 90 days days and 250 to 300 days for those treated with 200 or 300 onabotA, without differences between the two doses [Cruz et al., 2011; Ginsberg et al., 2012]. No differences were found between patients with SCI or MS in terms of clinical response to onabotA [Cruz et al., 2011; Ginsberg et al., 2012].

When pooled data were analysed by etiology, both MS and SCI patients treated with the toxin exhibited decreases from baseline in urinary incontinence episodes that were significantly larger than in those treated with placebo. A significantly higher percentage of MS and SCI patients were dry during week 6 after treatment than in the placebo group [Ginsberg et al., 2013]. The change in the number of voluntary voids per week was examined only in MS patients, the majority of whom did not use intermittent self-catheterization at study entrance. Following onabotA 200 U treatment, a decrease from baseline of 2 micturitions per day at week 6 and around 3 micturitions per day at week 12 was deteced [Ginsberg et al., 2013]. There was no difference in terms of continence between patients on or off anticholinergic medication [Ginsberg et al., 2013]. Antibody formation against onabotA were not detected in the pivotal RCT during the first treatent cycle [Cruz et al, 2011; Ginsberg et al., 2012].

As a consequence of the symptomatic improvement detected after onabotA injection, NDO patients of both MS and SCI etiologies found a significant improvement in quality of life whether analysed by the I-QoL Questionnaire (Ginsberg et al., 2012; 2013), the 3 domain scores of the I-QoL Questionnaire (avoidance and limiting behavior, psychosocial, and social embarrassment), the modified Overactive Bladder Patient Satisfaction with Treatment Questionnaire (OAB-PSTQ), or the Patient Global Assessment [Chancellor et al., 2013]. The change from baseline in I-QOL score was analysed in patients who did not perform CIC at baseline. Surprisingly, the magnitude of the I-QoL improvement was similar whether they did or did not require this maneuver after toxin administration [Ginsberg et al., 2012].

The symptomatic improvement brought by BoNT/A injection in the bladder does not coincide with the moment of injection. The onset of BoNT/A effect was evaluated in a small open-label prospective study that specifically investigated the chronology of the symptomatic changes. Some improvement in urgency, nocturia and frequency could already be demonstrated as soon as 2 days after neurotoxin injection in NDO patients [Kalsi et al., 2008]. In a large RCT with SCI and MS patients treated with OnabotA, 200 or 300U, significant decrease in the number of incontinence episodes over placebo were first detected at week 2 after injection [Cruz et al., 2011; Ginsberg et al, 2012].

About 60% of the patients were taking antimuscarinics and maintained the same dose throughout the pivotal studies. A recent subanalysis of the pooled data of the 2 pivotal studies showed that similar reductions in urinary incontinence episodes and proportion of patients fully dry were achieved, regardless of anti-cholinergic use. Moreover, increment of maximal cystometric, decrease in detrusor pressure, improvement in quality of and median time to patient request for re-treatment were similar in anticholinergic users and non-users [Ginsberg et al., 2013; Sievert et al., 2012] These observations go along with previously made suggestions by Reitz et al. [2004a; b] and Grosse et al. [2005] that a substantial proportion of SCI patients could reduce or interrupt anti-muscarinic medication after BoNT/A injection.

Doses of onabotA below 200 U were tested in patients with SCI below T1. Patients (n= 73) with NDO and UI (C14 UI episodes/week) received 30 intradetrusor injections of onabotA (50 U [n = 19], 100 U [n = 21], or 200 U [n = 17]) or placebo (n = 16) via cystoscopy, avoiding the trigone for the treatment of NDO. Linear dose response for UI episodes/week was identified with a maximal effect detected with 200 U and no effect observed in patients treated with 50U [Apostolidis et al., 2013].

A consequence of BoNT/A treatment in NDO patients is the decrease in the incidence of severe urinary tract infections. In 30 SCI patients Gamé et al. [2008] observed that the number of pyelonephritis, orchitis and prostatitis in the 6 month before onabotA 300U, 1.75±1.87 per patient, decreased to 0.2±0.41 in the first 6 month after treatment. In 17 SCI patients that received onabotA injections for a period of 6 years, the number of urinary tract infection at the sixth year was 1.8±0.5 per year, significantly lower than at baseline, 6.7±2.1 [Giannantoni et al., 2008]. In a multicentre, cross-sectional retrospective cohort study, data from 214 NDO patients treated in 7 German centers were collected. The rate of urinary tract infections in 12 months preceding and in the 12 months following onabotA was 68% and 28%, respectively [Boy et al., 2008]. The reason for these findings is unclear but may lie in a decreased maximum detrusor pressure resulting in less bladder wall ischemia and vesicoureteral reflux [Wefer et al., 2009].

Multiple Sclerosis patients represent a particular subgroup of patients in whom a careful analysis of the efficacy and safety of BoNT/A requires additional attention if voluntary voiding is present before treatment. The first cohort studies used onabotA 300 U and while this dose was effective in improving or curing urinary incontinence most patients non-catheterizing at baseline had to initiate CIC [Kalsi et al., 2007; Khan et al., 2011]. Despite this drawback, improvements in quality of life were quite remarkable indicating that patients may prefer CIC to incontinence [Kalsi et al., 2007; Khan et al., 2011]. The large pivotal phase 3 studies [Cruz et al., 2011; Ginsberg et al., 2012) showed that 200 and 300 U of onabotA had exactly the same efficacy in terms of continence and duration of effect but 200 U had a much lower risk of urinary retention and de novo CIC.

The efficacy and safety of 100 U of onabotA in MS patients non-catheterising before onabotA injection was recently compared against placebo. Injections of 1ml each were carried out in 30 places above the trigone containing onabotA (n=66) or saline (n=78). OnabotA 100U significantly improved UI episodes/day compared with placebo (-3.3 vs -1.1; P<.001), and improved all the key urodynamic parameters like maximal cystometric capacity and maximal detrusor pressure. Improvements in I-QOL total score with onabotA were 4 times higher than placebo (40.4 vs 9.9; P<.001). Median duration of effect was 11.9 for onabotA and 2.9 months for placebo (P<.001). The risk of UTI (25.8%) and de novo CIC (15.2%) after 100 U onabotA was half of that observed with 200 U of toxin injections [Chartier Kastler et al., 2016]. This RCT confirmed therefore the small pilot studies that investigated onabotA 100 U in non-catheterising MS patients [Mehnert et al., 2010] and points out to such dose as the ideal to start treatment of in MS patients with NDO resistant to oral pharmacotherapy but not requiring any form of bladder catheterization. From the initial pivotal trials, it was possible to conclude that there is no risk of MS exacerbation after onabotA administration. The annualized event rate was 0.36 and 0.19 in the onabotA and placebo populations, respectively, therefore in the lower range of the annualized rate known for the general MS population risk, that varies between 0.2 and 1.2 in general MS population [da Silva et al., 2015].

Although not officially approved for NDO, abobotA has been the object of investigation in a few comparative clinical trials. A small study randomized a total of 31 NDO patients due to spinal cord injury, myelomeningocele, trauma at birth, multiple sclerosis and myelitis to intravesical injections of abobotA 500 U or placebo [Ehren et al., 2007]. Patients in the abobotA arm had a significantly higher cystometric capacity at 6 and 12 weeks, lower maximum detrusor pressure and episodes of urinary incontinence and less consumption of antimuscarinic drugs. Efficacy and safety of abototA were, additionally, investigated in NDO patients that had abandoned anticholinergic therapy. Two doses, 500 U (n = 39) or 750 U (n = 38) were compared. Complete continence at day 30 was observed in 22 patients (56.4%) and 28 patients (73.7%) receiving 500Uor 750U. The median delay in the reappearance of leakages was 168 days. Although there was a trend towards a greater improvement with 750 U, no statistically significant differences in terms of clinical and urodynamic variables and QoL were found between the treatment groups. Excellent tolerability was reported for both doses.

A single-center retrospective study investigated 750 U intradetrusor injection of abobotA in 81 consecutive patients performing CIC. Six weeks after the first injection, the success rate, defined as a combination of no incontinence episode, a number of catheterization <8 reported in a 3-day bladder diary and the lack of

detrusor overactivity, was reported in 64.2 %. Mean reinjection number was 3.9 and mean interval between reinjection was 8.8 ± 3 months. The clinical efficacy rate after each reinjection (up to fourteen) was at least 86.7 % [Peyronnet et al., 2016].

Recently a phase IIa, randomised, placebo controlled, pilot study enrolled 47 patients with NDO and urinary incontinence resulting from spinal cord injury (SCI) or multiple sclerosis (MS). Patients were treated with 15 intra-detrusor injections of abobotA 750 U or the equivalent placebo (n = 16 and 7) or 30 injections of AbobotA 750 U or the equivalent placebo (n = 17 and 7). Primary endpoint was change from baseline in mean number of daily incontinence episode frequency at day 84. Adjusted mean changes from baseline were -3.2 and -1.7 in the 15 injections group for abobotA and plcebo respectively. In the 30 injections group the change was -3.2 and -2.6, respectively for the toxin and placebo. Statistically significant improvements in maximum cystometric capacity, maximum detrusor pressure and volume at first contraction were reported in the toxin groups compared with placebo. Three muscle weakness episodes were reported as serious adverse events in two tetraplegic and one paraplegic patient, all in the 15 injections group [Denys et al., 2016].

8.1.1.2 BoNT/A in IDO Patients

The enthusiasm of investigators rapidly produced a reasonable number of pilot studies investigating BoNT/A in patients with IDO refractory to antimuscarics. Although proper dose-escalating studies capable of defining ideal doses were lacking, investigators opted for the administration of BoNT/A in doses smaller than those initially used in NDO. That is the reason why most pilot studies used either onabot 200 U or abobot 500 U ([see list at the end, see also Mangera et al,, 2011] and 4 RCT trials compared onabotA 200 U against placebo [Kuo, 2005b; Sahai et al., 2007; Brubaker et al., 2008; Flynn et al., 2009; Tincello et al., 2012]. Due to high incidence of voiding dysfunction associated with the use of onabotA 200U in IDO patients one large cohort, 100 patients, investigated the effect of onabot 100 U.

Two large well designed dose escalating placebo controlled studies investigated the ideal dose of onabotA. Dmochowski et al. [2010d; see also Rovner, 2011] enrolled 313 OAB wet and experiencing 8 or more urinary urgency incontinence episodes a week and 8 or more micturitions daily at baseline. They received 50, 100, 150, 200 or 300 U intradetrusor onabotA, or placebo. Durable efficacy was observed for all groups treated with 100 U dose or higher but in dose response curve doses greater than 150 U contributed minimally to the symptomatic improvement. As the use of CIC was also dose dependent, 100 U offered the best balance between efficacy and safety. Denys et al. [2012] randomised 99 OAB patients to receive a single injection of either placebo or onabotA 50 U, 100 U or 150 U. A >50% improvement versus baseline in urgency and urge urinary incontinence (UUI) in 65% and 56% of patients who respectively received 100 and 150 U. Complete continence was observed in 55% and 50% patients after 100 U and 150 U. The dose of 100 U seemed to offer the best balace between efficacy and increase of PVR.

A few additional studies contributed to defined 100 U as rhe ideal dose for refractory OAB treatment. Cohen et al. [2009] randomized 44 OAB-dry and wet patients to receive 100 U or 150 U. No significant differences in clinical or urodynamic outcome measures were noted between the two doses. QOL was significantly improved in both groups with no difference between 100 U or 150 U. Altaweel et al. [2011] randomized 11 patients for onabotA 100U and 11 patients to onabotA 200 U. No clinical or urodynamic differences were detected between the 2 groups at 3-months follow-up. Urinary retention occurred in 2 patients in the 200 U and in 1 patient in the 100 U arm. The same conclusion was withdrawn by Schmid et al. [2006] who injected onabotA 100 U in 100 IDO patients refractory to antimuscarinic therapy. Treatment remained highly effective, incontinence and urgency sensation disappearing in 86% and 82% of patients, respectively, during an average period of 6 months. Temporary urinary retention only occurred in 4% of the cases, with additional 15% reporting moderate voiding difficulties

Data from two large pivotal phase 3 studies in which patients were randomized to receive 20 injections of 0.5 mL each above the trigone, containing 5 U per injection with a total of 100 U or only saline are now available [Chapple et al., 2013; Nitti et al., 2013). These studies enrolled mostly female patients with idiopathic OAB with ≥3 urgency urinary incontinence (UUI) episodes over 3 days and ≥ 8 micturitions per day and a postvoid residual less than 100 mL who were inadequately managed by anticholinergics. The co–primary efficacy end points were change from baseline in the number of UI episodes and the proportion of patients with a positive treatment response on the treatment benefit scale (TBS) at week 12.

The Chapple et al. [2013] study randomized 277 patients to onabotA and 271 for saline injection. At baseline the average number of daily UI episodes was above 5 per day. OnabotA significantly decreased UI episodes per day at (-2.95 for onabotA versus -1.03 for placebo; $p < 0.001$). Significant reductions in frequency, urgency episodes per day and nocturia were also observed. Changes in TBS indicate that patients perceived a significant improvement in their condition (62.8% for onabotA versus 26.8% for placebo; $p < 0.001$). Clinically meaningful improvements from baseline in all I-QOL and KHQ multi-item domains indicated positive impact on quality of life.

The Nitti et al. [2013] study randomised 280 for onabotA and 277 for saline. In average patients experienced more than 5 episodes of UI per day. At week 12 there were greater decreases from baseline in the

mean daily UI in the active group ((–2.65 for onabotA and –0.87 for saline, p <0.001). The percentage of fully dry patients at week 12, was 22.9% after onabotA and 6.5% with saline. The other key OAB symptoms, frequemcy, urgency and nocturia also improved after onabotA. Of interest, all changes in OAB symptoms detected at week 12 were already present at week 2. A higher proportion of onabotA treated patients reported a positive treatment response on the TBS vs those on placebo. Large, clinically significant improvements in all I-QOL and KHQ multi-item domain scores were noted after onabotA.

A pooled analysis of the two pivotal phase 3 studies [Sievert et al., 2014] included a population of 1,105 patients randomized to onabotulinumtoxinA 100 U (n = 557) or placebo (n = 548) confirmed the results of the 2 RCT and allowed additional insights into the effect of onabotA 100 U in OAB patients. Patients treated with onabotA 100 U had an average decline of 2.8 episodes of urinary incontinence per day whereas the reduction in the placebo group was only 0.95 episodes per day (p < 0.001). In the group submitted to onabotA the rate of dry patients at week 12 was 27.1%, significantly higher than the rate of 8.4% in the placebo group (p<0.001). Moreover, 60.5 % of onabotA treated patients reported a reduction ≥50% from baseline in urinary incontinence episodes compared to 31% in the placebo group (p < 0.001). Other key OAB symptoms were also substantially improved by toxin treatment. The decrease from baseline in the number of episodes of urinary urgency per day was 3.30 and 1.23 in the onabotA and placebo groups, respectively. As to urinary frequency, there was a decrease of 2.35 and 0.87 micturitions per day, respectively. The median time to request retreatment was 24 weeks following treatment with onabotA compared with 13 weeks with placebo.

Further breakdown of the pooled data [Sievert et al., 2014] showed that the number of previous anticholinergic drugs does not seem to influence the outcome of onabotA treatment. The number of prior anticholinergics also did not affect the improvement caused by onabotA in urinary urgency episodes per day and in the number of micturitions per day. The rate of satisfaction was also independent from the number of previously used anticholinergic drugs. When analysing the efficacy of onabotA by the reasons why the anticholinergic treatment was stopped, insufficient efficacy or intolerable side effects, the symptomatic improvement and patient satisfaction after onabotA was similar in the two subgroups and comparable with the results achieved by the overall pooled population [Sievert et al., 2014]. However, the latter data should be compared with those of a retrospective analysis of a single center cohort that evaluated the efficacy of 100-150 U of onabotA injections in 85 patients. Results were superior in patients who did not tolerate anticholinergics than in those who abandoned the medication due to poor efficacy (86% vs. 60%, respectively) [Makovey et al., 2011].

Drake et al. [2015] conducted another post hoc analysis of the two pivotal phase 3 studies where the effect of the treatment was examined according to the severity of the incontinence at study entry. Patients with < 2, between 2 and 5 or > 5 UUI episodes per day had decreases in incontinence episodes of 2.7, 3.0 and 3.8, respectively. The percentages of patients with a reduction of more than 50% in the urinary incontinence episodes in each subgroup were 56.6%, 66.5% and 56.7%, respectively. All these numbers were significantly better than in the placebo groups, indicating that OnabotA is effective regardless of the grade of urinary incontinence at baseline.

A large placebo controlled RCT was conducted in 8 centers in UK (the RELAX study) and randomised a total of 240 women with refractory DO to receive onabotA 200 U or placebo distributed by 20 bladder wall sites above the trigone (10 U/1ml) [Tincello et al., 2012]. Primary outcome was voiding frequency per 24 h at 6 months. Secondary outcomes included urgency and incontinence episodes and quality-of-life data. A total of 122 women received onabotA and 118 received placebo. Median leakage episodes were already significantly reduced by week 6 and at 6 months were 1.67 in onabotA vs 6.0 in the placebo group. Continence was more common after onabotA (31% vs 12%). Significant decreases also occurred in voiding frequency (8.3 vs 9.67) and in daily urgency episodes (3.83 vs 6.33). Quality of life scores were better in the toxin group.

Other small RCTs have been conducted on IDO using onabotA 200 U [Sahai et al., 2007, Brubaker et al. 2008) or a combination onabotA 200 or 300 U [Flynn et al., 2009]. These studies were extensively reviewed in the 2013 edition of this book, but their relevance after the large RCTs of Chapple et al. and Nitti et al. make their detailed analysis today superfluous. Only safety data of these small studies will be mentioned below. A small open-label prospective study specifically investigated the chronology of the effect of onabot 200 U in IDO patients. Urgency, nocturia and frequency improved as soon as 4 days in IDO patients, a time-period slightly longer than that reported in NDO cases [Kalsi et al., 2008].

Successful OAB treatment with onabotA does not appear to be related to the existence of DO. In a subanalysis of the dose finding study for onabotA, no differences in outcomes were found between those with and those without baseline DO [Rovner et al., 2011]. Likewise, in a cohort of 5 male and 27 female patients with OAB and without DO, improvement in frequency and urinary incontinence was observed after treatment with onabotA [Kanagarajah et al., 2012]. Two doses were tested, 100 and 150 U, without no clinically relevant differences between them [Kanagarajah et al., 2012]. Thus, in clinical practice there is little justification to indicate routinely urodynamic testing in subjects with OAB symptoms refractory to oral medication to decide onabotA administration.

8.1.1.3 Adverse events in OAB and NDO Patients After BoNT/A Injection

In NDO the most common adverse events were UTI and de novo CIC [Cruz et al., 2011; Ginsberg et al., 2012; 2013).

In the SCI population, the majority of which was performing CIC at baseline, the incidence of UTI was similar across all treatment groups (around 50%). In the MS population, the rate of UTI was highest in the onabotA 300 U arm (saline 32%, 200U: 58.5%, 300U: 70%) in the study by Cruz et al. [2011] whereas the incidence of UTI was similar, around 50%, after 200 and 300 onabotA doses in the study by Ginsberg et al., [2012]. The high incidence of UTI among MS patients in the pivotal studies was related with dose dependent increase in PVR and necessity of de novo CIC. The latter was considered necessary in 12.2% of the patients after after saline, 29.5 after 200 U, and 42.2 after 300U in the study by Cruz et al. [2011]. Ginsberg et al. [2012] observed that the incidence of de novo CIC in patients not catheterizing at baseline was dose 10% on placebo, 35% on 200 U and 42% on 300 U, and also mainly affected MS patients. The pooled data of the two pivotal studies showed that the incidence of UTIs was similar among all treatment groups for SCI patients ($P = 0.534$), but was higher in the onabotA-treated MS patients compared with placebo ($P<0.001$). However, very few complicated UTIs were reported: pyelonephritis was reported in one MS patient (onabotA 300U group) and in two SCI patients (both in the placebo group), and urosepsis was reported in two SCI patients (both in the placebo group). Among patients non-catheterizing at baseline that received 200 U of onabotA about 1/3 required CIC. The period of time in which CIC was required was long lasting (>36 weeks) in about half of them [Ginsberg et al., 2013]. The risk of urinary retention and de novo CIC in MS patients non-catheterising before treatment may be substantially decreased by using a lower dose of the toxin. Using 100U of OnabotA in non-catheterising MS patients de novo CIC (15.2%) and the rate of UTI (25.8%) was half of that observed with 200 U of toxin injections [Chartier Kastler et al., 2016)

Paralysis of the striated musculature due to systemic leakage of the toxin has never been reported with the doses tested in the several studies reviewd here. Transient muscle weakness was, nevertheless, reported with AbobotA application in several studies [Wyndaele and Van Dromme, 2002; Akbar et al., 2007; Del Popolo et al., 2008]. Among 199 NDO patients followed during 8 years, 5 developed hypostenia when injected with after abotbotA 1000 U [Del Popolo et al., 2008]. In another study with 44 patients, 3 adults also treated with 1000 U developed muscular weakness which subsided after 5 to 7 weeks [Akbar et al., 2007]. In a recent phase IIa RCT with abobotA 750 U, 3 cases of muscle weakness episodes were reported in two tetraplegic and one paraplegic patient among 15 NDO patients who received the toxin in 15 injection sites [Denys et al., 2016). No such cases were reported with onabotA by Karsenty et al. [2008]. The reason for the less frequent transient muscle weakness among onabotA-treated patients is unclear but might be related with the larger size of its molecule which limits diffusion into the blood stream or a dose of abobotA which is more powerful that the doses used with onabotA. Anyway, the risk of hyposthenia associated with abobotA might be avoided by using lower doses of the toxin, no more that 750 U for adults and 20 units/kg for children [Akbar et al., 2007, Del Popolo et al., 2008] or by avoiding high amounts of toxin per injection site. In addition, caution should be used in selecting high risk patients for botulism including children, patients with low pulmonary reserve or patients with myasthenia gravis. Aminoglycosides should be avoided during BoNT-A treatment since they might blockade motor plates and therefore enhance BoNT/A effect.

Episodes autonomic dysreflexia in SCI patients during injection were rare. Ginsberg et al. [2012] in 167 injected patients reported 7 events of autonomic dysreflexia.

Data from long-term studies that followed the large RCT are now available. In NDO, most common adverse events during 4-year follow-up were urinary tract infections and urinary retention. De novo CIC rates were 29.5%, 3.4%, and 6.0% (200U), and 43.0, 15.0, and 4.8% (300U) for treatments 1–3, respectively; de novo CIC rates were 0% for treatments 4–6 [Kennelly et al., 2015]. UTI ranged between 20% and 30% along the follow-up without relevant differences bewteen patients treated with 200 U or 300 U [Kennelly et al., 2015]. In OAB studies UTI was the most common adverse event and ranged between 17.0% after treatment cycle 1 and 14.4% after treatment 6. CIC was necessary in 4.0% after the first treatment but this incidence decreased in all subsequent treatment cycles and was below 1% after treatment cycle 5 and 6. The median duration of CIC ranged from 3.1 to 8.3 weeks [Nitti et al., 2016].

Although it is a concerned frequently rose by caregivers, at this moment there is no evidence that repeated BoNT/A injections cause detrusor atrophy or bladder wall fibrosis. Whether onabotA or abobotA were used, repeated injections in NDO patients in the short to medium term did not decrease bladder compliance which would presumably be the case if fibrosis were to develop [Reitz et al., 2007; Del Popolo et al., 2008]. Histological inspection of injected bladders did not show inflammatory changes, fibrosis, or dysplasia after repeated treatments and independently of the neurogenic or non-neurogenic origin of the detrusor overactivity [Haferkamp et al., 2004; Compérat et al., 2006; Apostolidis et al., 2008]. Rather the reverse, one study demonstrated that NDO patients treated with BoNT/A had less fibrosis than nontreated patients [Compérat et al., 2006]. Curiously, the presence of eosinophilic infiltrate was shown to increase in specimens of patients receiving multiple treatments, a finding that could not be fully explained [Apostolidis et al., 2008].

In OAB, the dose finding study conducted by Dmochowski et al. [2010] the proportion of patients with posttreatment PVR of 200 ml or greater was dose dependent and patients requiring CIC were 0%, 3,6%, 9,1% 12,7% 18,2% and 16,4 after placebo or 50, 100, 150, 200 and 300 U onabotA injections. In what concerned UTI this complication occurred in 16,3%, 33,9%, 44%, 48.1% and 34.5% patients after placebo, and 50, 100, 150, 200 and 300 U onabotA injections, respectively .

In the pivotal studies the most common adverse event was uncomplicated UTI followed by urinary retention. In the Chapple et al. [2013] study, UTI occurred in 24.1% of the onabotA patients and 9.6% in the placebo group. The majority of patients treated with onabotA (75.8%) did not have an increase from baseline in PVR excceding 100 ml and only 8.8% had PVR increases exceeding 200 ml. The proportion of patients who initiated CIC in the first 12 weeks after treatment was 6.9% following onabotA and 0.7% after placebo injection. In the Nitti et al study [2013] UTI, again the most frequently reported AE occurred in 15.5% for onabotA and 5.9% for placebo in the first 12 weeks after treatment. All UTIs were uncomplicated, coursing without pyelonephritis. Other notable adverse events that occurred in the first 12 weeks at a higher incidence in patients treated with onabotA were dysuria (12.2%) assymptomatic bacteriuria (5.0%) and urinary retention (5.4%). PVR significantly increased in patients treated with the toxin, with the highest increase being detected at week 2 (49.5 ml). A total of 8.7% had a 200 ml or greater increase from baseline in PVR. CIC was necessary in 6.1% ptients treated with onabotA and in none in the placebo group. For more than half the patients who initiated CIC the duration was 6 weeks or less.

In the RELAX study, as mentioned before, the dose of onabotA used was 200 U. UTI occurred in 31% vs 11% in the onabotA and placebo groups, respectively. Voiding difficulty requiring CIC occurred in 16% of cases that received the toxin and in 4 % of patients that received placebo [Tincello et al., 2012].

In a small RCT, CIC was required in 37.5% of patients treated with 200 U of onabotA [Sahai et al., 2007]. In another small RCT comparing onabotA 200U vs placebo, PVR increased above 200 ml in 43% of the women in the BONT/A group and UTI developed in 75% of these women [Brubaker et al., 2008].

Currently it is not possible to identify beforehand patients who will develop voiding difficulties after BoNT/A injection. The positive or negative status of the ice water test does not correlate with the risk of urinary retention after onabotA injection in NDO patients [Huwyler et al., 2007]. A retrospective analysis of 217 patients receiving their first intravesical BoNT/A injection for refractory IDO in a tertiary center concluded that risk factors for dysfunctional voiding and urinary retention included male gender (p = 0.013), baseline postvoid residual (PVR) > 100 ml (p = 0.003) and onabotA > 100 U (p = 0.029) [Kuo et al., 2010]. Also in a retrospective analysis of a cohort of 67 patients with IDO treated with onabotA 200 U CIC was necessary in 19 (28%). When compared to those not requiring CIC, those that started CIC had lower pretreatment maximum flow rate (15 vs 22 mL/s, *P*=0.003), lower projected isovolumetric pressure (43 vs 58, P=0.02) and lower bladder contractility índex (113 vs 180, P=0.001) [Sahai et al., 2009].

Hematuria may occur after toxin injection in the bladder wall of OAB or NDO patients but in most of the times is mild in nature and does not require any active treatment.

8.1.1.4 BONT/A in Children and Elderly Patients

In children, the dose of BoNT/A should be calculated according to body weight. Doses of between 12 U/kg of weight up to a maximum dose of 300 U [Schulte-Baukloh et al., 2002] and 4 U/Kg [Corcos et al., 2002] have been used for onabotA. The maximum suggested for abobotA is 20 U/kg up to a maximum of 400 U [Altaweel et al., 2006; Akbar et al., 2007). BoNT/A has been essentially assayed in children with myelomeningocele [Schulte-Baukloh et al., 2002; 2003; Corcos et al., 2002; Riccabona et al., 2004; Kajbafzadeh et al., 2006; Altaweel et al., 2006]. Like in adults, the toxin increased bladder capacity and decreased maximal detrusor pressure. In 26 children with a mean age of 6,9 years, 19 of them (73%) became completely dry between clean intermittent catheterizations while 88% reported a global improvement in urine incontinence. Interestingly, in 11 (73%) out of the 15 children who had vesicoureteral reflux before injection, reflux either disappeared or decreased in grade. BONT/A also improved bowel function in 66% of the children with intestinal problems [Kajbafzadeh et al., 2006]. The success rate in terms of continence and cessation of anticholinergic medication may, however, be substantially inferior to that seen in adults, potentially due to irreversible bladder wall changes associated with longstanding detrusor overactivity [Altaweel et al., 2006]. In a group of 20 children with myelomenigocele continence was achieved in only 13 children. At a second injection, this number also did not change appreciably [Altaweel et al., 2006].

A recent systematic review found a total of 13 studies reported on 368 children receiving BoNTA for NDO, none with a placebo comparator arm. The only parameters reported with consistency between studies were the MCC and MDP, which changed by bewteen 42 to 59% [Mangera et al., 2014].

To date, two case series have looked at the use of BoNT/A in children with non-neurogenic OAB refractory the anti-cholinergics. Both studies have shown an excellent response to treatment [Hoebeke et al., 2006; Marte et al., 2010]. Data have been updated recently [McDowell et al., 2011]. A total of 57 children of both gender received abobotA 12 U/kg up to a maximum dose of 480 U in multiple bladder sites. A total disappearance of OAB symptoms occurred in

66% and a partial improvement in 19% of the patients. About half of the cases had repeated injections after a mean time slightly exceeding 6 months No cases of voiding dysfunction or UTI were reported [McDowell et al., 2011].

Electromotive administration of BoNT/A may represent a substantial breakthrough among children. In 15 children with NDO due to myelomeningocele, electromotive administration of abobotA instilled in the bladder in a dose of 10 U/kg, proved very effective and safe. The mean reflex volume (99 ± 35 ml to 216 ± 35 ml) and maximal bladder capacity (121 ±39 ml to 262 ± 41 ml) increased substantially while maximal detrusor pressure decreased from 75 ± 16 cm H2O to 39 ± 10 cm H2O. Urinary incontinence improved in 12 patients (80%) [Kajbafzadeh et al., 2011].

Elderly patients represent, as well, a very special population where urgency and incontinence are not only very distressful but also particularly prevalent. Nevertheless, only one study specifically addressed efficacy and safety of BoNT/A in elderly patients. Twenty-one patients with refractory IDO (18 females and 3 males) with a mean age of 81.2 years (range 75 to 92) received onabotA 200 U in 20 bladder sites [White et al., 2008]. A significant decrease in the number of daily voids, from 11.4 ± 1.67 to 5.19 ± 0.83 and incontinence pads per day, from 4.0 ± 0.89 to 1.3 ± 0.60, occurred. One month after treatment 16 of the 21 patients (76%) reported greater than 50% improvement in symptoms after 1 injection while only 3 did not show improvement after 2 injections [White et al., 2008]. Mean time to deterioration was 7.12 months. There were no treatment related complications.

8.1.1.5 Effect of BoNT/A on Quality of Life

Firm evidence that BoNT/A bladder injection in NDO and IDO patients increases quality of life can be extracted from several RCT in which QoL changes were in most cases a secondary outcome parameter.

One pivotal phase 3 study in NDO patients used the I-QoL questionnaire to evaluate quality of live changes in SCI and MS patients randomized to 200 and 300 U of onabotA or placebo. Change from baseline was 24 points for both onabotA doses at 6 and 12 weeks but only 11 points at week 6 and 8 points at week 12 in the placebo group. The I-QoL questionnaires requires that a minimum change of 11 point occur in order to QoL to be detectable by patients, a barrier that was overcome by both OnabotA doses [Cruz et al., 2011]. Improvements were present both in SCI and MS patients. In another large phase 3 trial these data were totally confirmed [Ginsberg et al., 2012]. Interestingly, a comparison in QoL in patients performing and non-performing CIC in the placebo, 200U and 300U arms did not show differences in patient perception, indicating that improvement in the continence condition was a more relevant outcome [Ginsberg et al., 2012]. Improvements from baseline in the avoidance, limiting behavior, psychosocial and social embarrassment domains of the I-QoL Questionnaire were greater after onabotA treatment. Responses to the OAB-PSTQ and to the Patient Global Assessment also demonstrated superior mean improvements from baseline in 200 U onabotA than in placebo treated group [Chancellor et al., 2013]. The Canadian multicenter double-blind study [Herschorn et al., 2011a] that randomised to onabotA 300 U or placebo 57 incontinent patients with NDO secondary to spinal cord injury or multiple sclerosis also found significant advantage of onabotA in terms of I-QoL score. A small exploratory, multicenter, randomized, double blind placebo controlled trial by Schurch et al. [2007] which randomized 59 NDO patients with urinary incontinence for onabotA 200U or 300U or placebo found that. I-QOL scores improved significantly over placebo, at all time points whether 300U or 200U were used.

The importance of continence for patients' quality of life is also confirmed by the study of 43 MS patients treated with onabotA 300 U [Kalsi et al., 2007]. Although 98% of patients had to perform CIC after treatment, there were sustained improvements in all quality-of-life scores with a mean duration of effect was 9.7 months. Results were maintained with repeat treatments for 11.7 months. These results were confirmed in a larger MS cohort by Khan et al. [2011]. Urogenital Distress Inventory and Incontinence Impact Questionnaire 7 scores showed considerable improvement 4 weeks after onabotA 300 U treatment even when repeated 6 times. Again, the fact that 76% of the patients were dry seemed more relevant for QoL score than the necessity of CIC that was required by almost all patients [Khan et al., 2011].

Improvement in QoL was also found in a study that compared abobot 500 U versus /750 in a NDO population predominantly suffering from SCI. A disease- and organ-specific Qualiveen questionnaire with four domains (limitations, constraints, fears, and feelings) was used to assess the Specific Impact of Urinary Problems on QoL The initial evaluation was repeated at days 30, 90, 180, and 360. Identical improvements were detected for the two doses [Grise et al., 2010]. A single center, double blind, placebo controlled study performed by Ehren et al. [2007] randomised 37 NDO patients with incontinence to abobotA 500 U or placebo. Patients in the AbobotA group showed greater improvement in quality-of-life parameters compared to the placebo group. Amore recent study that compared 750 U of abobotA injected in 15 or 30 sites showed increases in I-QOL scores were observed in both groups and to a lesser extent the placebo groups at day 14 and 84 after injection which were statistically significant differences only for the 15 injection sites group [Denys et al., 2016].

In IDO/OAB, the dose finding study by Dmochowski et al. [2010] in which placebo and onabotA 50, 100, 150, 200 and 300 U were compared showed a sustained improvement in the King's Health Questionnaire score only in patients that received doses of 100

U or higher. In contrast, patients randomized to onabotA 50 U had changes similar to those observed after placebo [Dmochowski et al., 2010]. The dose finding study by Denys et al. [2012] showed an I-QoL improvement in patients receiving onabotA 100 U and 150 U, though at some time points scores were only numerically higher than in placebo or 50U groups. The general health status, as measured by the EQ-5D visual analogue scale also improved in patients that received 100 or 150 U [Denys et al., 2012].

In the pivotal study conducted by Chapple et al. [2013] in OAB patients there were significant improvements in the I-QOL total summary score and all three domain scores in the onabotA group vs placebo. The improvement far exceeded the predefined minimal important difference (MID) of a 10-point increase. Improvements from baseline in all seven multi-item domains of the KHQ were also greater in the onabotA group. The same was observed by Nitti et al. [2013]. Large, clinically significant improvements in all I-QOL and KHQ multi-item domain scores were noted after onabotA vs placebo treatment in OAB patients. Improvements from baseline for onabotA, in contrast to placebo, were considerably greater than the predefined minimally important differences.

The RELAX study [Tincello et al., 2012] showed significant improvement in ICIQ-SF and I-QoL scores. However, none of the questionnaires were restored to the normal score (0 for ICIQ; 100 for IQOL) [Tincello et al., 2012].

Two small RCT with OAB/IDO patients [Sahai et al., 2009] used the King's Health Questionnaire (KHQ) at baseline and at 4 and 12 weeks, after injection of onabotA 200 U or saline in 16 and 18 patients of both genders. Overall QoL was significantly improved in the onabotA treated patients compared with placebo in the KHQ subdomains, 'Incontinence Impact', 'Emotions', 'Physical imitations', 'Social Limitations' and 'Severity Measures' at the two time-points.

8.1.1.6 Repeated Injections in NDO Patients

Median time for NDO patients due to SCI or MS to request a retreatment was around 300 days after onabotA 200 or 300 U but only 92 days after placebo [Cruz et al., 2011]. Therefore, for patients that respond to BoNT/A a programme of reinjections is inevitable.

With the objective of evaluating the long-term efficacy and safety of repeated onabotA injections, patients who completed the two pivotal phase III studies were invited to participate in a long-term study. At the start of the extension study, patients that had received onabotA 200 U or 300 U continued with the same dose while dose on placebo were randomized to receive the active compound in one of the two doses. Later, with the license of 200 U, all patients were converted to this dose. The primary assessment was the change from baseline in urinary incontinence episodes during the week 6 after each injection. The first analysis was carried out after 5 treatment cycles [Kennelly et al., 2013]. Update of the long-term study in patients that were treated up to 4 years was reported recently [Kennelly et al., 2015]. OnabotA 200 U consistently reduced UI episodes/day, ranging from –3.2 to –4.1 across six treatments (variations from baseline). Volume/void consistently increased, nearly doubling after treatment. I-QOL improvements were consistently greater than twice the minimally important difference. Overall median duration of effect was 9.0 months for patients treated with 200 U. In the reduced number of cases treated with 300 U results were similar [Kennelly et al., 2015]. However, patients did not request the same number of treatments along the 4 yeras follow-up. While some patients required 8 re-injections, others asked only for 2. Patients with fewer treatments had a slightly fewer baseline episodes of incontinence per day than those that required 7 or 8 treatments. Nonetheless, the daily episodes that were observed in week 6 after each treatment indicated a similar efficacy of onabotA, regardless of the number of injections requested. This suggests that patient preference for retreatment was not motivated by a different degree of toxin efficacy.

Rovner et al. [2016] reanalysed this large cohort looking only to the 227 patients who did not abandon the study and therefore completed the 4-year period of analysis. Patients reported 4.3 urinary incontinence episodes per day at baseline and received 1.4 to 1.5 onabotA treatments per year. The decrease in urinary incontinence following onabotA consistently ranged from -3.4 to -3.9 episodes per day across 4 years. A high proportion of patients achieved 50% or greater and 100% urinary incontinence reductions in each year (range 86.6% to 94.1% and 43.6% to 57.4%, respectively). Consistent and clinically relevant improvements in I-QOL scores were observed in each treatment year. The overall median duration of effect of onabotA range beween 3.0 to 49.2 months and 26.0% or more of patients experienced a duration of effect of 12 months or greater. The most common adverse event was urinary tract infection with no increased incidence with time the proportion of UTI in the years 1 to 4 were 21.5%, 20.9%, 17.3% and 18.9%, respectively [Rovner et al., 2016].

Toxin-neutralizing antibody formation (i.e., seroconversion), occurred in three patients who received onabotA 200U (one in each of cycles 2, 8, and 9) and five patients who received 300U [Kennelly et al, 2015].

It may be interesting to compare this study with data extracted from real-life practice, in a population of NDO subjects mainly composed by SCI and MS patients. The number of patients requesting retreatments substantially decrease during follow-up and 5 years after the initial injection only 10% of the original cohort remained on treatment. The explanation for such decrease includes the progression of the neurological disease, which can be particularly expected in MS patients. The worsening of the motor capacities will restrain a significant number of these patients to a bed-ridden condition in which the advantages of

onabotA injections may no longer be perceived. One should remember that the regulatory studies excluded patients wheel-chair bound or bed-ridden. In addition, a significant number of SCI patients had bladder augmentation or urinary diversion during the period of analysis.

Three studies were identified that assessed the effect of repeated injections of onabotA and abobotA in NDO patients. A cohort of 199 patients with spinal cord lesions treated with abobotA 500 U to 1000 U was analysed retrospectively, after 8 years of repeated injections. The intervals of between injections remained constant. Urodynamic improvements, patients' satisfaction with treatment and number of pads or other protective devices was also constant after treatments [Del Popolo et al., 2008]. Intervals exceeded 12 months in 19.5% of the patients, ranged between 10 and 12 months in 40.2%, was < 10 months in 30.5% and < 6 months in only 10% of the patients [Del Popolo et al., 2088].

In another study, 20 consecutive NDO (SCI 18, MS 2) patients received at least five intradetrusor injections of onabotA 300 U in 30 sites above the trigone. Intervals between injections remained constant, between 193 and 199 days. Clinical continence improved significantly after the first injection and then remained constant after repeat injections. The median reflex volume increased from a 200 ml at baseline to values between 440 and 500 ml at follow-up studies. The presence of NDO decreased by 60–75%. Maximum cystometric capacity increased more than 2 folds and maximum detrusor pressure from a median of 70 cm H2O to values of about 20 cmH2O [Reitz et al., 2007].

In a MS cohort with137 patients who underwent detrusor onabot 300 U, 99 (72%) returned for a second treatment, and 47, 25, 14 and 5 returned for re-treatments 3 to 6, respectively. The median interval for 1st, 2nd , 3rd, 4th, and 5th re-injections ranged between 12 and 13 months. The outcome in terms of continence did not differ among treatments [Khan et al., 2011].

8.1.1.7 Repeated Injections in IDO/OAB

The median time to request a retreatment in the Chapple et al. [2013] and Nitti et al. [2013] RCTs was was 24 weeks following treatment with onabotA implicates that repeated njections are necessary if treatment is required.

Patients participating in the two phase 3 studies were invited to participate in a long-term, 3-year extension study to determine the efficacy and safety of repeated onabotA 100 U injections for the management of OAB. This is the largest cohort with the longest follow-up available until now. Treatments were requested by participants upon reappearance of OAB symptoms and once eligible, patients were re-injected with a similar 100 U dose of onabotA. An interim analysis after 5 treatment cycles showed that the decrease from baseline of UUI episodes remained stable, around 3 episodes per day and the proportion of patients reporting a high satisfaction rate remained high, ranging from 70% to 90 %. The duration of the effect remained stable or even increased in subsequent treatments. However, for reasons that are unclear patients that received up to 5 treatments were a minority when compared with those that requested only 1 or 2 injections. These results were up-dated recently by Nitti et al. [2016]. From the initial 839 patients enrolled, a total of 829 received one or more

treatments and 430 (51.3%) completed the 3.5-year study period. At baseline the mean

episodes of UI per day was 5.6 and the I-QOL total score was low. The decrease of UI episodes ranged between -3.1 and -3.8 episodes per day wether patients received 1 to 6 treatments. The median duration of effect, calculated as the time to requalify to a retreatment was 7.6 months. The median duration of effect was 6 months or less in 34.2% ofthe participants, between 6 to 12 months in 37.2% and greater than 12 months in 28.5% [Nitti et al., 2016]. The overall incidence of toxin neutralizing antibody formation was 0.4% [Nitti et al., 2016].

Real-life studies offer contradictory results concerning persistence on an onabotA program. Malde et al. [2014] reported that in a group of 100 patients with refractory OAB 90% would return to the program in the future and 93 % would recommend the treatment to a friend. Moreover, 81% accepted the treatment as life-long. On the other hand, Mohee et al. [2013] found that 66.3% of patients discontinued therapy at 36 months. The main reasons for abandonment were UTIs and the need for CIC. In a single-centre retrospective study [Marcelissenet al., 2016] the persistence on treatment of a total of 128 women with at least 5-year follow-up after their first injection and a mean follow-up 97 (60-125) months was investigated. Of all patients, 30 % were still on BoNT-A treatment at the last follow-up visit. Of the 70 % that discontinued treatment, 27 % had insufficient effect and 43 % had tolerability issues. Most patients discontinued treatment after the first (79 %) and second (19 %) injections. Only 2 % of patients discontinued treatment after more than two injections during follow-up. In these ladt two studies [Mohee et al., 2013; Marcelissen et al., 2016] the majority of patients were treated with onabotA 200 U. A high rate of adverse events related with the high dose used may have, therefore, contributed to the low persistence in treatment.

Other 4 studies were identified that analysed repeated injections in IDO patients. In general, longer duration of BoNT/A effect and a relatively higher rate of treatment drop out is seen among IDO patients. A cohort of 34 IDO patients treated with onabotA 200 U [Sahai et al., 2010] was updated with 100 patients [Dowson et al., 2012]. A statistically significant reduction in frequency, urgency, and urge urinary incontinence were seen following onabotA 200 U injection compared to baseline. Such improvement was again

maintained after repeated injections. The mean inter-injection interval was 322 days. Interestingly, 37% of the patients stopped treatment after the first two injections, dropouts being rare thereafter. The most common reason for discontinuing treatment was poor efficacy (13%). CIC related issues was pointed out by 11% of patients despite the incidence of CIC after the first injection being 35% [Dowson et al., 2012].

In a prospective, observational study after 1 single onabotA 100 U injection, 26 patients were followed up for 2 years. One patients did not respond (primary failure), 3 were lost to follow-up, and 11 patients had a repeated injection at 5–26 months. At 2 years 7 of the remaining 11 patients were recommended repeated injection or another treatment, and four required no other treatment.

Schmid et al. [2008] reported on 25 women and 5 men that received repeated (2) injections of onabotA for treatment of IDO. The interval between two subsequent treatments ranged between 4 and 26 months (mean 12 months). Improvement of OAB symptoms, quality of life and urodynamic parameters were observed after reinjection.

8.1.1.8 Cost-effectiveness of BoNT/A

Economic aspects of BonT/A are a concern due to the price of the drug and the need for repeated cystoscopies, very often performed under general anaesthesia and under close monitoring to detect and treat eventual episodes of autonomic dysreflexia. Nevertheless, In UK, in a cohort of 101 patients with detrusor overactivity, 63 of whom of neurogenic origin, BonT/A treatment was shown to be cost-effective in both NDO and IDO cases [Kalsi et al, 2006]. Costs were based on the resources used by typical patients in UK and in the cost-effectiveness of 200-300 U BoNT/A (Botox) compared with standard care [Kalsi et al., 2006]. In Germany, a multicenter cost analysis showed that BonT/A (onabotA) treatment halved costs for incontinence aids and for urinary tract infection treatment in 214 NDO patients. In patients using incontinence aids, mean costs per patient decreased from €2 to €1 per day, whereas the mean cost of drugs to treat UTIs per patient decreased from €163 to €8 per year [Wefer et al., 2009].

Also in NDO patients, break-even point for BoNT/A and augmentation cystoplasty costs may be reached at five years. However, BoNT/A may be substantially more cost-effective if the duration of effect of each injection is superior to 5 months or if the complications associated with augmentation cystoplasty overtake 40% of the patients [Padmanabhan et al., 2011].

For OAB/IDO, an assessment of costs, from a US payer perspective, extending up to 3 years, was made for 3 interventions, sacral neuromodulation, BoNTA, and augmentation cystoplasty in patients refractory to antimuscarinics. The initial treatment cost was $22,226, $1,313, and $10,252 for sacral neuromodulation, BoNTA, and augmentation cystoplasty respectively. Three years after initiating treatment, the cumulative cost was $26,269, $7651, and $14,337 respectively. Sensitivity analyses revealed that sacral neuromodulation persisted as the most costly intervention [Watanabe et al., 2010].

Visco et al. [2016] analysed cost and effectiveness data from participants in the Anticholinergic versus Botox Comparison randomized trial of daily anticholinergic medication versus 100 U of intradetrusor Botox injection. They concluded that Botox and anticholinergic medications have similar costs and effectiveness in the first 6 months of UUI treatment. If costs and outcomes are considered through 9 months, Botox may have significantly lower costs but similar symptom control as anticholinergics.

8.1.1.9 Clinical Comparisons and Switch Between Different BoNT/A Brands

Different brands of botulinum toxin type A cannot be used interchangeably. The molecular weights are different. OnabotA is a 900 kDa molecule, abobotulinumtoxinA is approximately 500 kDa and incobotA, is a 150 kDa molecule [Cruz, 2014]. In addition, potency of these brands is impossible to compare due to the distinct tests used to evaluate it. While onabotA's potency is determined by the EC50 (amount of toxin required to provoke a response halfway between the baseline and the maximum response) of cleaved synaptosomal associated protein of 25 kDa (cSNAP-25) in differentiated neuroblastoma cells, abobotA potency is determined by the mouse LD50 (amount of toxin that kills 50% of the mice) [Cruz, 2014]. Despite the fact that they are not licenced both abobotA and incobotA are however being used in real-life clinical practice to treat NDO and OAB. As doses for these brands were never established by appropriate dose finding studies in the lower urinary tract, empiric conversion ratios are applied with unknown consequences.for the comparison of the outcomes. Mangera et al. [2011] in a systematic review identified good-quality studies that evaluated onabotA for all the indications in adults. However, that was not the case with abobotA. Although this does not imply that onabotA is more effective than abobotA, it should be a consideration when counselling patients on the use of botulinum toxin in urologic applications., either in terms of predicting outcomes or in determining doses to be used.

A study compared two different brands of BonT/A, onabot A 200 or 300 U against the Chinese BoNT/A Presigne in the same dosage. Improvement in MCC was significantly greater with onabotA Botox versus Prosigne (+103.3% vs. +42.2%; P = 0.019). Continence was achieved by week 12 in 16 onabotA recipients (76.2%) and in 10 Presigne recipients (47.6%; P = 0.057) [Gomes et al., 2010]. Future studies seems, therefore, justified to assess the relative potencies of the different brands of BoNT/A.

A few studies have examined the consequences of changing botulinum toxin type A brands to treat bladder dysfunction. Ravindra et al. [2013] initially treated OAB patients with onabotA with a standard dose of

200 U. Then, they switched to abobotA with a standard dose of 500 U based on an empiric conversion ratio of 1:2.5 between the two toxins. The onabotA (n = 101) and the abobotA cohorts (n = 106) had similar reductions in frequency, nocturia and daily incontinence episodes. No difference in the duration of the effect was observed. However, the abobotA group had almost twice the rate of symptomatic urinary retention requiring CIC (42% versus 23%).

Peyronnet et al. [2016] assessed the results of onabotA detrusor injections when abobotA detrusor injection failed. Twenty-six patients with SCI (n=14), MS (n=9), myelomeningocele (n=2) and myelitis (n=1) in whom a first injection of 750 U abobotA in 20 sites failed in treating NDO received onabotA 300 U in 30 sites. The reasons for the failure of first treatment were not clear and in no case a second injection of abobotA was attempted. OnabotA injections brought continence to 65.4% and detrusor overactivity was relieved in 57.7% of the patients.

In another study Peyronnet et al. [2015] reviewed the charts of 58 NDO patients who received either onabotA or abobotA for the management of NDO. A toxin switch was carried out in 29 patients, whereas the other 29 patients received a reinjection of the same toxin at the same dose. The success rate was higher in patients who switched toxin (51.7% vs 24.1%, P = 0.03). Patients treated with a switch from abobotA to onabotA and those treated with a switch from onabotA to abobotA had similar success rates (52.9% vs 50%)

Switch between brands is currently clearly being made on empiric grounds. In particular the lack of effect of a treatment with a particular brand should not be seen as a compulsory reason for switching to another brand. In a recent sub-analysis of the NDO patients included in the onabotA pivotal studies whom experienced <50% reduction in urinary incontinence episodes following the first onabotA treatment, about 1/3 had a positive response in subsequent injections [Denys et al., 2015]. Even in patients with an initial response below 25%, marked improvements were found in subsequent treatments. As a matter of fact, in 10 of the 23 patients with <25% reduction at the first treatment, mean urinary incontinence reduction was ≥50% in all subsequent injections. Thus, an initial low response does not necessarily predict a permanent low response to subsequent treatments.

Reasons for the lack of response to botulinum toxin A injection in the bladder wall cannot be attributed neither to the lack of SNAP-25, an indispensable membrane protein nor to the formation of antibodies against the toxin which is a rare event. Rather, inappropriate storage the vials, incorrect toxin reconstitution, or incorrect technique of administration, including the type of needle used, should be more obvious reasons for treatment failure [Karsenty et al., 2014]. A large variation of the number of bladder neurons expressing cleaved SNAP-25, the end-product of botulinum toxin A activity, after 1 injection of a fixed dose of onabotA was recently shown in experiments conducted in rodent bladder. The amount of cleaved protein after onabotA injection reached a 5-fold variation between experiments [Oliveira et al., 2015].

8.1.1.10 Comparison Between BoNT/A and Other Treatments

BonT/A has been compared to other OAB treatments only rarely as it is assumed that its introduction should follow the failure of first line oral pharmacotherapy, antimuscarinics and the beta3 agonist mirabegron. However, given the frequently suboptimal efficacy and long-term compliance of anticholinergic medications, researchers must assess whether BONT/A has a role as first line therapy for women with OAB. The Anticholinergic Versus Botulinum Toxin A Comparison Trial (ABC trial) [Visco et al., 2012] randomization of 249 women with OAB who had 5 or more episodes of urgency urinary incontinence in a 3-day bladder diary. For a 6-month participants were randomly assigned to one intradetrusor injection of 100 U of onabotA plus daily oral placebo daily or oral anticholinergic medication (solifenacin, 5 mg initially, with possible escalation to 10 mg and, if necessary, subsequent switch to trospium XR, 60 mg) plus one intradetrusor injection of saline. The primary outcome was the reduction from baseline in mean episodes of urgency urinary incontinence per day recorded in 3-day diaries over the 6-month [Visco et al., 2012]. The mean reduction in episodes of urgency urinary incontinence per day, from a baseline average of 5.0 per day, was 3.3 in the onabotA group and 3.4 in the anticholinergic group (P = 0.81). Complete continence was reported by more commonly in the onabotA than in the anticholinergic group, 27% vs 13% (P = 0.003), respectively. The toxin group had higher rates of catheter use at 2 months (5% vs. 0%, P = 0.01) and UTI (33% vs. 13%, P<0.001) than the anticholinergic group. The latter on the other hand had a higher rate of dry mouth (46% vs. 31%, P =0.02) [Visco et al., 2012].

In a similar study researchers randomised patients with OAB and urinary incontinence to receive double placebo (n = 60), onabotA 100 U injection plus placebo (n = 145), or oral solifenacin plus placebo injection (n = 151) for 12 weeks. Co-primary endpoints were change from baseline in urinary incontinence episodes/day and the proportion of patients with 100% reduction in urinary episodes at week 12 after injection. Overall, patients had 4.9 urinary incontinence episodes per day. At week 12, mean reduction from baseline in urinary incontinence episodes/day was significantly greater with either onabotA (-3.2) or solifenacin (-2.6) versus placebo (-1.3; P < .001 for both). Reduction in urinary incontinence episodes/day was significantly greater with onabotA than solifenacin (post-hoc analysis; P = .022). The proportion of patients with 100% reduction in urinary incontinence episodes at week 12 was significantly better for onabotA (33.8%) and solifenacin (24.5%) compared with placebo (11.7%) [Everaert et al., 2016]

The Rosetta study compared onabotA 200 U bladder injections against SNM (interStim) in refractory OAB patients [Amundsen et al., 2014]. The proportion of randomised patients suitable for SNM implant was identical in the two arms. At baseline the onabotA group (n=190) had 5.4 and the SNM (n=174) had 5.2 episodes of urinary incontinence per day. OnabotA 200 U resulted in a significantly greater mean daily reduction in UUI episodes over 6 months, which averaged one episode/day. A significantly greater number of patients experienced a complete resolution (20% vs 4%) or 75% reduction of UUI episodes (46% s 26%) with OnabotA 200 U treatment than with SNM InterStim.

In addition, a survey in 50 OAB patients, with a mean age of 61 years, 74% prefer onabotA and only 26 % chose SNM as first treatment option. In those who preferred onabotA, 54 % disliked the thought of a foreign body in the back, 45.9 % made the option due to a short waiting list and 43.24 % made the choice based on the quicker onset of benefit. In the SNM group 61.5 % were averse to the potential need for repeated injections and 46.1 % chose SNM to avoid the risk of urinary retention associated with the toxin [Balchandra and Rogerson, 2014].

Although the outcomes of SNM (interStim) seem worse than those of onabotA it should be noticed that SNM may be useful in non-responders to onabotA. In a small cohort with 20 patients 17 (85%) had discontinued onabotA because of lack of efficacy and 3 had been treated successfully with BonT/A but requested a more permanent solution. In 14 patients (70%) the test stimulation was successful and they received a definitive implant. Of the 14 patients 5 even showed a decrease of greater than 90% in leakage episodes. One year after implantation 11 patients (79%) were satisfied with SNM [Smits et al., 2013]. This study suggests therefore that half of patients non-responders to onabotA may still have a chance of long term improvement with SNM.

8.1.1.11 BONT/A in IC/PBS

BoNT/A significantly inhibits the noxious sensory input from the bladder [Vemulakonda et al., 2005; Rapp et al., 2006; Lucioni et al., 2008]. Moreover, BoNT/A decreases the urinary levels of NGF and BDNF which may contribute to decrease the bladder allodynia observed in these patients [Pinto et al., 2010; 2014). Therefore, several pilot studies were carried out in the last few years. None is placebo controlled, a fact that limits the scientific value of the observations. On the other hand, different techniques of administration have been assessed. These two facts may explain some heterogeneity of results.

The first pilot study with 13 females observed that, 9 (69%) had subjective improvement after onabotA 100 or 200 U injected in the trigone and above the trigone. Mean scores in the Interstitial Cystitis Symptom Index and the Interstitial Cystitis Problem Index improved by 71% and 69%, respectively. Daytime frequency, nocturia, and pain measured by a Visual Analogue Scale (VAS) decreased by 44%, 45%, and 79%, respectively. Symptom improvement lasted a mean of 3.7 months (range 1 to 8) [Smith and Chancellor, 2004]. In another pilot study with 15 patients, Giannantoni et al. [2006; 2008] reported similar obervations after bladder injection of onabotA 200 U (150U above the trigone, 50 U in the trigone). Subjective improvement at 1- and 3-month follow-up occurred in 86% of the patients but at 5-month only persisted in 26.6%. Importantly, 9 patients experienced moderate to severe voiding difficulties [Giannantoni et al., 2006; 2008] A third study could not demonstrate any effect of onabotA in 13 IC/PBS patients treated with onabotA 100–300 U in the bladder [Davies et al., 2006].

Three other studies, which added substantial modifications to the above protocol, reported, on the contrary, considerable improvement in clinical and urodynamic outcomes after BoNT/A adminitration.

A prospective, randomized study enrolled 67 patients with refractory IC/PBS. Of these, 44 patients received suburothelial injection of onabotA 200 U (15) or 100 U (29) followed by cystoscopic hydrodistention 2 weeks later. The control group (23 patients) only received hydrodistention. The IC/PBS symptom score significantly decreased in all three groups, but VAS pain reduction and urodynamic improvement were only observed at 3 months in the arms that received onabotA, without any relevant differences between the two doses. A successful result at 12 and 24 months was reported in 55% and 30% of onabotA treated patients, respectively, compared with only 26% and 17% in the control group. The validity of these positive long-term results should however be interpreted with caution since all patients remained on baseline pentosan polysulphate throughout the study [Kuo and Chancellor, 2009].

Taking in consideration that most of the bladder nociceptors course in the trigone, Pinto et al. [2010] restricted 100 U onabotA injections to the trigone, in 10 sites (10 U/ 1 ml each. Twenty-six women with positive findings at cystoscopy and biopsy were enrolled. All patients reported subjective improvement at 1- and 3-month follow-up in pain, daytime and nighttime voiding frequency, O'Leary-Sant score and QoL. Bladder volume to first pain and maximal cystometric capacity more than doubled. Treatment remained effective in >50% of the patients for 9 months. Retreatment was equally effective in all cases, with similar duration of the effect up to four consecutive treatments (Pinto et al., 2013). No cases of dysfunctional voiding were reported after trigonal injections of onabotA 100 U. Also, PVR at urodynamics and bladder contractility index were not impaired [Pinto et al., 2010; Pinto et al., 2013]. Interestingly trigonal injections of onabotA 100 U were equally effective in patients with and without Hunner´s lesions [Pinto et al., 2014].

The third was a small placebo controlled trial comparing periurethral injections of onabotA 50U (n=9) versus saline (n=11). The rationale was to investigate

the participation of periurethral somatic afferents to pain. The solution, 2 ml, was injected in the region of the bladder neck, at the 3 o'clock and 9 o'clock positions. Unfortunately, there was no differences between the onabotA and the at 3-month follow-up in terms of symptoms.

8.1.2 BoNT/B

Some humans repeatedly injected with BoNT/A may develop resistance to the toxin, possibly due to antibody formation. Although this event seems very rare in the case of bladder injections, a minimum interval of 3 months between two BoNT/A injections is generally recommended to decrease its occurrence. If resistance appears, recent reports [Dykstra et al., 2003; Pistolesi et al., 2004; Reitz et al., 2004] investigated the replacement of BoNT/A serotype by BoNT/B. At this moment empiric doses of BoNT/B are being used as there is no clear potency equivalents for the two serotypes and between BoNT/B brands.

In 3 patients with spinal NDO, bladder injection of 5000 U [Pistolesi et al., 2004] or 7500 U [Reitz and Schurch, 2004) of BoNT/B (Neurobloc ®) restored bladder function for 6 months [Reitz and Schurch, 2004]. Interestingly, one patient experienced dry mouth and dry eyes that resolved within 20 days. As this side effect was not reported after bladder BoNT/A application, it is possible that different toxin serotypes have some different degrees of organ affinity. Dykstra et al. [2003] carried on a dose escalation study with BoNT/B (rimabotB) in 15 female patients with OAB. They used doses of 2500, 3750, 5000, 10,000, and 15,000 U injected at 10 sites. Only one patient failed to respond and a clear dose-dependent effect, was observed, with the longest response seen in those injected with 15,000 U. Two patients, both injected with 15,000 U, experienced dry mouth and general malaise. In another study involving IDO and NDO patients, in which rimabotB 5000 U were used, Hirst and coworkers [2007] observed a limited duration of action, with most of the symptomatic beneficial effects wearing off by 10 weeks in most of the patients. The short duration of action for BoNT/B at safe doses may, therefore, limit the clinic usefulness of this serotype.

BoNT is effective for treatment of both NDO and IDO and has an acceptable adverse effect profile (Table 2).

8.2. Capsaicin and Resiniferatoxin (RTX)

8.2.1 Rationale for Intravesical Vanilloids

The rationale for intravesical vanilloid application in patients with detrusor overactivity (DO) was offered by the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent upon a sacral micturition reflex [de Groat, 1997]. The C-fiber micturition reflex is usually inactive but it was shown that it is enhanced in patients with chronic spinal-cord lesions above sacral segments [de Groat, 1997] in those with chronic bladder outlet obstruction [Chai et al., 1998) and in those with IDO [Silva et al., 2002]. In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of sub-urothelial C-fibers expressing TRPV1 [Brady et al., 2004]. Curiously, NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas non-responders experience a non-significant variation [Brady et al., 2004]. A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX [Apostolidis et al., 2005; 2006].

Changes in sub-urothelial C-fiber innervation expressing neuropeptides [Smet et al. 1997] or TRPV1 [Liu and Kuo, 2007] were also reported in patients with and sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the over-expression of the receptor in the bladder mucosa [Liu and Kuo, 2007]. In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry further indicating that TRPV1 play a role in premature bladder sensation [Liu et al., 2007].

8.2.2 Intravesical Capsaicin

Intravesical capsacin for NDO was studied in 6 non-controlled [Fowler et al., 1992; Fowler et al., 1994; Geirsson et al., 1995; Das et al.,1996; Cruz et al., 1997, De Ridder et al., 1997] and one controlled clinical trial [de Seze et al., 1998]. Capsaicin was dissolved in 30% alcohol and 100-125 ml (or half of the bladder capacity if lower than that volume) of 1-2 mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. Best clinical results were found among patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70-90% the patients [Fowler et al., 1994, Cruz et al., 1997; De Ridder et al., 1997]. In patients with complete spinal cord lesions the success rate was much lower [Geirsson et al., 1995].

Only one small randomized controlled study compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin and found a significant regression of the incontinence and urge sensation. In contrast, only 1 among the 10 patients that received ethanol had clinical improvement [de Seze et al., 1998].

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. The possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions has progressively restrained its use. The relevance of capsaicin might however be back with a recent observation by de Séze et al. [2006] with a new capsaicin formulation. They conducted a double-blind placebo controlled study with a glucidc solution of capsaicin in 33 NDO patients. The glucidic-capsaicin

treated group showed improvement both in symptoms and urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent [de Sèze et al., 2006].

8.2.3 RTX in NDO

Resiniferatoxin (RTX) has the advantage over capsaicin in being much less pungent [Cruz et al., 1997]. Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al., 1997; Lazzeri et al., 1997; 1998; Silva et al., 2000; Kuo, 2003). Different RTX concentrations, 10 nM, 50 nM, 100 nM and 10 μM were tested. RTX brought a rapid improvement or disappearance of urinary incontinence in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to first detrusor contraction and maximal cystometric capacity. In general, in patients receiving 50-100 nM RTX the effect was long-lasting, with a duration of more than 6 month being reported. In patients treated with 10 μM doses, transient urinary retention may occur [Lazzeri et al., 1998].

In a recent placebo-controlled study, the urodynamic effects of RTX in NDO patients was specifically evaluated. Only in the RTX arm a significant increase in first detrusor contraction and maximal cystometric capacity was found [Silva et al., 2005]. RTX also caused a significant improvement in urinary frequency and incontinence [Silva et al., 2005].

RTX, 600 nM was compared against BONT/A (Botox, 300U) in a study involving 25 patients with NDO due to chronic spinal cord injury [Giannantoni et al., 2004]. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BONT/A turned out to be more effective.

8.2.4 RTX in IDO

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 mL to 440 ± 153 mL at 30 days, and to 391 ± 165 mL at 90 days. An increase in mean MCC from 291 ± 160 mL to 472 ± 139 mL at 30 days and to 413 ± 153 mL at 90 days was also observed. These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency [Silva et al., 2002]. Subsequent small open label studies confirmed these observations using either a single high (50-100 nM) or multiple low (10 nM) dose approaches [Kuo, 2003; Dinis et al, 2004b; Kuo et al., 2005a].

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials [Kuo et al., 2006; Rios et al., 2007]. Kuo et al. [2006] randomised 54 patients to receive 4 weekly instillations of a low concentration RTX solutions (10 nmol/L) or the vehicle solution, 10% ethanol in saline [Kuo et al., 2006] Three months after completing the 4 intravesical treatments, the RTX treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group, 14.2% and 7.1% respectively. At 6 months, treatment remained effective in 50% patients in the RTX group but only in 11% in the placebo group [Kuo et al., 2006]. Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 ml of either RTX 50 nM or placebo. Patients were followed-up only for 4 weeks. During this period a single 50 nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence [Rios et al., 2007].

8.2.5 RTX and Urgency

The involvement of bladder C-fibers in IDO has led some investigators to explore the role of these sensory afferents to the genesis of urgency. In a non-controlled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved following intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely due to improvements in scores related to urgency, in addition to improvement in nocturia and frequency [Dinis et al., 2005]. In another open-label study 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain/discomfort, and without urodynamic evidence of DO received one single 50 nM RTX solution. A trend towards an improvement of urgency was noticed [Apostolidis et al., 2006].

In a quasi-randomised study, 23 OAB patients with refractory urgency entered a 30-day run-in period in which medications influencing the bladder function were interrupted. At the end of this period patients filled a 7-day bladder diary. Then, patients were instilled with 100 ml of 10% ethanol in saline (vehicle solution) and 30 days later a second 7-day diary was collected. Finally, patients were instilled with 100 ml of 50 nM RTX in 10% ethanol in saline and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 1 and 3 months after RTX instillation the number of episodes of urgency decreased to 39 ± 9 ($p = 0.002$) and 37 ± 6 ($p = 0.02$), respectively [Silva et al., 2007].

8.2.6 Intravesical RTX and IC/PBS

TRPV1 involvement in pain has stimulated the investigation of RTX as a treatment for bladder pain in IC/PBS. After desensitization of bladder C-fibers, RTX reduces the spinal expression of c-fos, a pain evoked gene, in animal models of cystitis [Dinis et al., 2004a]. TRPV1 knock-out mice, which do not express the receptor in the bladder, do not experience an increase in the frequency of bladder reflex contractions or in the expression of c-fos in the spinal cord during cystitis [Charrua et al., 2007]. Patients with IC/PBS have more TRPV1 expressing sensory fibers in their

bladder mucosa than normal individuals [Mukerji et al., 2006].

In a placebo-controlled study of 18 patients with IC/PBS, Lazzeri et al. [2000] reported an improvement in pain and urinary frequency after administration of intravesical RTX in 10 nmol/L concentration. This effect was short-lasting, eventually due to the use of a low dose of RTX. Chen and co-workers conducted a dose-escalating study and concluded that the most commonly reported adverse event with RTX was pain during instillation. However, at 10 or 5 nM RTX was safe and could improve bladder pain [Chen et al., 2005]. Additionally, 3 non-controlled studies have also reported bladder pain improvement after intravesical RTX [Lazzeri et al., 2004; Apostolidis et al., 2006; Peng and Kuo, 2007]. A randomized, double-blind study in 163 patients with IC/PBS, in which several doses of intravesical RTX (10 nmol/L, 50 nmol/L, and 100 nmol/L) were compared with placebo, failed, however, to show any advantage for the neurotoxin over placebo in terms of overall symptoms, pain, urgency, frequency, nocturia, or average voided volume during 12 weeks of follow up [Payne et al., 2005].

9. OTHER DRUGS

9.1. Baclofen

Gamma-amino-butyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex in several points along its central pathway [de Groat, 1997; Pehrson et al., 2002]. Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin induced detrusor overactivity, suggesting that the inhibitory actions of GABA(B) receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium [Pehrson et al., 2002]. In spinal intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)-like changes whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions [Miyazato et al., 2009]. After spinal cord injury (SCI), Miyazato et al. [2009] found signs of hypofunction of the GABAergic system (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased), and showed that activation of GABA(A) and GABA(B) receptors in the spinal cord inhibited DO as evidenced by a reduction in non-voiding contractions. GABA(B) receptor activation preferentially reduced DO prior to inhibiting voiding contractions while GABA(A) receptor activation inhibited DO and voiding contraction at the same concentration.

As a GABA agonist on GABA(B) receptors, *baclofen* was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier [Taylor and Bates, 1979]. ADX71441 is a selective positive allosteric modulator of the $GABA_B$ receptor ($GABA_B$ PAM), which is orally available and showed promising effects in animal models of micturition disturbances [Kalinichev et al., 2014]. Further studies of this agent would be of interest.

Baclofen is one of the most effective drugs for the treatment of spasticity following spinal cord injury, traumatic or hypoxic brain injury, and cerebral palsy [Ochs, 1993], and *intrathecal* baclofen was shown to be useful in some patients with spasticity and bladder dysfunction [Bushman et al., 1993]. Baldo et al. [2000] found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric whereas maximal detrusor pressure decreased. At ten days, the volume to first detrusor contraction had increased from 143 ml to 486 ml. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

10. COMBINATIONS

10.1. α_1-AR Antagonists with Antimuscarinics or β_3-AR Agonists

Traditionally, male lower urinary tract symptoms (LUTS) were thought to result from benign prostatic obstruction (BPO) secondary to benign prostatic enlargement (BPE). However, male LUTS may arise from prostatic pathology, bladder dysfunction, or both. Thus, diagnosis and appropriate treatment of men with overactive bladder (OAB) symptoms are complex and difficult. α_1-AR antagonists remain the most widely used pharmacologic agents for relief of bladder outflow resistance as they relax prostatic and urethral smooth muscle tone, which is the dynamic component of BPO. In contrast, antimuscarinics, which function by competitively blocking muscarinic receptors, are the first-line pharmacologic treatment for OAB. Given the prevalence of combined voiding and OAB symptoms, as well as the finding that the quality of life (QoL) of these patients is affected primarily by the symptoms of OAB, it is logical for this category of patients to be given antimuscarinic drugs.

A number of studies have demonstrated the superior efficacy of combination treatment with an α_1-AR antagonist and an antimuscarinic for alleviating symptoms of benign prostatic hyperplasia (BPH) and concomitant OAB compared to either monotherapy [Saito, et al., 1999; Athanasopoulos et al., 2003; Lee et al., 2005; Ruggieri et al., 2005; Kaplan et al., 2006, MacDiarmid et al., 2006; Kaplan et al., 2013a; van Kerrebroeck et al., 2013a; b Van Kerrebroeck et al., 2013]. The combination treatment is now recommended treatment for men with moderate-to-severe LUTS in those with predominant storage symptoms by AUA, EAU, and NICE.

The therapeutic benefits of combining an antimuscarinic agent (propiverine) with α_1-AR antagonists

(tamsulosin) compared to α_1-AR antagonists alone were reported by Saito and colleagues [Saito et al.. 1999]. The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the α_1-AR antagonist-alone group. The post-void residual (PVR) was unchanged in both groups, and there was one case (1.5%) of acute urinary retention (AUR) with the combined treatment. Subsequently, Lee et al. [2005] compared the efficacy and safety of combination therapy using propiverine and doxazosin in 211 men with urodynamically confirmed bladder outlet obstruction (BOO) and OAB symptoms for 8 weeks. Compared with doxazosin monotherapy, patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of international prostate symptom score (IPSS). Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial (TIMES study) demonstrated the efficacy and safety of tolterodine extended release (ER) alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO [Kaplan et al. 2006]. In their primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 (p<0.001 vs. placebo; p=0.001 vs. tolterodine ER; p=0.03 vs. tamsulosin). In their secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any dietary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (−8.02 vs. placebo, −6.19, p=0.003) and QoL (−1.61 vs. −1.17, p=0.003). Although there were significant improvements in total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients that received tolterodine ER versus placebo were not significant. A subanalysis [Rovner et al., 2008] of data from the TIMES study focused on the urgency perception scale and concluded that the group of 217 men who received tolterodine plus tamsulosin showed significantly improved urgency variables and patient-reported outcomes. Moreover, this group of patients reported increased satisfaction with the treatment as well as a greater willingness to continue the treatment. Another subanalysis [Kaplan et al., 2008b] of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS. Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms.

Maruyama et al. [2006] reported different results in their prospective, randomized, controlled study in which naftopidil (25-75 mg/day), an α_{1d}-AR antagonist, was administered alone or in combination with propiverine hydrochloride (10-20 mg/day) or oxybutynin hydrochloride (2-6 mg/day) for 12 weeks to 101 BPH patients. In their study, the IPSS and QoL indexes improved significantly in both groups, with no marked differences between groups. Maximum flow rate (Qmax) and PVR showed an improvement trend in both groups, again with no differences between groups. However, the median post-therapeutic PVR was significantly higher in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, p = 0.021). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy (22.9%) group versus the monotherapy group (5.0%, p = 0.038). The authors concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy. Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than in the monotherapy group.

In caution of increased PVR or voiding symptoms, low-dose antimuscarinic therapy was studied in men with OAB and BPO. Kang et al. [2009] evaluated the efficacy and safety of combined treatment with tamsulosin 0.2 mg and propiverine hydrochloride (10 mg) compared with tamsulosin monotherapy. After 3 months, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index was significantly different between the groups in favor of the combination group. No cases of AUR were recorded in this low-dose study.

The efficacy and safety of solifenacin in combination with tamsulosin were assessed in several large-scale RCTs, including the VICTOR [Kaplan et al., 2013] and SATURN [Van Kerrebroeck et al,. 2013b] trials. The VICTOR trial [Kaplan et al., 2013] was a randomized, placebo-controlled study assessing solifenacin 5 mg as an add-on therapy to α_1-AR antagonists treatment in men with residual OAB symptoms. Significant reductions in daytime frequency, the primary outcome of the study, were achieved in both solifenacin (and tamsulosin) and placebo (and tamsulosin) trials compared to baseline, but the difference between the two drug groups was not significant. Solifenacin add-on significantly reduced daily urgency episodes compared to placebo, but this was the only significant efficacy difference between solifenacin and placebo. Seven patients (3%) in the solifenacin group developed retention problems, with three requiring catheterisation, versus none in the placebo group. The SATURN study was a randomized, placebo-controlled trial evaluating the combination of different doses of solifenacin (3, 6, and 9 mg/day) with tamsulosin versus tamsulosin alone in men with voiding and storage LUTS [Van Kerrebroeck et al., 2013].

Decreases in micturition frequency and total urgency and frequency scores and increases in void volume per micturition were significantly greater with increasing solifenacin dosage in the combination groups versus with tamsulosin monotherapy. In a post-hoc analysis, patients with at least two urgency episodes and at least eight micturitions per 24 h at baseline showed clear improvements in storage and QoL parameters with combination treatment over tamsulosin alone. The subgroup of patients with fewer storage symptoms experienced little or no additional benefit from combination therapy compared with tamsulosin monotherapy. Combination therapy was well tolerated, and adverse events were consistent with the safety profiles of each individual compound. Mean PVR volume increased with increasing solifenacin dose, but the changes were not clinically relevant and were not accompanied by an increase in the incidence of retention.

A meta-analysis compared the efficacy and safety of treatment with α-blockers and anticholinergics to α-blocker monotherapy among men with storage urinary symptoms related to benign prostatic hyperplasia (BPH) [Filson et al., 2013]. Combination therapy produced a significantly greater reduction in IPSS storage subscore (Δ -0.73, 95% CI -1.09 - -0.37) and voiding frequency (Δ -0.69 voids, 95% CI -0.97 - -0.41) than monotherapy. There was also a greater reduction in Qmax (Δ -0.59 ml/sec, 95% CI -1.04 - -0.14) and an increase in PVR (Δ 11.60 ml, 95% CI 8.50-14.70) with combination therapy. The number of patients needed to be treated with combination therapy to cause 1 acute urinary retention episode was 101.

More recently, the efficacy and safety of a fixed-dose combination (FDC) tablet containing solifenacin 6 mg plus an oral controlled absorption system (OCAS™) formulation of tamsulosin (TOCAS) 0.4 mg has been studied in a phase III trial (NEPTUNE). NEPTUNE, which included 1,334 men with LUTS/BPH who had moderate-to-severe storage symptoms and voiding symptoms, showed that an FDC of solifenacin 6 mg plus TOCAS improved storage symptoms and QoL compared with TOCAS alone [van Kerrebroeck al., 2013]. FDC treatment was also well tolerated and exhibited an adverse event profile similar to those reported for the individual monotherapies. Consequently, a once-daily FDC tablet of solifenacin 6 mg plus TOCAS 0.4 mg aimed at treating both storage and voiding symptoms in men with LUTS/BPH is licensed and available in several countries, including the UK. NEPTUNE and NEPTUNE II open-label extension studies further evaluated long-term (up to 52 wk) safety and efficacy of flexible dosing of two FDC of solifenacin plus TOCAS (Soli 6 mg plus TOCAS 0.4 mg or Soli 9 mg plus TOCAS 0.4mg) in men with moderate to severe storage and voiding symptoms [Drake et al., 2015]. Reductions in total IPSS and total urgency and frequency score (TUFS) during NEPTUNE were maintained for up to 52 wk of FDC treatment, with mean reductions of 9.0 (standard deviation [SD]: 5.7) and 10.1 (SD: 9.2), respectively, from baseline to end of treatment. Urinary retention occurred in 13 of 1208 (1.1%) patients receiving one or more FDCs in NEPTUNE and/or NEPTUNE II; 8 (0.7%) required catheterization. Responder and health-related QoL (HRQoL) analyses of the NEPTUNE study reported that men treated with an FDC of solifenacin 6 mg plus TOCAS consistently had significantly improved outcomes compared with both the placebo and TOCAS [Drake et al., 2016]. There was a significant correlation between the reduction in total urgency frequency score and the improvement in HRQoL defined by the IPSS QoL score, the OAB-q symptom bother score, the overall patient global impression bladder symptoms, and the general health of the patient. Sokol et al. expected that the positive HRQoL data for FDC of solifenacin 6 mg plus TOCAS are likely to translate into improved persistence of treatment and possibly increased confidence to prescribe combined therapy as the initial treatment for moderate-to-severe LUTS/BPH.

Ichihara et al. [2015] evaluated the efficacy and safety of add-on treatment with mirabegron for overactive bladder symptoms remaining after α1-blocker (tamsulosin) treatment in men with benign prostatic obstruction. The change in post-void residual urine volume was significantly greater in the combination group. Six patients (out of 76) experienced adverse events in the combination group, and urinary retention was observed in 1 patient. Nevertheless, the authors concluded that combination was effective and safe in these patients.

10.2. Combined Antimuscarinics

Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effects of detrusor stability and continence, especially for patients with spinal cord injury or neurologic diseases such as multiple sclerosis or meningomyelocele. When antimuscarinic treatments fail, invasive procedures such as the injection of botulinum toxin, electrical nerve stimulation, or augmentation cystoplasty are necessary. In patients who failed to respond or showed suboptimal response to antimuscarinic drugs but tolerated the treatment well, it was shown that increasing the daily dose may lead to significant improvements of OAB symptoms. A significant decrease of incontinence episodes was observed after doubling the recommended daily doses of trospium chloride and tolterodine to 90 and 8 mg, respectively, in patients with persistent neurogenic detrusor overactivity (NDO) [Horstmann et al., 2006]. Another non-invasive approach in patients with refractory NDO or OAB is the combination of two different antimuscarinic drugs; this has been demonstrated as effective and safe in several clinical studies including patients with either NDO [Amend et al., 2008; Nardulli et al., 2012] or OAB [Bolduc et al., 2009; Kosilov et al., 2014a; b] (Table 3).

Positive results were speculated to be due to 1) synergistic activation of different muscarinic receptors or

interactions of receptors on different parts of the bladder wall, 2) undiscovered faster metabolism of antimuscarinics requiring an increased dosage of different antimuscarinic drugs, 3) down-regulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug.

Study	Patients (*n*)	Initial antimuscarinics	Combined antimuscarinics	Efficacy results
Amend et al. (Amend, Hennenlotter et al. 2008)	NDO (27)	Oxybutynin 30mg/day Tolterodine 2×8mg/day Trospium 3×30 mg	+trospium 45–90 mg +oxybutynin 15–30 mg +tolterodine 4–8 mg	UI episodes decreased: 8.6±2.7 to 1.3±0.9 7.0±1.5 to 0.6±0.7 7.5±2.7 to 2.0±1.5
Nardulli et al. (Nardulli, Losavio et al. 2012)	NDO (12)	Oxybutynin 15mg/day Oxybutynin 15mg/day	+trospium 80 mg +solifenacin 10 mg	UI episodes decreased: 5.3±SD to 0.8±SD 4.5±SD to 1.0±SD
Bolduc et al. (Bolduc, Moore et al. 2009)	NDO (19) OAB (14)	Tolterodine 4mg	+solifenacin 5 mg +solifenacin 10 mg	UI episodes decreased: 100% in 17 pts > 90% in 14 pts 50–89% in 2 pts
Kosilov et al. (Kosilov, Loparev et al. 2014a)	OAB (313)	Trospium 60mg + solifenacin 20mg (198) or Placebo (115)		Significant decrease in UI episodes compared to placebo
Kosilov et al. (Kosilov, Loparev et al. 2014b)	OAB (341)	Trospium 60 mg/day + solifenacin 20 (58) Trospium 30 mg/day + solifenacin 10 (55) Trospium 30 mg/day + solifenacin 10 (62)		Cyclic therapy with high-dose combination showed the most successful treatment without increase in side effects
Kosilov et al. (Kosilov, Loparev et al. 2016)	OAB & BPH (338)	solifenacin 5 mg + trospium 5 mg + tamsulosin 0.4 mg vs. tamsulosin 0.4 mg		UI episodes decreased: 3.4(0.8) to 0.9(0.7)

Table 3. Clinical studies of combined antimuscarinic treatments

A combined antimuscarinic regimen using tolterodine, oxybutynin, and trospium was evaluated as a non-invasive alternative by Amend and colleagues [Amend et al., 2008] for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dosed antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dosed antimuscarinic monotherapy. After a 4-week combined regimen, incontinence episodes decreased, and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side-effects were comparable to those seen with normal-dose antimuscarinics.

Kosilov and colleagues evaluated the effectiveness of cyclic therapy of combined high–dosed trospium and solifenacin depending on severity of OAB symptoms in elderly men and women. They found that cyclic therapy of high-dose solifenacin and trospium in elderly patients with moderate or severe symptoms of OAB enabled patients to maintain a longer therapeutic effect with an acceptable level of side effects [Kosilov et al., 2014a].

They conducted another study to evaluate the efficiency of treatment for severe symptoms of OAB with cyclic therapy of combined antimuscarinic drugs in elderly men and women and determined that cyclic therapy with combined antimuscarinics appeared to be effective for controlling severe OAB in elderly patients, increasing the compliance level (76–84%). However, continuous therapy with standard doses of trospium and solifenacin results in low adherence and high rates of treatment withdrawal (≥ 66%) despite satisfactory clinical and urodynamic results.

The effectiveness of combination therapy with two different antimuscarinics was also evaluated in patients with severe symptoms of OAB and BPH [Kosilov et al., 2015b; Kosilov et al., 2016]. Patients in the experimental group for 2 months received treatment with a daily combination of solifenacin 5 mg and trospium 5

mg simultaneous with tamsulosin 0.4 mg. Patients in the control group were treated only with tamsulosin. In the experimental group, the number of episodes of incontinence reduced from a moderate level of 3.4 (0.8) per day to 0.9 (0.7) per day, and most urodynamic indices normalized significantly.

In the control group, changes in urodynamic indices were not significant. The quantity of side effects did not exceed the level that is commonly found in patients receiving antimuscarinic monotherapy. The authors concluded that combination of trospium and solifenacin in standard doses is an efficient and safe method for managing severe symptoms of OAB over the course of treatment with tamsulosin in patients with OAB/BPH [Kosilov et al., 2016]. However, in patients with OAB/BPH, the efficacy and side effects of combination therapy using different antimuscarinics should be further evaluated.

10.3. Antimuscarinics and 5α-Reductase Inhibitors

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α_1-AR antagonist, a 5α-reductase inhibitor, or combination therapy with both drugs. Both α_1-AR antagonist and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance α_1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, while 5α-reductase inhibitors reduce prostate volume. Several trials have demonstrated the efficacy and safety of combination therapy with antimuscarinics and α_1-AR antagonist for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study [Kaplan et al., 2006] suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates [Roehrborn et al., 2008; Roehrborn et al., 2009]. Chung and coworkers conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with large prostates (≥30 g) and persistent OAB symptoms after α_1-AR antagonist therapy who had been unsuccessfully treated with dutasteride alone [Chung et al., 2010]. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months, and α_1-AR antagonist therapy had failed. All patients were given 4 mg tolterodine ER daily for 12 weeks and had discontinued α_1-AR antagonist before the start of the study. At 12 weeks, the frequency (-3.2/24hrs, $p < 0.02$), urgency (19.2%, $p < 0.03$), number of severe OAB episodes (71.4%, $p < 0.05$), and incidence of nighttime voiding (-0.9, $p < 0.003$) were found to have decreased significantly from baseline. IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 ($p < 0.001$). Storage symptoms decreased from 9.8 to 4.5 ($p < 0.001$). Dry mouth occurred in four (7.5%) subjects, constipation in one (2%), and decreased sexual function in two (3.9%). PVR increased by 4.2 mL, Qmax decreased by 0.2 mL/s, and no patients went into retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well-tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO. Their results indicate that antimuscarinics are safe and effective in select patients with OAB and BPO when used in combination with 5α-reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in patients with persistent OAB symptoms and LUTS secondary to BPO.

Dutasteride was evaluated in terms of OAB symptoms and bladder ischemia in men with BPE [Wada et al., 2015]. Twenty-four weeks after dutasteride treatment, bladder vascular resistive index (RI) significantly decreased, and urgency score of IPSS was significantly improved from 2.3 ± 1.9 to 1.4 ± 1.4 ($P < 0.01$). In 20 patients with persistent urgency after dutasteride, RI was less improved than in an additional 10 patients without urgency. Post-treatment bladder outlet obstruction index (BOOI) and PdetQmax in patients with persistent urgency were significantly higher than in those without urgency after dutasteride. The authors suggested that reduction of obstruction and improvement of bladder ischemia might play important roles in the beneficial impact of dutasteride on OAB symptoms.

10.4. α_1-AR Antagonists with 5a-Reductase Inhibitors

The Medical Therapy of Prostatic Symptoms Study (MTOPS) and Combination of Avodart® and Tamsulosin study (ComBAT) have demonstrated that superiority of combinations of α_1-AR antagonists with 5-α reductase inhibitors over monotherapy for improving clinical outcomes and preventing symptomatic progression, risk of AUR, and BPH-related surgery [McConnell et al., 2003; Roehrborn et al., 2010]. Currently, a combination of α_1-AR antagonist with a 5-α reductase inhibitor is recommended by the American Urological Association (AUA) and European Association of Urology (EAU) for men with bothersome moderate to severe LUTS, high risk of disease progression-enlarged prostate (prostate volume > 40 mL), and higher PSA [McVary et al., 2011; Oelke et al., 2013]. The possible disadvantage of combinations of α_1-AR antagonists with 5α-reductase inhibitors is the increased incidence of adverse events, since there are concomitant effects of both classes of drugs [Fullhase et al., 2013; La Torre et al., 2016]. Potential side effects (e.g., ejaculation dysfunction with α_1-AR antagonists or loss of libido with 5α-reductase inhibitors) might be additive and may negatively affect patient quality of life and, especially, sexual function.

10.5. Antimuscarinic with β_3-Adrenoceptor Agonists

Since the mechanism of action of β_3-adrenoceptor agonists is different from that of antimuscarinics, it might prove to be a useful treatment in patients experiencing adverse events to antimuscarinics or insufficient symptom improvement. In addition, combining

β_3-AR agonist with an antimuscarinic may potentially improve efficacy in the treatment of OAB. Several clinical trials have demonstrated the efficacy and safety of the combination therapy of antimuscarinics and β_3-AR agonists. Abrams et al. reported results of a phase II trial (Symphony) of combination treatment with mirabegron and solifenacin in patients with OAB [Abrams et al., 2015]. A total of 1306 patients were randomly assigned to 12 groups: placebo, 6 combination groups (solifenacin 2.5, 5, or 10 mg plus mirabegron 25 or 50 mg), and 5 monotherapy groups (solifenacin 2.5, 5, or 10 mg, or mirabegron 25 or 50 mg) for a 12-week treatment period. The primary endpoint was change from baseline to end of treatment in mean volume voided per micturition (MVV). All combinations with solifenacin 5 or 10 mg improved MVV significantly comparing to solifenacin 5 mg monotherapy, and a decreasing trend in the mean number of micturitions per 24 hours was observed with increasing solifenacin and mirabegron doses. The three drug combinations (solifenacin 5 mg plus mirabegron 50 mg, solifenacin 10 mg plus mirabegron 25 mg, and solifenacin 10 mg plus mirabegron 50 mg) demonstrated significant improvements compared to both solifenacin 5 mg and placebo.

No severe adverse events were reported, and treatment was generally well tolerated. In Japan, Yamaguchi et al. conducted a multicenter, open-label, phase IV study (MILAI study) to assess the safety and efficacy of mirabegron in combination with solifenacin in OAB patients who were being treated with solifenacin 2.5 mg or 5 mg once daily for at least 4 weeks [Yamaguchi et al., 2015]. A total of 223 patients were randomly assigned to one of 4 groups: solifenacin 2.5 mg plus mirabegron 25 mg (n=35), solifenacin 2.5 mg plus mirabegron 50 mg (n=37), solifenacin 5 mg plus mirabegron 25 mg (n=58), or solifenacin 5 mg plus mirabegron 50 mg (n=93) for a 16-week treatment period.

Table 4. Current status of possible future drugs/targets

Negative proof of concept
Potassium channel openers
Prostaglandin receptor antagonists
Positive proof of concept
Neurokinin receptor antagonists
Vitamin D3 receptor agonists
Monoamine reuptake inhibitors
Opioid receptor agonists
Cox inhibitors
Promising based on animal data
Rho- kinase - inhibitors
Drugs acting on GABA receptors
Purinergic system – P2X3 receptor antagonists
Cannabinoid system – exocannabinoids; FAAH inhibitors
TRP channel family – TRP channel antagonists

The overall incidence of drug-related TEAEs was 23.3%, and all TEAEs were mild or moderate. All treatments showed significant improvements in OABSS total score, overactive bladder questionnaire short form (OAB-q SF) score (symptom bother and total HRQL score), mean number of micturitions/24 h, mean number of urgency episodes/24 h, mean number of UI episodes/24 h, mean number of urgency UI episodes/24 h, mean volume voided/micturition, and mean number of nocturia episodes/night.

Recently, a phase IIIB trial (BESIDE) in incontinent OAB patients was carried out in Europe [Drake et al., 2016]. A total of 2174 patients with OAB who remained incontinent despite solifenacin 5 mg once daily during 4-wk single-blind run-in were randomized 1:1:1 to a double-blind daily combination (n=727), solifenacin 5 mg (n=728), or 10 mg (n=719) for 12 wk. The primary efficacy end-point was change in mean number of incontinence episodes per 24 h. Key secondary efficacy end points were change in mean number of micturitions per 24 h and the number of incontinence episodes noted in the 3-d voiding diary. All combinations significantly improved daily incontinence episodes ($p=0.001$), daily micturitions ($p<0.001$), and incontinence noted in a 3-d voiding diary ($p=0.014$) compared to solifenacin 5 mg monotherapy. The combination of drugs was not inferior to solifenacin 10 mg for key secondary end points and was superior to solifenacin 10 mg for improving daily

micturitions. All treatments were well tolerated. These results suggest that combination therapy of mirabegron 50 mg with solifenacin 5 mg may be an alternative to dose escalation of solifenacin in patients with insufficient response to solifenacin 5 mg monotherapy.

11. FUTURE POSSIBILITIES

Much nonclinical and clinical research is ongoing, both involving modifications of existing options and directed at identifying novel pharmacological principles involved in LUTS/OAB pathophysiology, and this has been extensively discussed in several reviews [Yeo et al., 2013; Zacche et al 2014; Sacco and Bientinesi, 2015; Bechis et al. 2015, Andersson, 2015; 2016]. Details on some of the drugs under discussion are given below as is a critical summary of the current situation (Table 4).

11.1. Peripherally Acting Drugs

11.1.1 $P2X_3$-Receptors and $P2X_3$ Receptor Antagonists

During bladder filling the urothelium is stretched and ATP is released from the umbrella cells, thereby activating mechanotransduction pathways via stimulation of purinergic receptors on suburothelial sensory nerves to initiate the voiding reflex and to mediate the sensation of bladder filling and urgency [Burnstock, 2013; 2014]. P2X receptors are ligand-gated ion channels (Figure 19), and seven P2X receptor subunits have been identified from molecular studies and characterized functionally and pharmacologically [North and Surprenant, 2000; Gever et al., 2006; Ford and Cockayne, 2011]. Sensory nerve fibers expressing P2X3 immunoreactivity have been found projecting into the lamina propria, urothelium and detrusor smooth muscle (Ford and Cockayne, 2011), where this and several other P2X receptors are functionally expressed (Ford and Cockayne 2011; Shabir et al., 2013). As mentioned, ATP is released from the urothelium in response to bladder filling [Ferguson et al., 2007; Vlaskovska et al., 2001; Wang et al., 2005a], and studies using an isolated rodent bladder-pelvic nerve preparation have shown that bladder distension leads to increased afferent nerve activity that is mimicked by ATP and/or α,β-meATP [Namasivayam et al., 2009; Vlaskovska et al., 2001; Rong et al., 2002]. Intravesical infusion of ATP or α,β-meATP can directly stimulate bladder overactivity in conscious rats, in a manner that is concentration-dependent and sensitive to the ATP receptor antagonist, TNP-ATP [Pandita and Andersson, 2002]. Thus, P2X3 and P2X2/3 receptors may be important in sensing volume changes during normal bladder filling, and may participate in lowering the threshold for C-fiber activation under pathophysiological conditions.

Purinergic signaling in the bladder may be changed in different LUT disorders [Burnstock, 2014]. Thus, bladder inflammation can sensitize and enhance P2X receptor function on pelvic visceral and hypogastric splanchnic afferents in the lumbosacral and thoracolumbar DRG [Dang et al., 2005]. In bladder urothelial cells from patients with bladder pain syndrome/interstitial cystitis (BPS/IC), P2X3 receptor expression appears to be abnormally up-regulated in response to stretch [Sun and Chai, 2004; Sun et al., 2009].

An increased density of P2X3 and TRPV1-expressing nerve fibers has been observed in the bladders of patients with neurogenic detrusor overactivity, and following treatment with resiniferatoxin, patients responding to treatment showed diminished levels of both TRPV1 and P2X3 immunoreactivity [Brady et al., 2004].

P2X receptors, andin particular P2X3 receptors, have been of interest for treatment of LUT disorders for a long time [Ford et al., 2006: Ford and Cockayne, 2011; Ford, 2012; North and Jarvis, 2013]. Selective P2X3 antagonists, such as A-317491, were shown to effectively reduce the signs of cyclophosphamide-induced cystitis [Ito et al., 2008], and to improve bladder function in a rat spinal cord injury (SCI) model [Lu et al., 2007]. A-317491 produced a dose-dependent inhibition of non-micturition contractions, increased

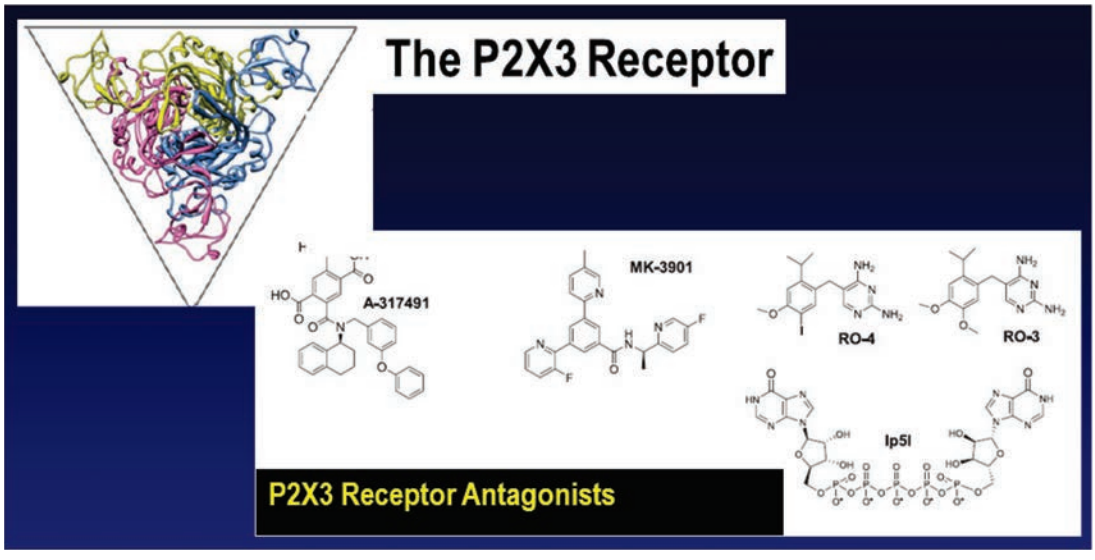

Figure 19: During bladder filling the urothelium is stretched and ATP is released from the umbrella cells, thereby activating mechanotransduction pathways via stimulation of purinergic receptors on suburothelial sensory nerves to initiate the voiding reflex and to mediate the sensation of bladder filling and urgency. Selective P2X3 antagonists have been shown to decrease signs of bladder overactivity in different animal models without affecting bladder contraction amplitude.

inter-micturition intervals, and bladder capacity, without influencing the amplitude of voiding contractions. Munoz et al. [2012] showed that SCI rats had significantly higher frequencies for field potentials and non-voiding contractions than normal rats. Intravesical ATP increased field potential frequency in control but not SCI rats, while systemic administration of the P2X3/P2X2/3 antagonist, AF-353 [Gever et al., 2010], significantly reduced this parameter in both groups. AF-353 also reduced the inter-contractile interval in control but not in SCI rats; however, the frequency of non-voiding contractions in SCI rats was significantly reduced. AF-353 was also studied in a closed cystometric model ("refill VIBC") in a urethane anesthetized rat model. A dose-dependent increase in volume threshold by up to 50–70%, with slightly reduced frequency, but no appreciable change in amplitude was demonstrated [Ford and Cockayne, 2011]. As AF-353 penetrates the blood–brain barrier [Gever et al., 2010], it was not clear whether these effects resulted from P2X3 antagonism at peripheral terminals within the bladder wall, or alternatively at central terminals in the spinal cord dorsal horn. It has been suggested that ATP can be released and act on spinal P2X3 and P2X2/3 receptors to affect afferent signals originating from the bladder [Ford, 2012]. Spinal ATP may then constitute an endogenous central presynaptic purinergic mechanism to regulate visceral sensory transmission. Further characterization of this spinal purinergic control in visceral activities may help the development of P2X3 and P2X2/3 antagonists to treat urological dysfunction, such as overactive bladder [Ford, 2012].

11.1.2 TRP Channel Antagonists

The transient receptor potential (TRP) channel superfamily has been shown to be involved in nociception and mechanosensory transduction in various organ systems, and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder, and may act as sensors of stretch and/or chemical irritation [Araki et al., 2008; Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder [Tominaga et al., 1998; Birder et al., 2001; Gevaert et al., 2007]. TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans [Ji et al., 2002; Charrua et al., 2009a]. TRPV4 was initially described in the urothelium of rodents and humans [Janssen et al., 2011]. Co-expression of the two receptors was observed in 20% of rat urothelial cells [Kullmann et al., 2009]. boducRecent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder co-express TRPV1 and TRPV4 [Cao et al., 2009; Charrua et al., 2012a]. The physiological meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild type (WT) controls [Birder et al., 2001]. In cystometries performed under anaesthesia, the TRPV1 KO mice phenotype seems also

very benign. Some studies reported that this animals have totally normal cystometric traces [Charrua et al., 2007]. However, other studies showed that TRPV1 KO mice develop a few non-voiding contractions preceding the voiding contraction [Birder et al., 2001; Frias et al., 2012]. Accordingly, TRPV1 antagonists (GRC 6211) did not show any relevant effect on bladder activity of intact rodents [Charrua et al, 2009b]. In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most probably due to incomplete bladder emptying [Gevaert et al., 2007] Cystometric studies carried out under physiological conditions revealed that TRPV4 KO mice have an marked increase in the inter-contraction interval when compared to wild-type (WT) littermates. [Gevaert et al., 2007; Birder et al. 2002]. Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the inter-contraction interval [Everaerts et al, 2010]. These observations indicated that TRPV4 has a role in the control of normal micturition reflex.

Indisputably, TRPV1 or TRPV4 have a role in the increase of micturition frequency associated with cystitis [Charrua et al., 2007; Everaerts et al., 2010]. While inflamed WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal c-fos expression [Charrua et al., 2007]). The The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide [Everaerts et al., 2010].

The blockade of TRPV1 and TRPV4 with specific antagonist confirm the observations carried out in knock-out animals. As a matter of fact, the TRPV1 antagonist GRC 6211 or the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis [Everaerts et al., 2010; Charrua et al., 2009b]. Recently, it was shown that the systemic co-administration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist [Charrua et al., 2012b]. The effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related with the application of some of these antagonists [Planells-Cases et al., 2011]. Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk of cardiac ischemia [Avelino et al., 2012] while TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence [Gevaert et al., 2007].

It is known for long that TRPV1 is involved in the emergence of neurogenic detrusor overactivity following spinal cord transaction [Avelino & Cruz, 2006]. A TRPV1 antagonist GRC 6211 has been shown to decrease reflex detrusor overactivity in rats after chronic spinal cord transaction. With increasing doses, it was possible to obtain a total suppression of bladder activity [Santos-Silva et al., 2012]. Kitagawa et al. [2013] evaluated the effects of the selective TRPV1 antagonist JTS-653 evaluated the effects of JTS-653 on the increased pelvic nerve discharge and intravesical pressure induced by intravesical infusion of capsaicin, in anesthetized rats. The drug significantly suppressed both parameters (Figure 20). The clinical relevance of this finding will be certainly further investigated in the future. Interestingly, Uvin et al. [2015] found evidence for involvement of TRPM8 in rat and mouse models of acute cold-induced urinary urgency.

There seem to be several links between activation of different members of the TRP superfamily and LUTS/DO/OAB, and further exploration of the involvement these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof of concept studies in humans are still lacking.

11.1.3 Vitamin D_3 Receptor Analogues

It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status. Weakened pelvic floor musculature is thought to be associated with the development of urinary incontinence and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction as well as vitamin D insufficiency [Kilic et al., 2016], and to date only case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al., 2012). Rat and human bladders were shown to express receptors for vitamin D [Crescioli et al., 2005], which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D_3 have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells [Crescioli et al., 2002; 2003; 2004]. Experiments in rats with bladder outflow obstruction, Schröder et al. [2006] showed that a vitamin D analogue, BXL-628 m(elocalcitol), at non-hypercalcemic doses, did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle which occurred with increasing bladder weight [Schröder et al., 2006]. The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007]. Upregulation of his pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO [Peters et al., 2006; Christ and Andersson, 2007]. In rats with outflow obstruction, previous elocalcitol-treatment improved the effects of tolterodine on bladder compliance [Streng at al., 2012]. It

was suggested that in rats elocalcitol exerted additional beneficial actions on outflow obstruction-induced functional changes during the filling phase of micturition, which may support combined therapy in BPH-related LUTS. If valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that the drug was able to arrest prostate growth within 12 weeks in men aged >or=50 years with prostatic volume > or = 40 ml [Colli et al., 2006]. In an RCT enrolling 120 female patients with OAB, where the primary endpoint was an increase in the mean volume voided, a significant increase vs placebo (22% vs 11%) was demonstrated [Colli et al., 2007]. Whether or not vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further RCTs. However, currently, the development of the drug seems to be stopped [Tiwari, 2009].

11.1.4 Prostanoid Receptor Agonists/Antagonists

Recent developments in the field of prostanoid receptors may open new possibilities to use selective prostanoid receptor antagonists for DO/OAB treatment [Aoki et al., 2009; Jones et al., 2009; Rahnama'i et al., 2012; Dobrek and Thor, 2015]. There is evidence suggesting that PGE2 contributes to the pathophysiology of DO/OAB: PGE2 infused into the bladder induces DO in humans and animals, increases PGE2 production in DO models and there are high concentrations of PGE2 in the urine of patients with OAB [McCafferty et al., 2008]. PGE2 is an agonist at EP receptors 1 to 4, all G-protein coupled, which mediate its physiological effects. Based on studies using knockout (KO) mice and EP1 receptor antagonists, it was suggested that the effects of PGE2 on bladder function were mediated through EP1 receptors (Schroder et al., 2004). EP receptors can be found on urothelium/urothelium, in detrusor smooth muscle and in intramural ganglia [Rahnama'i et al., 2010; Rahnama'i et al., 2011]. Functionally, it has been proposed that modulation of bladder activity exerted via EP1 receptors occurs via an afferent mechanism. Schröder et al. [2004] found no difference in urodynamic parameters between unobstructed EP1 receptor KO and WT mice. However, EP1 receptor KO mice did not respond to intravesical PGE2 instillation, while WT mice developed DO. The lack of EP1 receptor did not prevent bladder hypertrophy due to partial bladder outflow obstruction but after obstruction WT mice had pronounced DO, while this was negligible in EP1 receptor KO mice.

Lee et al. [2008] found that in normal rats, a selective EP receptor antagonist significantly increased bladder capacity, micturition volume and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE2, and decreased the frequency and amplitude of nonvoiding contractions in animals with BOO. More recently it has been shown that also EP3 receptor KO mice have a diminished response to bladder infusion of PGE2, and demonstrate an enhanced bladder capacity

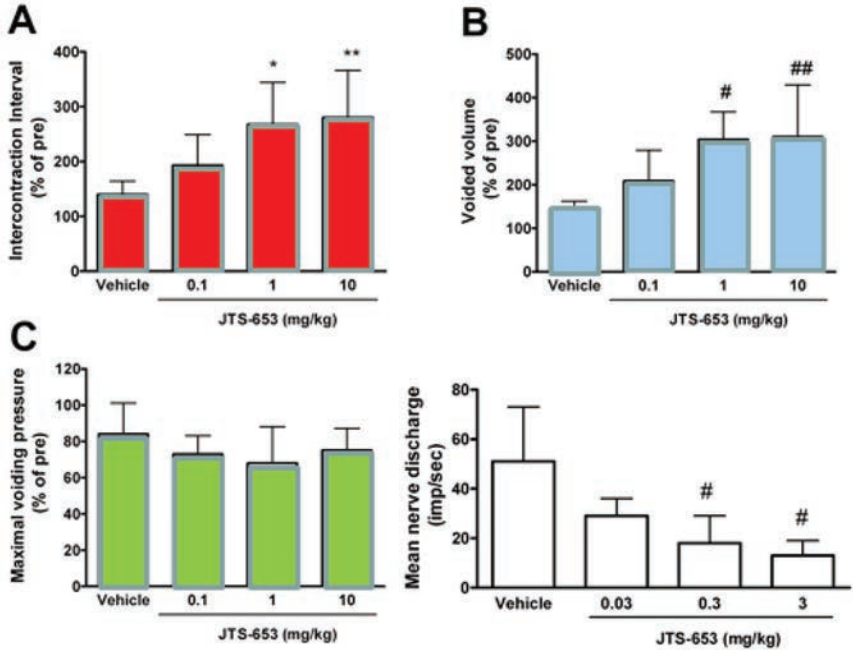

Figure 20: Effect of the selective TRPV1 antagonist JTS-653 given intravenously on capsaicin induced increase in pelvic nerve firing frequency (A) and IVP (B) in anesthetized rats. Modified from Kitagawa et al., J Urol. 2013 Mar;189(3):1137-46.

under basal conditions [Jones et al., 2009]. This findings suggest an important contribution for EP3 receptors in the modulation of bladder function under physiological conditions as well as under conditions of enhanced PGE2 production evoking DO. Thus, EP1 and EP3 receptors may have a role in PGE2 mediated DO.

Interestingly, activation of EP3 receptors evoked diuresis and EP3 receptor antagonism was found to induce an antidiuretic effect [Jugus et al., 2009]. Thus, to modulate bladder activity, it appears that the EP3 receptor has a role in regulating urine production. Both effects may be useful for treatment of DO/OAB. It cannot be denied that EP1/EP3 receptors constitute interesting and promising targets for drugs aimed at DO/OAB treatment. However, a randomised, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP-1 receptor antagonist, ONO-8539, in patients with the overactive bladder syndrome suggests that the role of EP1 receptor antagonism in the management of OAB syndrome is minimal [Chapple et al., 2011].

11.1.5 Cannabinoids

There is increasing evidence that cannabinoids can influence micturition in animals as well as in humans, both normally and in bladder dysfunction [Ruggieri, 2011; Hedlund, 2014: Hedlund and Gratzke, 2016]. The effects of the cannabinoids are exerted via two types of well defined receptors, CB1 and CB2, distributed widely in the body. However, additional receptor subtypes cannot be excluded [Pertwee et al., 2010; Ruggieri, 2011]. Both in the CNS and in peripheral tissues, CB1 and CB2 receptors have been identified; centrally CB1 and peripherally CB2 receptors seem to be predominant [Pertwee et al., 2010; Ruggieri, 2011] CBI as well as CB2 receptors have been identified in all layers of the human bladder [Merriam et al., 2008; Gratzke et al., 2009; Tyagi et al., 2009; Walczak et al., 2009]; their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB1 was higher than that of CB2 [Tyagi et al., 2009]. Gratzke et al. [2009] found higher expression of CB2 receptors, but not CB1 receptors, in the mucosa than in the detrusor. Compared to the detrusor, larger amounts of CB2receptor containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB2 receptors and VAChT (cholinergic neurons) were located in the detrusor. In general, activation of CB1 peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB2 appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions [Pertwee et al., 2010; Ruggieri, 2011]. Several animal studies have suggested a modulatory role of CB2 receptors in both afferent signalling and cholinergic nerve activity [Gratzke et al., 2009; 2010; 2011]. Thus, in vivo the selective CB2 receptor agonist, cannabinor, increased micturition intervals and volumes, and increased threshold and flow pressures, suggesting that peripheral CB2 receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabinor, bladder weight was lower, the ability to empty the bladder was preserved and non-voiding contraction frequency was low compared to those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids, is fatty acid amide hydrolase (FAAH). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB2 receptors. In rats, a FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechanoafferent functions [Strittmatter et al., 2011]. Aizawa et al. [2016] found that URB937, a peripherally restricted FAAH inhibitor, reduced BO and C-fibre hyperactivity in the rat bladder provoked by PGE2, suggesting an important role of the peripheral endocannabinoid system in bladder overactivity and hypersensitivity. Charrua et al. [2016] showed that URB937 in LPS induced cystitis decreased voiding contactions on a dose dependent manner in low to mederate doses. In high doses the FAAH inhibitor did the opposite effect, increasing voiding frequency. Moreover, in the same model of cystitis URB937 in the doses that decreased bladder overactivity decreased the levels of anandamide and increase the levels of palmitoylethanolamide in the bladder tissue. Therefore, more studies are necessary in this field to clearly understand the dynamic of endocannabinoids in peripheral tissues. In addition, there seem to be no clinical studies assessing the effects of FAAH inhibitors on LUTS or on LUT visceral functions in humans [Hedlund and Gratzke, 2016].

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminay report Blywert et al. [2003] demonstrated an effect of combined CB1/CB2 receptor activation on detrusor overactivity in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

The clinical experiences the cannabinoid treatment of micturition disturbances inclung LUTS are limited [Ruggieri, 2011], but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic overactive bladder (OAB) symptoms refractory to first-line treatment [Brady et al., 2004b; Freeman et al., 2006; Kavia et al., 2010]. Brady et al. [2004b] evaluated the efficacy of 2 whole plant extracts (δ9-tetrahydrocannabinol and cannabidiol) of Cannabis sativa in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency and nocturia decreased significantly following treatment. Freeman et al. [2006] tested in a subanalysis of a multicenter trial (the CAMS study) whether cannabinoids could decrease urge incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral

administration of the cannabis extract δ9-tetrahydrocannabinol or matched placebo. Based on incontinence diaries a significant decrease in incontinence episodes was demonstrated.

Kavia et al. [2010] assessed the efficacy, tolerability and safety of Sativex(®) (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and overactive bladder (OAB). The primary endpoint, reduction in daily number of urinary incontinence episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four out of seven secondary endpoints were significantly in favour of Sativex, including number of episodes of nocturia, number of voids/day, and number of daytime voids. The improvement in I-QOL was in favour of Sativex, but did not reach statistical significance.

Systemic cannabinoids have effects on the lower urinary tract that may have a therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT is incompletely known, and further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders. In a recent review, Hedlund and Gratzke [2016] concluded that currently "the endocannabinoid system can be considered as a potential drug target for pharmacological management of LUTS, with a more favourable adverse event profile than antimuscarinic agents".

11.1.6 Intraprostatic Injections of Drugs.

Intraprostatic injection therapy is probably the oldest minimally invasive surgical therapy for BPH and has been investigated for over 100 years with renewed interest recently. There are different injectables and various routes of administration, transperineal, transrectal and transurethral (Andersson, 2015].

11.1.7 Ethanol

Ethanol injection is one of the most investigated intraprostatic therapies and have been investigated for more than a decade [Goya et al., 1999]. However, the mechanism of action, patient selection and application of ethanol (the number of injection sites and the injection volume) have not been well investigated and long-term results are scarce. It seems that ethanol causes inflammation, coagulative necrosis with protein denaturation and cell membrane lysis, and, finally, sloughing of prostatic tissue resulting in cavity formation [Plante et al., 2003]. The majority of trials demonstrated a significant reduction in symptoms and post-void residual volume as well as a significant improvement in Qmax and QoL and prostate volume also decreased significantly in the majority of studies [Goya et al., 2004; Grise et al., 2004; Plante et al., 2007; Sakr et al., 2009]. The durability of clinical effects beyond 1 year seems poor. One trial with a mean follow-up of 3 years showed a retreatment rate of 41% [Goya et al., 2004].

11.1.8 BoNT/A

BoNT-A investigation for the treatment of benign prostatic enlargement (BPE) due to benign prostatic hyperplasia (BPH) started in 2003 [Maria et al., 2003] after the experimental study by Doggweiler et al. [1998] demonstrating prostatic atrophy in the rat after intraprostatic injection of the neurotoxin. In an exploratory study, which involved injection of 200 U of onabotA in moderate to large prostate glands, a rapid prostate volume decrease was induced and still present at 12 months [Maria et al., 2003]. Following this study, Kuo [2005] reported similar findings when injecting prostate glands of 50 ml or larger. BoNT/A injection in smaller prostate glands caused a much lesser reduction in prostate volume, but a 15% reduction was still observed [Chuang et al., 2005; Chuang et al., 2006c). Independent of the extent of prostate volume reduction, improvement of LUTS and flow were consistently reported [Maria et al., 2003; Kuo, 2005; Chuang et al., 2005; Chuang et al., 2006c], while a decrease in total serum PSA were observed only in some studies [Maria et al., 2003; Guercini et al., 2005]. In a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of BPH, Crawford and coworkers concluded that intraprostatic injection of 100 or 300 units of onabotA passed predetermined criteria for treatment efficacy and safety (30% improvement from baseline to 3 months in American Urological Association symptom index and/or maximum urinary flow rate and safety). The ideal dose was not found, but it seemed that the 100 U dose may be preferable due to similar efficacy with reduced costs and adverse effects [Crawford et al., 2011]. Some serious adverse events were reported, including 3 cases of urosepsis related to the onabotA injection. Other minor adverse events reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford et al., 2011).

Silva et al. [2008], selected a particular group of patients with high co-morbidity in which more invasive treatments were contraindicated. Intraprostatic BoNT/A injection was carried out transrectally, under ultrasound guidance. Twenty-one men with large BPE, 70±10 ml, on chronic indwelling catheter for at least 3 mo who were not candidates for surgery because of poor general condition received 200 U BoNT/A in the transition zone. Baseline prostate volume of decreased to 57±10 ml at 1mo and to 47±7ml at 3 months. At 1 month, 16 patients (76%) could resume voiding with a mean Qmax of 9.0±1.2 ml/s. At 3 months, 17 patients (81%) voided with a mean Qmax of 10.3±1.4 ml/s. Residual urine was not significant and mean serum total PSA showed a slight decrease [Silva et al. 2008]. The analysis of 11 patients

of the initial cohort showed that the duration of prostate atrophy after the single injection of 200U of BoNT/A was found to be about 18 months [Silva et al., 2009b].

Intraprostatic injection of BoNT/A seems devoid of sexual adverse events. Sixteen sexually active men aged > 60 years with BPH/benign prostatic enlargement (BPE) refractory to standard medical therapy received 200U of BoNT/A by transrectal route. Erectile function was evaluated using the International Index of Erectile Function – Short Form (IIEF-5) questionnaire. Orgasmic/ejaculatory function and libido were evaluated using questions 9, 10, 11 and 12 of the IIEF – Long Form. Intraprostatic injection of BoNT/A did not cause deterioration of any domain of sexual function [Silva et al., 2011].

Although necrosis of the gland at the places of BoNT/A injection could explain the rapid volume reduction, transrectal ultrasound examination of the glands, performed in these or in previous studies [Maria et al., 2003; Kuo 2005; Chuang et al., 2005; Silva et al., 2008, was unable to detect signs of cavitation that indirectly could suggest the presence of necrosis. Therefore, the reason for the decreased prostate volume should be more appropriately related to the widespread apoptosis detected in the gland after BoNT/A administration. Apoptosis was reported in rats, dogs, and humans, and affected both the epithelial and stromal components [Doggweiler et al., 1998; Chuang et al., 2005; Chuang et al., 2006b; Chuang et al., 2006d, Silva et al., 2009a].

Although until now, no important side-effects have been reported after intraprostatic injection of the neurotoxin in doses ranging between 100 and 300 U, a multicenter, double-blind, randomized phase II clinical trial of 100 and 300 unit doses of onabotA to treat the lower urinary tract symptoms of benign prostatic hyperplasia, was recently published [Crawford et al., 2011]. OnabotA prostatic injection met the two safety criteria proposed, (a dose failed if: 1- a life threatening, disabling or fatal event was determined to be related to the onabotA injection, or 2- 40% or more of the participants reported a moderate or severe side effect related to the botulinum toxin injection). Nonetheless, some serious AEs were reported, including 3 cases of urosepsis related to the onabotA injection and the remaining events were judged not related to the injection. Other minor AEs reported were urinary tract infection, pelvic pain, urinary retention, macroscopic hematuria and hematospermia [Crawford et al., 2011].

These findings were not reproduced, however, in two recent, large RCTs. One enrolled patients with IPSS > 12 and a peak flow rate (Qmax) between 5-15 ml/s [Marberger et al., 2012]. A total of 380 men met the inclusion/exclusion criteria, were randomized (ITT population), and received treatment via the transperineal (n = 63) or transrectal (n = 311) routes with either placebo (n = 94) or onabotA 100 U (n = 95), 200 U (n = 94), or 300 U (n = 97). The other [McVary et al., 2014] enrolled 427 men with IPSS score > 14 and Q max between 4 to 15 ml/s. All received initially a sham procedure to exclude cases with a high placebo response during the run-in phase. Then a total of 315 patients were randomized 1:1 to receive a single intraprostatic treatment of onabotA 200U or placebo. Although in both studies a substantial decrease in IPSS score and increase in Qmax occurred in the onabotA 200 U groups, the changes were not significantly different from those observed in the saline arm, indicating that they arose from a considerable placebo effect associated with the injection procedure.

The population enrolled in the Marberger and McVary trials may vary from those usually referred to minimal invasive BPH procedures. As a matter of fact, 51% of the men enrolled in the Marberger study, although having moderate to severe LUTS had never received treatment with licensed drugs for BPH/LUTS. In the McVary study [2014], 78.3% of the patients were not on α-AR antagonists or 5 ARI when they were enrolled in the study. From a total of 313 patients only 68 (21.7%) were on treatment, while all the others had meanwhile abandoned oral pharmacotherapy. Interestingly, patients unsatisfied with medical treatment for their BPH/LUTS seem to respond more positively to onabotA injection in the prostate. In the Marberger trial, an exploratory post hoc analysis of the subgroup of patients who had received α-AR antagonists showed a significant reduction from baseline in IPSS in the onabotA 200-U group versus placebo. A sub analysis of the population on concurrent BPH therapy in the McVary study showed an improvement in Qmax that was significantly greater in the onabotA than in the placebo arm.

Recently, a non-inferiority randomized clinical trial compared in BPH patients dissatisfied with oral pharmacotherapy prostatic injection of onabotA 200 U against optimized medical therapy [Robert et al., 2015]. Patients on optimized drug therapy received any possible drug combination for treatment of BPH/LUTS. The group submitted to toxin injection stopped oral medication 30 days after the procedure. Total IPSS at the end of treatment was similar in the two arms, allowing the conclusion that onabotA is not inferior to optimized medical therapy, in men with BPH/LUTS refractory to initial oral pharmacotherapy. Interestingly, in the onabotA group only 1 episode of acute urinary retention occurred. In contrast, 6 cases were observed in the optimized medical treatment group.

11.1.9 NX-1207

NX-1207 is a new drug under investigation for the treatment of LUTS associated with BPH [Kunit and Lusuardi, 2014]. It is a new therapeutic protein of proprietary composition with selective pro-apoptotic properties [Shore, 2011]. The drug is injected directly into the directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to non-regressive prostate shrinkage and both short- and

long-term symptomatic improvement. Information about the drugs is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two US Phase II trials have been performed [Shore, 2011]. One of them was a multicenter, randomized, non-inferiority study involving 32 clinical sites with 85 subjects and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Subjects and investigators on NX-1207 were double-blind as to dosage. The primary endpoint was change in AUASI at 90 and 180 days for a single injection of NX-1207 as compared to finasteride on a non-inferiority basis. Inclusion criteria included an AUA Symptom Score ‡ 15, diminished peak urine flow (< 15 ml/s) and a prostate size of > 30 and < 70 mg. The mean AUA Symptom Score improvement after 90 days in the intent to- treat group was 9.71 points for 2.5 mg NX-1207 (n = 48) versus 4.13 points for finasteride (n = 24) (p = 0.001) and 4.29 for 0.125 mg NX-1207 (n = 7) (p = 0.034). The 180-day results also were positive (NX-1207 2.5 mg non-inferior to open-label finasteride).

No significant changes in serum testosterone or serum PSA levels in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two US multicenter, double-blind, placebo-controlled Phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

Recently, the clinical development of this drug was suspended and clinicals trials going on in Europe suspended due to the releaseof negative data coming from a phase III trial run in the US.

11.1.10 PRX302

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by prostate-specific antigen (PSA). [Singh et al., 2007]. The safety and efficacy of PRX302 was evaluated in men with moderate to severe BPH [Denmeade et al., 2010]. The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS >12, a quality of life (QoL) score >3, and prostate volumes between 30 and 80 g. Fifteen patients were enrolled in phase 1 studies, and 18 patients entered phase 2 studies. Subjects received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase 1 subjects received increasing concentrations of PRX302 at a fixed volume; phase 2 subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax), IIEF, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase 1 study and 64% of men in the phase 2 study treated with PRX302 had >30% improvement compared to baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving >1 ml of PRX302 per deposit had the best response overall. There were no deleterious effects on erectile function. Adverse eventswere mild tomoderate and transient in nature. The major study limitation was the small sample size. The promising safety profile and evidence of efficacy in the majority of treated subjects in these phase 1 and 2 studies supports further development of PRX302 as a minimally invasive, targeted treatment for BPH.

To overcome theses limitations, a phase IIb study was carried out recently [Elhilali et al., 2013]. A total of 92 men with an IPSS ≥15, Q_{max} ≤12 ml/s and prostate volume beween 30 and 100 ml were randomized 2:1 to a single ultrasound guided prostatic injection of PRX302 (0.6 mg per g prostate) or placebo. Benign prostatic hyperplasia medications were prohibited. The toxin decreased IPSS score by approximately 9-point and increase Q_{max} by 3 ml/s, both changes being statistically significant when compared to vehicle. Efficacy was sustained for 12 months. PRX302 apparent toxicity was mild, transient, and limited to local discomfort/pain and irritative urinary symptoms occurring in the first few days, with no effect on erectile function. Further developments are therefore awaited.

11.2. Centrally Acting Drugs

Many parts of the brain seem to be activated during storage and voiding [see, Griffiths 2007; Fowler et al., 2008; Griffiths and Tadic, 2008], and there is increasing interest in drugs modulating the micturition reflex by a central action [Andersson and Pehrson, 2003, Yoshimura et al., 2014]. Several drugs used for pain treatment also affect micturition; morphine and some antiepileptic drugs being a few examples (Figure 21). However, central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, since selective actions may be difficult to obtain. Holstege [2005], reviewing some of the central mechnisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC), suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”

11.2.1 Gonadotropin-releasing Hormone Antagonists

The beneficial effects of the 5α-reductase inhibitors, finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as luteinizing hormone-releasing hormone: LHRH) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density following long-term androgen ablation [Schroeder et al., 1986; Peters et al., 1987; Bosch et al., 1989; Eri and Tveter, 1993]. With GnRH antagonists submaximal, non-castrating blockade of the androgen testosterone and consequently of dihydrotestosterone (DHT) can be achieved, thus avoiding medical castration. Several GnRH antagonists – such as cetrorelix, ozarelix and teverelix - have been tested in Phase IIA/IIB clinical trials for their ability to improve LUTS in patients with BPH [Colli and Tanko, 2011].

Debruyne et al. [2008] demonstrated in a phase 2 RCT that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS $\geq$ 13, peak urinary flow rates 5-13 ml/s), rapidly caused a significant improvement in the mean IPSS: the peak decrease was -5.4 to -5,9 vs -2,8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment of male LUTS.

Due to these results, two phase III studies were conducted in the United States and Europe [AEterna Zentaris] ; in the US study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

11.2.2 Gabapentin

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders [Striano and Striano, 2008]. It was originally designed as an anticonvulsant GABA (y-aminobutyric acid) mimetic capable of crossing the blood-brain barrier [Maneuf et al., 2003]. The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial [Maneuf et al., 2003]. It has been suggested that it acts by binding to a subunit of the $\alpha_2\delta$ unit of voltage dependent calcium channels [Gee et al., 1996; Striano and Striano, 2008]. Gabapentin is also widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone et al. [2006] reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters, and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-

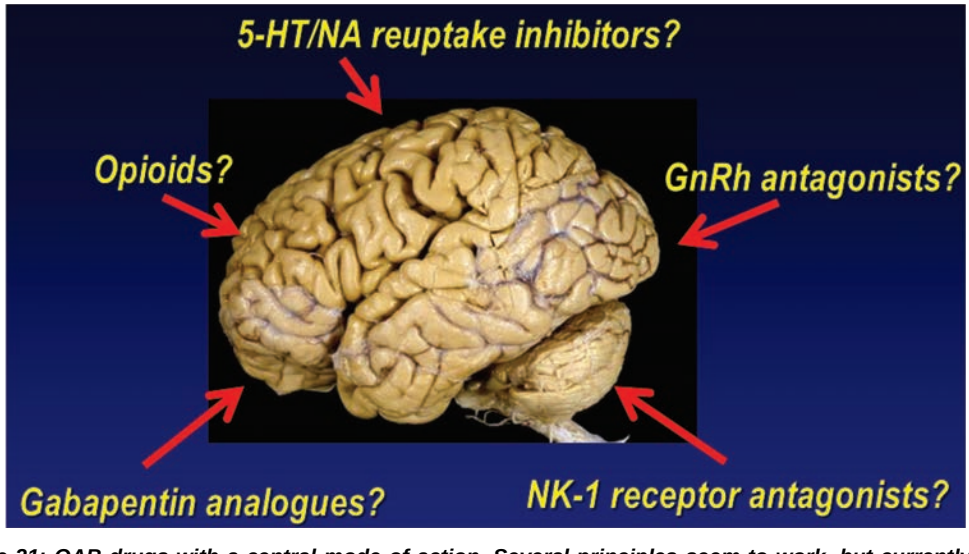

Figure 21: OAB drugs with a central mode of action. Several principles seem to work, but currently used drugs have low efficacy and/or unacceptable side effects. However, there is great potential for further developments

neurogenic DO. Kim et al. [2004] studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinics. They found that 14 out of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other $\alpha_2\delta$ ligands (e.g., pregabalin and analogs) will offer new therapeutic alternatives, but convincing RTC are still lacking.

11.2.3 Tramadol

Tramadol is a well-known analgesic drug [Grond and Sablotzski, 2004]. By itself, it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ-receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake [Grond and Sablotzski, 2004]. This profile is of particular interest, since both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placobo controlled study with duloxetine [Steers et al., 2007].

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction [Pehrson et al., 2003]. Tramadol also inhibited DO induced by apomorphine in rats [Pehrson and Andersson, 2003] – a crude model of bladder dysfunction in Parkinson´s disease. Singh et al. [2008] gave tramadol epidurally and found the drug to increase bladder capacity and compliance, and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini [2006] evaluated in a double-blind, placebo-controlled, randomized study, the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol sustained release every 12 h for 12 weeks. Clinical evaluation was performed at baseline and every two weeks during treatment. Tramadol significantly (p<001) reduced the number of incontinence periods per 24 hours from 3.2+/- 3.3 to 1.6+/-2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. However, the study was later retracted due to unacceptable statistical errors [Safarinejad and Hosseini, 2006; retracted 2014].

NK1-Receptor Antagonists

The main endogenous tachykinins, substance P (SP), neurokinin A (NKA) and neurokinin B (NKB), and their preferred receptors, NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control [Lecci and Maggi, 2001; Saffroy et al., 2003; Covenas et al., 2003]. NK1 receptor expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated [Ishizuka et al., 1994] in normal, and more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced detrusor overactivity was reduced by blocking NK1 receptor-expressing neurons in the spinal cord, using intrathecally administered substance P-saponin conjugate [Seki et al., 2002]. Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 1995].

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses, and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction [Gu et al., 2000]. Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-DOPA) stimulation [Ishizuka et al., 2000]. Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting [Massaro and Lenz, 2005], significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), as shown in a well-designed pilot RCT [Green et al., 2006]. The primary end-point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes, and urgency episodes. Aprepitant significantly (p<0.003) decreased the average daily number of micturitions (-1.3+/-1.9) compared with placebo (-0.4+/-1.7) at 8 weeks. The average daily number of urgency episodes was also significantly (p<0.047) reduced (-23.2+/- 32%) compared to placebo (-9.3+/-40%), and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. Aprepitant was generally well tolerated and the incidence of side effects, including dry mouth, was low. Since this initial proof of concept study suggested that NK-1 receptor antagonism hold promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with overactive bladder (8 or more average daily micturitions and 1 or more daily urge incontinence episodes) [Frenkl et al., 2010]. After a 1-week placebo run-in the patients were randomized to treatment with 8 weeks of daily 0.25, 1 or 4 mg serlopitant, 4 mg tolterodine extended release or placebo. Patients kept 7-day voiding diaries. The primary end -point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urge incontinence episodes and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change

from baseline in daily micturitions was significantly greater for 0.25 (-1.1) and 4 mg (-1.1) serlopitant, and for tolterodine (-1.5) than for placebo (-0.5), but not for 1 mg serlopitant (-0.8). No serlopitant dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopitant (3.3%) was comparable to placebo (4.6%) and lower than tolterodine (8.8%). Serlopitant was generally well tolerated. Haab et al. [2014] performed a phase II, multicenter, double-blind study in which adults with OAB symptoms >6 months were randomized to receive 1 of 3 doses of netupitant (50, 100, 200 mg) or placebo once daily for 8 weeks. The primary efficacy endpoint was percentage change from baseline in average number of daily micturitions at week 8. Urinary incontinence, urge urinary incontinence (UUI), and urgency episodes were also assessed. They found that the primary efficacy endpoint was similar in the treatment groups (-13.85 for placebo to -16.17 in the netupitant 200 mg group) with no statistically significant differences between netupitant and placebo.

NK-1 receptor antagonists may have a role in the treatment of overactive bladder, but at least the componds tested so far do not offer advantages in efficacy compared to tolterodine.

A different approach, modulation of neuropeptide release rather than NK receptor blockade, was tested in a pilot study with cizolirtine, which is a substance-P and CGRP release modulator at the spinal cord level. The modulation of substance-P and CGRP is probably related to the increase of extracellular levels of noradrenaline and serotonin. Cizolirtine 200 and 400 mg were compared to placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 68% and 81% of the patients on cizorlitine 200 and 400mg. More commonly reported side effects were gastro-intestinal in nature, including dry mouth and vomiting [Martınez-Garcıa et al., 2008]. No further developments of this compound have been reported.

11.3. Critical Summary

Based on review of the literature on what is described as “emerging” or “innovative” drugs/targets for treatment of LUTS/OAB, a long list of “possible” or “promising” alternatives can be constructed (Table 4). However, a critical review of these alternatives reveals that although many agents may have theoretically interesting profiles, they do not seem to be in active development for different reasons. For several drugs, proof- of -concept studies are available revealing either no effect, insufficient effect, or disturbing side effects.

Negative proof of concept (Table 4). K+ channel openers have shown great promise in preclinical experiments [Petkov, 2011], but so far the K-channel openers studied clinically- have yielded disappointing results [Andersson et al., 2013]. PGE2, acting via EP1 receptors, stimulates bladder contractile activity by sensitization of afferent nerves, and is increased in urine from patients with LUTS [Rahnama'i et al., 2012]. Despite promising results in animal experiments, a double-blind, placebo-controlled phase II study in OAB patients concluded that the role of an EP1 receptor antagonist in the management of OAB syndrome is minimal [Chapple et al., 2014].

Positive proof of concept (Table 4)Several neurokinin receptor antagonists have shown clinical efficacy, but not sufficient for further development [Green et al., 2006; Frenkl et al., 2019; Haab et al., 2014]. The monoamine reuptake inhibitor, duloxetine showed good efficacy in a randomized controlled clinical trial [Steers et al., 2007], but had many side effects. Side effects also stopped development of different COX-inhibitors (2).

A positive proof -of -concept study was reported for the opioid receptor agonist, tramadol [Safarinejad et al. 2006]. However, the study was later retracted due to unacceptable statistical errors.

Promising based on animal data (Table 4)**.** Up-regulation of the Rho-kinase pathway has been associated with bladder changes in diabetes, outflow obstruction, and idiopathic DO, making Rho-kinase inhibition a theoretically interesting principle for inhibition of bladder overactivity [Christ and Andersson, 2007]. The vitamin D3 agonist, elocalcitol, was shown to have an inhibitory effect on the RhoA/Rho kinase pathway [Morelli et al., 2007; Penna et al., 2009], and showed some promising effects in female patients with OAB symptoms [Digesu et al.,2012]. However, whether or not vitamin D3 receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB, requires further randomized controlled trials.

Several years ago Taylor and Bates performed a double-blind crossover trial of oral baclofen on patients with the “unstable bladder syndrome” with positive outcome [Taylor and Bates, 1979], but the principle of $GABA_B$ receptor stimulation was not further developed until recently. ADX71441 is a selective positive allosteric modulator of the $GABA_B$ receptor ($GABA_B$ PAM), which is orally available and showed promising effects in animal models of micturition disturbances [Kalinichev et al., 2014]. Further studies of this agent would be of interest.

Other promising targets seem to be the purinergic [Ford and Cockayne, 2011: Ford and Undem., 2013; North and Jarvis., 2013; Andersson, 2015] and cannabinoid [Ruggieri. 2011; Hedlund, 2014; Hedlund and Gratzke 2016] systems, and different members of the TRP channel family [Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. P2X3-receptor antagonists are currently being developed for treatment of non-bladder diseases, but clinical experiences in bladder disorders have not yet been reported. Clinical studies with the use of exo-

cannabinoids on LUTS are scarce and essentially restricted to MS patients, and the results have so far not been convincing. However, amplification of the activity of endocannabinoids by fatty acid amino hydrolase (FAAH) inhibitors, inhibiting their degradation, may be an attractive approach (Hedlund and Gratzke., 2016], but again clinical proof of concept is lacking. Several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder and urethra, and may act as sensors of stretch and/or chemical irritation [Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013; Deruyver et al., 2014; Franken et al., 2014]. The therapeutic potential for TRPV1 channel agonists (capsaicin, resiniferatoxin) has been convincingly demonstrated. However, the adverse effect of hyperthermia of the first generation TRPV1channel antagonists has delayed development. Nevertheless, TRP channels still may be one of the most exciting targets for future LUT drugs.

III. DRUGS USED FOR TREATMENT OF STRESS INCONTINENCE

1. STRESS INCONTINENCE IN WOMEN

Many factors seem to be involved in the pathogenesis of stress urinary incontinence (SUI) in women: urethral support and function, bladder neck support and function of the nerves and musculature of the bladder, urethra, and pelvic floor [Delancey, 1997; Mostwin et al., 2005, Koelbl et al., 2009; Chapple and Milsom, 2012]. Pure structural factors cannot be treated pharmacologically. However, SUI in women is generally thought to be characterized by decreases in urethral transmission pressure and, in most cases, resting urethral closure pressure [Henriksson et al., 1979; Hilton and Stanton, 1983, Koelbl et al., 2009]. It, therefore, seems logical that increasing urethral pressure should improve the condition.

Factors which may contribute to urethral closure include the tone of the urethral smooth and striated muscle (the rhabdosphincter) and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacological evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released noradrenaline [Andersson, 1993; Andersson and Wein, 2004; 2012]. A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. The pharmacological treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated musculature, either directly or through increased motorneuron activity. Several drugs may contribute to such an increase [Andersson and Wein, 2012], but relative lack of efficacy or/and side effects have limited their clinical use.

1.1. α-Adrenoceptor Agonists

Several drugs with agonistic effects on peripheral α-ARs have been used in the treatment of SUI (Table 5). Noradrenaline (NA) has a central role of in increasing the excitability of urethral rhabdosphincter motorneurons in the rat analogue of Onuf's nucleus, an effect due at least in part to α_1-AR dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI [Yashiro et al., 2010]. Ephedrine and norephedrine (phenylpropanolamine; PPA) seem to have been the most widely used [Andersson and Wein, 2012]. The original United States Agency for Healthcare Policy and Research Guidelines [Agency for Healthcare Policy and Research, 1992] reported 8 randomized controlled trials with PPA, 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in continence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3% respectively. The most recent Cochrane review on the subject [Alhasso et al, 2005, reprinted virtually unchanged in 2008] assessed randomized or quasi-randomized controlled trials in adults with stress urinary incontinence which included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 12, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, and RO 115-1240 in 1). The authors concluded, "there was weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of pad changes and incontinence episodes, as well as, improving subjective symptoms". There was not enough evidence to evaluate the merits of an AR agonist compared with estrogen, whether used alone or in combination.

Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to AR stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations [Andersson and Wein, 2012]. Kernan et al. [2000] reported the risk of hemorrhagic stroke to be 16 times higher in women less than 50 years of age who had been taking PPA as an appetite suppressant

(statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant).

There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some [Bent et al., 2003] had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003, the Food and Drug Administration of the US decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate α_1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects [Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998].

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman et al. [2004] reported on a phase 2 randomized crossover study with RO 115-1240, a peripheral active selective $\alpha_{1A/1L}$-AR partial agonist [Blue et al., 2004] in 37 women with mild to moderate SUI

A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-3774076, a CNS penetrating partial α_{1A}-AR agonist, increased peak urethral pressure in dogs and was selective with respect to α_{1B} and α_{1D} receptors, but heart rate and blood pressure changes caused significant concern (Conlon et al., 2009). Furuta et al. [2009] reported that the α_2-AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that α_2-AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing

1.2. β-Adrenoceptor Agonists. Clenbuterol

β-AR stimulation is generally conceded to decrease urethral pressure [Andersson, 1993], but β_2-AR agonists have been reported to increase the contractility of some fast contracting striated muscle fibers and suppress that of slow contracting fibers of others [Fellenius et al.,1980]. Some β-AR agonists also stimulate skeletal muscle hypertrophy – in fast twitch more so than slow twitch fibers [Kim et al., 1992]. Clenbuterol has been reported to potentiate the field stimulation induced contraction in rabbit isolated periurethral muscle preparations, an action which is suppressed by propanolol and greater than that produced by isoprotererol [Kishimoto et al, 1991]. These authors were the first to report an increase in urethral pressure with clinical use of Clenbuterol and to speculate on its potential for the treatment of SUI. Yaminishi et al. [1994] reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β-AR blockade.

Yasuda et al. [1993] described the results of a double-blind placebo controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from 11.7± 17.9g to 6.0± 12.3g for drug and from 18.3± 29.0g to 12.6± 24.7g for placebo, raising questions about the comparability of the 2 groups.

The “significant” increase in MUCP was from 46.0± 18.2 cm H_2O to 49.3± 19.1 cm H_2O, versus a change of -1.5 cm H_2O in the placebo group. 56/77 patients in the clenbuterol group reported some degree of improvement versus 48/88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles.

Drug	Level of Evidence	Grade of Recommendation
Clenbuterol	3	C
Duloxetine	1	B
Ephedrine	3	D
Estrogen	2	D
Imipramine	3	D
Methoxamine	2	D
Midodrine	2	C
Norephedrine (phenylpropanolamine)	3	D

Table 5. Drugs used in the treatment of stress incontinence. Assessments according to the Oxford system (modified)

Ishiko et al. [2000] investigated the effects of clenbuterol on 61 female patients with stress incontinence

in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of stress incontinence and the patient's own impression were used as the basis for the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al [1997] reported positive results with clenbuterol (20 mg b.i.d. for 1 month) in 9 of 14 patients with mild to moderate stress incontinence after radical prostatectomy. No subsequent published reports have appeared. Further well-designed RTCs investigating effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.

There have been no recent reports of clinical trials with α_1- or β -AR agonists or antagonists for SUI.

1.3. β-Adrenoceptor Antagonists

The theoretical basis for the use of β-AR antagonists in the treatment of stress incontinence is that blockade of urethral β-ARs may enhance the effects of noradenaline on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence [Gleason et al., 1974; Kaisary, 1984] but there are no RCTs supporting such an action. In the Gleason et al. [1974] study, the beneficial effects become manifest only after 4 to 10 weeks of treatment, a difficult to explain phenomenon. Donker and Van der Sluis [1976] reported that β-AR blockade did not change UPP in normal women. Although suggested as an alternative to α-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

1.4. Imipramine

Imipramine, among several other pharmacological effects has classically been reported to inhibit the reuptake of noradrenaline and serotonin in adrenergic nerve endings. In the urethra this could be expected to enhance the contractile effects of noradrenaline on urethral smooth muscle. Gilja et al. [1984] reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean maximal urethral closure pressure (MUCP) from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin et al. [1999] assessed the efficacy of imipramine (25 mg imipramine three times a day for three months) as a treatment of genuine stress incontinence in 40 women. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of "successful treatment" was 60% (95% CI 11.8-75.2). There are no RCTs on the effects of imipramine on SUI. No subsequent published reports have appeared.

Interestingly, Gillman [2007] reported that clomipramine had far greater 5-HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with less effects than imipramine on 5-HT uptake (desipramine superior).

1.5. Duloxetine

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor, which has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function [Thor et al., 1995; Katofiasc et al., 2002]. Bladder capacity was also increased in this model, both effects mediated centrally through both motor efferent and sensory afferent modulation [Fraser et al., 2003]. The sphincteric effects were reversed by α_1-AR (praxosin) and 5-HT_2 receptor (LY 53857) antagonism, while the bladder effects were mediated by temporal prolongation of the actions of serotonin and norephinephrine in the synaptic cleft [Fraser et al., 2003]. Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 h [Sharma et al., 2000].

Thor et al. [2007] describe the mechanisms of action and the physiologic effects of duloxetine. 5-HT (serotonin) and NA terminals are dense in spinal areas associated with lower urinary tract functioning especially around the pudendal nerve neurons in Onuf's nucleus. These are projections from separate areas in the brain stem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in Onuf's nucleus causing contraction of the urethral rhabdosphincter (Figure 22).

The rhabdosphincter innervation is proposed as distinct from that of the levator ani [Thor and de Groat, 2010]. The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5-HT (through 5-HT_2 receptors) and NA (through α_1-ARs). 5-HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and the rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for $5HT_{1A}$ (indirect through a supraspinal stimulation), TRH, Vasopressin, NMDA and AMPA; inhibitory effects are similarly mediated by κ_2 opioid, α_1 ARs, GABA-A, GABA-B and glycine receptors [Thor and de Groat, 2010]. Some CNS penetrant selective 5-HT_{2C} agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the

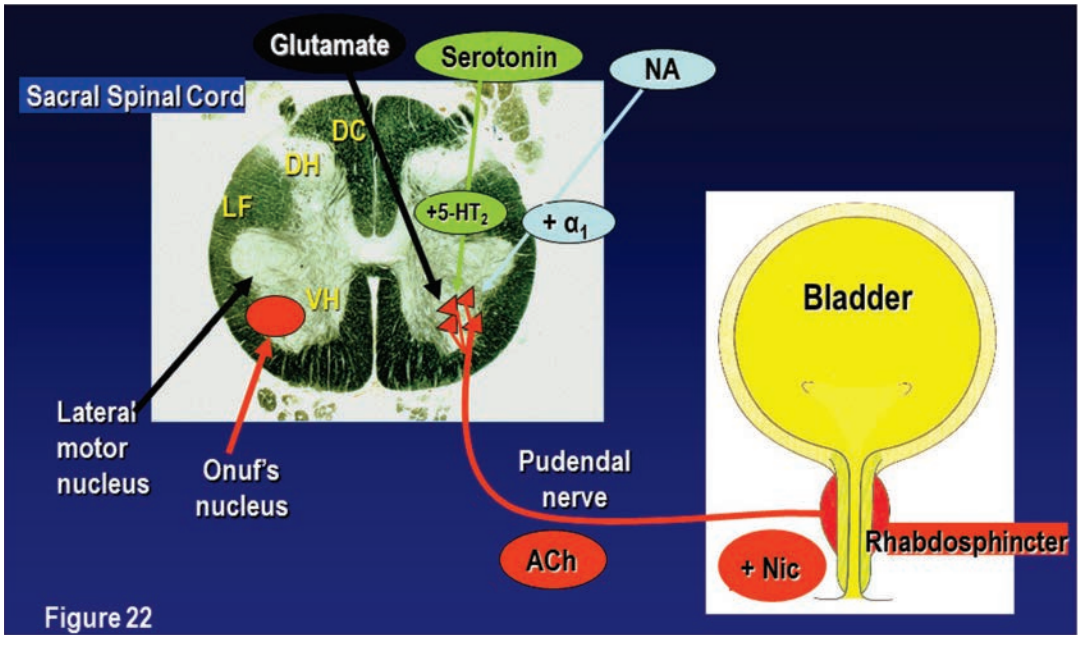

Figure 22: The striated urethral sphincter is innervated by the pudendal nerve, which contains the axons of motor neurons whose cell bodies are located in Onuf's nucleus. Glutamate exerts a tonic excitatory effect on these motor neurons, and this effect is enhanced by noradrenaline (NA) and serotonin (5-HT), acting on α1- adrenoceptors and 5-HT2-receptors, respectively. By inhibition of the reuptake of noradrenaline and serotonin, duloxetine increases the contractile activity in the striated sphincter (nicotinic receptors: + Nic). DC = dorsal commissure; DH = dorsal horn; VH = ventral horn; LF = lateral funiculus; ACh = acetylcholine

treatment of SUI [Brennan et al., 2009, Andrews et al., 2011].

Several RTCs have documented the effect of duloxetine i SUI [Norton et al., 2002; Dmochowski et al, 2003; Millard et al., 2004; Van Kerrebroeck et al., 2004; Ghoneim et al., 2005]. A Cochrane review of the effects of duloxetine for stress urinary incontinence in women is available, the last substantive amendment listed as 25 May 2005 [Mariappan et al., 2005]. Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to 1 or 2 of the primary references. An additional analysis "performed under the auspices of the Cochrane Incontinence Group" was performed on just the 9 primary trials comparing duloxetine and placebo, and published separately [Mariappan et al., 2007]. The results can be summarized as follows. Subjective "cure" in the duloxetine 80 mg daily (40 mg b.i.d.) was higher than in the placebo group (10.8% vs 7.7%, overall RR = 1.42; 95% CI, 1.02-1.98; p = 0.04). The estimated absolute size of effect was about 3 more patients cured of every 100 treated. Objective cure data, available from only 1 trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in I-QOL (WMD for 80 mg: 4.5; 95% CI 2.83-6.18, p<0.00001). Adverse effects in 6 trials were analysed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event and the incidence ranged from 23-25% and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness and insomnia, overall RR 1.30 (95% CI, 1.23-1.37). Across these 6 trials 17% in the drug group withdrew, 4% in the placebo arm. In the 2007 article, the authors conclude by saying that further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared to other current minimally invasive and more invasive approaches in patients with varying severity of SUI, and that "longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications".

Hurley et al. [2006] characterized the safety of duloxetine for treatment of SUI in women, using an integrated database generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (N=958) or placebo (N=955), examining adverse events (AEs), serious adverse events (SAEs), vital signs, electrocardiograms, and laboratory analytes. AEs occurring initially or worsening during the double-blind treatment period were considered treatment-emergent (TEAE). Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common TEAEs included: nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most TEAEs that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall

AE discontinuation rates were 20.5% for duloxetine and 3.9% for placebo (P<.001). Most discontinuations (83%) occurred within the first month of treatment. SAEs were uncommon and did not differ between treatments. Statistically significant, but clinically unimportant mean increases in heart rate (2.4 bpm) and systolic and diastolic blood pressure (<or=2 mmHg) occurred. No arrhythmogenic potential was observed and any rare, transient, asymptomatic increases in hepatocellular enzymes normalized. The autors concluded that duloxetine was safe and tolerable, although transient AEs were not uncommon. Hashim and Abrams [2006] suggested, to reduce the risk of nausea, to begin with a dose of 20 mg twice daily for 2 weeks, then to increase to the recommended 40 mg b.i.d. dosage.

Ghoniem et al. [2005] randomized women with SUI to 1 of 4 treatment combinations: duloxetine alone (40 mg b.i.d.), pelvic floor muscle training, combination and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, while pad results and QOL data favored combination therapy to single treatment. Cardozo et al. [2004b] reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett et al. [2006], offered a 4-week course to women awaiting a TVT operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8/33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of AEs, 9 (27%) found the drug ineffective.

Bent et al. [2008], reported on the effects of 12 weeks of duloxetine (40 mg b.i.d.) vs placebo in a large group of women with MUI. For SUI episodes, the mean IEF (incontinence episode frequency) per week decreased 58.9% with drug (7.69 to 3.93) vs 43.3% for placebo (8.93 to 6.05). Interestingly, corresponding decreased for UUI episodes were 57.7% vs 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute change for SUI amounted to -3.76 episodes per week for drug, -2.87 for placebo. Nausea was reported by 18% of patients on drug, 4.5% on placebo. Corresponding percents for other AEs include, dry mouth (12 vs 2.8), dizziness (9.7 vs 2.4), constipation (8.3 vs 4.2), fatigue (6.7 vs 2.8). Nausea and dizziness were less common in a subgroup taking concurrent antidepressants. Women 65 years and older with SUI or stress predominant MUI (S-MUI) were given duloxetine (40 mg b.i.d. after a 2-week start on 20 mg b.i.d.) or placebo for 12 weeks by van Leeuwen et al. [2008]. They conclude, “this study supports the use of duloxetine in elderly women with SUI or S-MUI”. The data show an absolute change in SUI + S-MUI episodes of -11.7 and -6.9 IEF/week (drug and placebo) and median percent changes of -52.5% vs -36.7% from 24h diaries, both significant at p<0.001. However, the changes for SUI alone were -53% vs -42% (NS) while for S-MUI alone they were -51.6% vs -32.7% (p<0.001). Nausea was less than in other trials (7.5% vs 3.1%), perhaps due to the lower starting dose. Other AEs included fatigue (14.2% vs 5.4), constipation (10.4 vs 0.8), dizziness (9.0 vs 4.6), excess sweating (5.2 vs 0).

Schagen van Leeuwen et al. [2008] investigated efficacy and safety of duloxetine in elderly women with stress urinary incontinence or stress-predominant mixed urinary incontinence. Duloxetine-treated patients had a significantly greater decrease from baseline to endpoint in mean incontinence episode frequency/week than placebo-treated patients (-52.47% vs. -36.70%). The responder rate (> or =50% reduction in incontinence episode frequency/week) was 57.1% in the duloxetine group and 35.2% in the placebo group (P<0.001). Significant benefits of duloxetine were also demonstrated for weekly continence pad usage, mean time between voids, incontinence quality of life questionnaire scores (P<0.001), and global impression of improvement ratings (P<0.001). Patients with depressive symptoms and cognitive impairments were few and changes were insignificant.

Persistence on duloxetine was studied by Vella et al. [2008] who found that only 31% of an original cohort of 228 were still taking drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, 33% to lack of efficacy. Bump et al. [2008], however, reported that the positive effects of duloxetine were maintained in patients who continued treatment up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months

Shaban et al. [2010] concluded that duloxetine is “optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE guidelines in the UK”. Similar sentiments are expressed by Robinson and Cardozo [2010].

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union (European Medicines Agency, Scientific Discussion, 2005) in women with moderate to severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI, but is approved for the treatment of major depressive disorder (20-30 mg b.i.d. initially, 60 mg once daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily, fibromyalgia (c0 mg once daily initially, 60b mg once daily maintenance) and chronic musculoskeletal pain (30 mg once daily initially,60 mg once daily as maintenance. The product information contains a “black box” warning of “increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders”, noting also that “depression and certain other psychi-

atric disorders are themselves associated with increases in the risk of suicide" [Prescribing Information, revised September 2011, Eli Lilly and Company, Indianapolis, Indiana 46285]. Other warnings and precautions in the U.S. in the United States Product Information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding SSRIs and SNRIs), abrupt discontinuation (may result in dizziness, paresthesias, irritability and headache), inhibitors of CYP1A2 (such as ciprofloxacin), thioridaxine (do not administer concomitantly) potent inhibitors of CYP2D6 (may increase concentration), and others. Adverse events for 6801 drug and 4487 placebo-treated patients reported in the US Product Information (treatment for the indications mentioned) are nausea (24% vs 8%), dry mouth (13 vs 5), fatigue (10 vs 5), somnolence (10 vs 3), insomnia (10 vs 6), constipation (10 vs 4), dizziness (10 vs 5).

2. STRESS URINARY INCONTINENCE IN MEN

Although a problem of significant magnitude, especially after radical prostatectomy (RP) for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention.

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by radical prostatectomy. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle and extrinsic paraurethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra [Koelbl al., 2009].

Tsakiris et al (2008) searched for articles on drug treatment of male SUI published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using α-AR agonists, β_2-AR antagonists or SNRSs. Only one of these included a comparison arm (Filocamo et al, 2007), 40 mg b.i.d. duloxetine plus pelvic floor exercise (PFE) vs PFE with placebo. The results suggested a positive effect of drug, but were a bit confusing. Of those patients completing the 4-month trial (92/112) 78% of the drug treated patients vs 52% of those in the placebo group were "dry". However, one month after the end of the study, the corresponding figures were 46% vs 73%, a shift still observed 2 months later. The authors of the review article suggested further larger and well designed studies on duloxetine for this potential usage.

Cornu et al. (2011) reported a series of post RP men with SUI or MUI (stress predominant) randomized to duloxetine (I5) and placebo (16) after a 2-week placebo run in. Dosage was 20 mg b.i.d. for 7d, 40 mg b.i.d. for 67d, 20 mg for 14d. Subjects were at least 1 year post surgery. Outcome measures included percent decrease in IEF, 1h pad test and various QOL measures. Statistical significance for IEF percent decrease occurred only at week 8 & 12 [(-) 52.2 $\pm$ 38.6% vs (+)19 $\pm$ 43.5%] but there was clearly a trend at 4 weeks. There was no statistical difference in 1h pad test weights but there was in various QOL scores. A 50-100% decrease in IEF was seen at 12 weeks in over half of the patients. Adverse events for drug and placebo included fatigue (50 vs 13%), insomnia (25 vs 7), libido loss (19 vs 7), constipation (13 vs 7), nausea (13 vs 7), diarrhea (13 vs 7), dry mouth (6 vs 0), anorexia (6 vs 0), and sweating (25 vs 20). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QOL. There were 4 men with MUI in the drug group, 5 in the placebo group. Results for SUI and UUI were not separated. One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy or neuromuscular function. In an uncontrolled usage study on men with post RP SUI, Collado Serra et al. (2011) reported that the benefit remained in 85% after the drug was stopped. In that series, 25% of patients withdrew because of AEs and 33% because of lack of effect.

Usage of duloxetine for SUI in the male is universally off label. A drug for this indication would be welcome. Larger controlled and better designed studies are necessary to provide conclusive positive or negative data on this subject.

IV. DRUGS TO TREAT UNDERACTIVE BLADDER/DETRUSOR UNDERACTIVITY

The Underactive Bladder (UAB: symptom diagnosis) and Detrusor Underactivity (DUA: urodynamic diagnosis) have multifactorial pathophysiologies, which introduce obvious therapeutic problems [Andersson, 2014; Miyazato et al., 2014; Osman et al., 2014; Osman and Chapple, 2014]. Not only can the pathophysiologies vary between patients (Figure 23), but also in an individual patient several factors may contribute, and it is not always possible to identify "major" and "minor" players that can be targets for treatment. Since complete bladder emptying is dependent on an intact central nervous system (CNS) control, normal sensation and detrusor smooth muscle activity, coordinated bladder and urethral sphincter function, and voluntary initiation of voiding, incomplete bladder emptying and urinary retention can result from disturbances of any of these components. If there are irreversible changes at any level, e.g., in the bladder wall (loss of nerves, loss of muscle tissue, increased

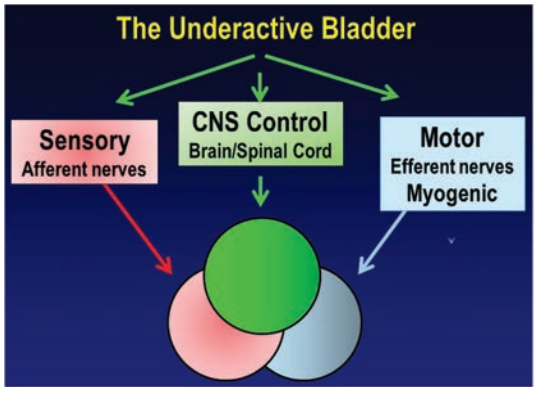

Figure 23: The Underactive Bladder have multifactorial pathophysiologies. Since complete bladder emptying is dependent on an intact central nervous system (CNS) control, normal sensation and detrusor smooth muscle activity, coordinated bladder and urethral sphincter function, and voluntary initiation of voiding, incomplete bladder emptying and urinary retention can result from disturbances of any of these components. From Andersson, Curr Opin Urol. 2014 Jul;24(4):363-9.

collagen deposition), the possibilities of successful pharmacological treatment are reduced.

Detrusor Hyperactivity with Impaired Contractility [DHIC: Resnick and Yalla, 1987] is a diagnosis related to both overactive bladder (OAB)/detrusor overactivity (DO) and UAB/DUA, and the condition creates therapeutic problems. However, as pointed out by several investigators, UAB/DUA and OAB/DO may not be separate disease entities [Semins and Chancellor, 2004; Chancellor, 2014; Nomiya et al., 2014; Zhao et al., 2016]. Instead, chronic untreated or treatment-refractory OAB/DO, caused by neurologic diseases, diabetes, BOO, ischemic bladder dysfunction, or aging, may progress to DO with impaired contractility and eventually to UAB/DU. Progression of OAB/DO to UAB/DUA has been demonstrated in animal models [Nomiya et al., 2014; Zhao et al., 2016] and, if proven also in humans, suggests that early education, behavioral modification, and medical treatment may alter and/or prevent progression to UAB/DUA [Chancellor et al., 2014].

To what extent drug treatment of associated morbidities (e.g., diabetes, Parkinson's disease, multiple sclerosis) also can improve impaired bladder emptying has only been investigated to a limited extent.

1. PHARMACOLOGICAL PRINCIPLES USED FOR TREATMENT

To improve bladder emptying, agents that increase the contractile force of the detrusor, decrease outflow resistance, or improve detrusor contractility and decrease outflow resistance at the same time, would theoretically be useful [Wein, 2012]. In addition, agents that improve decreased sensation (increase afferent activity and/or the perception of bladder filling) seem attractive [Smith, 2010]. However, in many cases the pathophysiology of UAB/DUA is complex, simultaneously involving several mechanisms [Andersson, 2014; Miyazato et al., 2014; Osman et al., 2014; Osman and Chapple, 2014]. This implies that targeting only one potentially important mechanism will not always have the desired effect.

1.1. Muscarinic Receptor Agonists and Cholinesterase Inhibitors

It is well established the acetylcholine is the main contractile transmitter in the detrusor muscle, and that release of this agent induced by activation of the parasympathetic outflow from the spinal cord leads to a co-ordinated bladder contraction and bladder emptying with simultaneous relaxation of the outflow region [Andersson and Arner, 2004]. Standard pharmacotherapy of impaired bladder emptying has for a long time included muscarinic receptor agonists, such as bethanechol and carbachol to directly stimulate muscarinic receptors on the detrusor muscle, or choline esterase inhibitors, like distigmine to reduce the degradation of acetylcholine. However, based on available information it has been considered that little, if any, beneficial effects can be obtained in preventing or treating UAB/DUA [Barendrecht et al., 2007; Andersson et al., 2013]. Why do not these drugs work? One of the reasons is that direct stimulation of detrusor muscarinic receptors will cause contraction (contracture) of the bladder without simultaneous relaxation of the outflow region. Activation of the cholinergic nerves of the outflow region by spinal parasympathetic outflow will not only release acetylcholine for bladder contraction, but also nitric oxide, relaxing the urethra. In addition, systemic administration of a muscarinic receptor agonist has no selectivity for the bladder which means that action on non-target sites will cause adverse effects. Another factor is that both bethanechol and carbachol have low oral bioavailability which makes it difficult to attain "active" blood concentrations.

Bethanechol seems to be the best investigated of the parasympathomimetic drugs. Even if beneficial effects have been reported, most studies have shown no significant effect vs placebo in the treatment of UAB/DUA [Barendrecht et al. 2007]. Attempts have been made to increase the usefulness of muscarinic agonist stimulation. Riedl et al. [2000] used electromotive administration of intravesical bethanechol and could identify patients with an atonic bladder and adequate residual detrusor muscle function. They concluded that patients who do not respond to the electromotive administration of bethanechol do not benefit from oral bethanechol and are candidates for catheterization. To combine bladder contraction and outflow relaxation,

Hindley et al. [2004], in a placebo-controlled study, treated 19 patients with DUA with a combination of intravesical PGE_2 and oral bethanechol. They concluded that there was evidence of a pharmacological

effect with a limited therapeutic efficacy compared with placebo. However, this treatment was not recommended as routine, but only for the occasional treatment of a patient with DUA. In summary, available information shows that the beneficial effects that can be obtained with carbachol and bethanechol in preventing or treating UAB/DUA are small or negligible [Barendrecht et al., 2007; Andersson et al., 2013].

A number of studies have tested the effect of distigmine bromide on voiding efficiency, but the results have been conflicting. In a double-blind study, Shah et al [1983] investigated the effect of distigmine bromide versus placebo on voiding after prostatectomy 93 patients. The results showed a trend towards improvement, but no statistically significant increase in post-operative flow rates, in reduction in bladder volume, and in the incidence of re-catheterisation in the patients treated with the drug. In a prospective randomized study on 100 patients undergoing vaginal surgery for genital prolapse, Savona Ventura et al [1991] compared distigmine bromide, phenoxybenzamine hydrochloride, and prostaglandin $F_{2\alpha}$, to prevent urinary retention. They found that all agents appeared to increase the incidence of an elevated residual urinary volume by about three times. Even if the mechanisms behind these findings are difficult to explain, they clearly do not encourage the use of these agents on the indication.

Philp and Thomas [1980] gave distigmine bromide to 23 patients with paraplegia due to suprasacral spinal cord injury who retained a reflex micturition. There was a marked reduction of the residual urine volume in all patients whilst being on parenteral distigmine. The oral preparation of the drug proved less effective and this was attributed to poor absorption from the gut. Tanaka et al. [2001] found in 14 patients with poor detrusor contractility after transurethral prostatectomy (TURP) that oral administration of distigmine bromide (5 mg three times daily for 4 weeks) resulted in subjective as well as objective improvement; the International Prostate Symptom Score (IPSS) was reduced from a mean of 18.9 to a mean of<10 and the maximum flow increased from a mean of 8.9 ml/second to a mean of >12 ml/second. In addition, detrusor contractility tended to improve. Bougas et al. [2004] investigated 27 patients (11 men and 16 women) with poor detrusor function established using pressure-flow studies. They were treated with distigmine bromide for 4 weeks which resulted in a statistically significant reduction of residual volume (from a mean of 329.1 to a mean of 156.8 ml), obviating the need for intermittent self-catheterisation in 11 patients. In addition, maximum flow rate and detrusor pressure at maximum flow increased, although not significantly. The drug was generally well tolerated by the majority of patients.

It is obvious that the most positive effects of distigmine have been obtained in non-placebo controlled studies with small patient materials with various diagnoses. It cannot be excluded that in some selected patient categories distigmine may have a positive effect, but the lack of adequately designed studies implies that a fair assessment of the drug as a general treatment of UAB/DUA is not possible.

In a recent pilot study on 19 patients with DUA, Sugimoto et al. [2015] studied the effects of acotiamide, a drug approved in Japan for treatment various gastrointestinal disorders [Doi et al., 2004]. Acotiamide "appears to exert an antagonistic effect on muscarinic M1, M2, and M3 receptors and thereby inhibit the negative feedback system by blocking muscarinic auto receptors that regulate acetylcholine release." The main outcome parameter of the study was post-void residual (PVR) which after acotiamide changed from 161.4±90.0 mL at baseline to 116.3±63.1 mL at 2- weeks post-treatment. This may be statistically significant but is not very impressive. If the mechanism of action of the drug is increased acetylcholine release, it may not differ from other parasympathomimetic drugs.

For all parasympathomimetic drugs, well-designed, randomized controlled trials on well-defined patient materials are lacking, implying that these drugs cannot be recommended for general use, but may be utilized for personalized treatment of UAB/DUA.

1.2. α-Adrenoceptor Antagonists

The role of α-adrenoceptor (AR) antagonists in the treatment of voiding symptoms in men with bladder outflow obstruction (BOO) is well documented [Michel, 2010; Lepor et al., 2012]. Although most men with voiding symptoms do not necessarily have UAB/DUA, the drugs may improve bladder emptying in these patients. The use of α_1-AR antagonists has repeatedly been shown to be beneficial in patients with acute urinary retention due to benign prostatic enlargement[McNeill et al., 2004; 2005; Fitzpatrick et al., 2012]. These drugs are believed to facilitate bladder emptying by relaxing tone at the bladder neck. Administration of alfuzosin 10 mg daily almost doubles the likelihood of a successful trial without a catheter, even in patients who are elderly with a PVR > 100 mL. Continued use of alfuzosin significantly reduced the risk of BPH surgery in the first 3 months; however, this effect was not significant after 6 months [Fitzpatrick and Kirby, 2006; Emberton et al., 2008a; b; Kalejaiye et al., 2009]. Thus, α_1-AR antagonists provide rapid symptom relief from outlet obstruction caused by benign prostatic enlargement and delay the time to acute urinary retention; however, they do not decrease the overall risk of acute urinary retention or surgery [Emberton et al., 2008a;b; Edwards, 2008; Fitzpatrick et al., 2012].

Acute urinary retention may ocur after surgery. Buckley and Lapitan [2010] reviewed drugs used for treatment of post-operative urinary retention either alone or in combination, assessing cholinergic agents, α_1-AR blockers, sedatives and prostaglandins. A statistically significant association between intravesically administered prostaglandins and successful voiding was detected, but no such association was found for the other drugs

investigated. When cholinergic agents were combined with sedative there was an improved likelyhood of spontaneous voiding compared with placebo.

Supporting this, α_1-AR antagonists have been widely used in the conservative management of acute urinary retention caused by BOO as shown in systematic reviews of available data [Creta et al., 2015: Guan-Jun et al., 2015].

In patients with neurogenic bladder, reduction of urethral resistance during voiding by α-AR antagonists have been reported to be useful [Yamanishi et al., 1999, Sakakibara et al., 2000; Schulte-Baukloh et al 2002; Moon et al., 2015]. However, most of the studies have been performed on small patient materials with varying diagnoses and all studies have not been positive. In a study of 14 children from age 6 to 16 years with neurogenic bladder and LPP > 40 cm H_2O, Kroll et al. [2016] found no evident efficacy of doxazosin after 6-8 weeks of treatment. Yamanishi et al. [2004] reported in a prospective single-blind randomized study that the combination of a cholinergic drug (bethanechol) and a α_1- AR antagonist (urapidil) was more effective than monotherapy in improving urination in patients with UAB/DUA. Theoretically, the approach of enhancing detrusor contractility and lowering urethral resistance simultaneously seems attractive. However, in the study by Yamanishi et al. [2004], monotherapy with bethanechol seemed to be marginal, and whether the combination therapy really is better than monotherapy with α-AR antagonist has to be confirmed in appropriately designed studies.

1.3. Prostanoids

Previous experimental studies have shown that e.g., prostaglandin (PG) E_2 can both increase detrusor contraction and relax the urethra in humans [Andersson and Wein, 2004]. PGE_2 does not only stimulate detrusor contraction directly, but may also enhance the efficacy of other contraction-mediating transmitters. In addition, PGE_2 can increase afferent activity both by stimulating the urothelial and myogenic pathways [Maggi et al., 1984; 1988].

Intravesical instillation of PGE_2 and other prostanoids has been reported (no controlled randomized trials) to stimulate bladder contractile activity acutely [Andersson et al., 1978; Wagner et al., 1985, Tammela et al., 1987, Schlussler, 1990], but not without side effects (e.g., uterine contraction). Experiences from patients with chronic bladder emptying difficulties [Delaere et al., 1981] or neurogenic bladder dysfunction [Vaidyanathan et al., 1981] have not been encouraging. The question is whether useful actions can be sorted out from the mixture of effects exerted by PGE_2. The effects of this prostanoid are produced through four types of EP-receptors (EP1-EP4), each mediating separate actions [Sugimoto and Narumiya, 2007]. EP1 and EP3 receptors seem to mediate the excitatory bladder effects of PGE_2 both on afferent activity and on smooth muscle, and EP2 receptors are known to mediate bladder and urethral relaxation. Drugs stimulating both EP3 and EP2 receptors simultaneously would have an interesting profile, and provided that they show selectivity for the bladder over e.g., the uterus and the gastrointestinal tract, they should be interesting to test in patients with UAB. ONO-8055 is a highly potent and selective agonist for both EP2 and EP3 receptors on CHO cells [Sekido et al., 2016]. The compound contracted bladder strips and relaxed urethral strips. Awake cystometry in a model of neurogenic bladder (lumbar spinal stenosis) showed that ONO-8055 significantly decreased bladder capacity, residual urine, and voiding pressure. Compared with the vehicle, tamsulosin and ONO-8055 significantly decreased urethral pressure. The authors concluded that ONO-8055had potential to ameliorate neurogenic UAB/DUA. However, to prove this controlled clinical trials are required.

1.4. Transient Receptor Potential (TRP) Channel Agonists

TRP channels are widely distributed in the LUT and stimulation and blockade of these channels may have a potential application for treatment of various voiding disturbances, including UAB/DUA [Everaerts et al., 2008; Andersson et al., 2010; Skryma et al., 2011; Avelino et al., 2013, Franken et al., 2014; Deruyver et al., 2015]. Agents such as capsaicin and resiniferatoxin stimulate bladder activity via activation of Transient Receptor Potential (TRP) channel V1 [Maggi et al., 1989] This should make small molecule TRPV1 agonists an interesting future option for treatment of UAB/DUA, provided that they do not desensitize the afferent nerves.

TRPM4 channels seem to regulate human detrusor smooth muscle excitability and contractility and are critical determinants of human urinary bladder function, actions that may be worthwhile exploring [Hristov et al., 2016].

Even if the pharmacological profile of some of the TRP channel active drugs (based on preclinical studies) seem promising for treatment of UAB/DUA, which agent (s) to choose for further development remains speculative since there are no published clinical experiences.

1.5. 5-Hydroxytryptamine (Serotonin)

Many preclinical studies have shown serotonin, acting on a variety of receptor subtypes both peripherally and on the central nervous system, to have diverse effects on micturition [Ramage, 2006]. If some of these effects were valid also for humans, they would have potential interest for the treatment of UAB/DUA [Ramage, 2006]. Serotonin has a well-established contractile effect on human bladder strips mediated by 5-HT_4 receptors via facilitation of cholinergic neuromuscular transmission [Tonini et al., 1994; Candura et al., 1996], and an occasional case report suggests efficacy in some cases of UAB/DUA with cisapride [Franceschetti et al., 1997], a 5-HT_4 agonist with 5-

HT_3 antagonist activity,widely used to promote gastrointestinal motility, but withdrawn because of cardiac (long QT) side effects [Quigley et al., 2011]. Whether or not analogues without this side effect would be useful can only be speculated on.

1.6. Botulinum Toxin

Kuo [2007] treated 27 patients with idiopathic low detrusor contractility with urethral injection of onabotA. It was found that patients with normal bladder sensation combined with a poor relaxation or hyperactive urethral sphincter were significantly more likely to recover normal detrusor function. Further studies on such patients would be desirable.

Conclusions

The current pharmacological possibilities to effectively treat UAB/DUA are limited. Dependent on the multifactorial pathophysiology of the condition, treatment with approved agents have to be personalised and to be successful therapy has to be directed to both the major mechanism involved and the associated morbidities.

V. HORMONAL TREATMENT OF URINARY INCONTINENCE

1. OESTROGENS

1.1. Oestrogens and the Continence Mechanism

The oestrogen sensitive tissues of the bladder, urethra and pelvic floor all play an important role in the continence mechanism. For women to remain continent the urethral pressure must exceed the intra-vesical pressure at all times except during micturition. The urethra has four oestrogen sensitive functional layers all of which have a role in the maintenance of a positive urethral pressure 1) epithelium, 2) vasculature, 3) connective tissue, 4) muscle.

Two types of oestrogen receptor, (α and β) have been identified in the trigone of the bladder, urethra and vagina as well as in the levator ani muscles and fascia and ligaments within the pelvic floor [Smith et al., 1990; Copas et al., 2001; Gebhardt et al., 2001]. After the menopause oestrogen receptor α has been shown to vary depending upon exogenous oestrogen therapy [Fu et al., 2003]. In addition, exogenous oestrogens affect the remodeling of collagen in the urogenital tissues resulting in a reduction of the total collagen concentration with a decrease in the cross linking of collagen in both continent and incontinent women [Falconer et al., 1998; Keane et al., 1997]. Studies in both animals and humans have shown that oestrogens also increase vascularity in the peri-urethral plexus which can be measured as vascular pulsations on urethral pressure profilometry [Robinson et al., 1996; Endo et al., 2000; Versi and Cardozo, 1986].

1.2. Oestrogens for Stress Urinary Incontinence

The role of oestrogen in the treatment of stress urinary incontinence has been controversial despite a number of reported clinical trials [Hextall, 2000]. Some have given promising results but this may have been because they were small observational and not randomised, blinded or controlled. The situation is further complicated by the fact that a number of different types of oestrogen have been used with varying doses, routes of administration and duration of treatment.

Fantl et al. [1996] treated 83 hypo-oestrogenic women with urodynamic stress incontinence and/or detrusor overactivity with conjugated equine oestrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for three months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables had not changed significantly in either group. Jackson et al. [1996] treated 57 post menopausal women with urodynamic stress or mixed incontinence with Oestradiol 2 mg or placebo daily for six months. There was no significant change in objective outcome measures although both the active and placebo groups reported subjective benefit.

Two meta-analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee the use of oestrogens to treat all causes of incontinence in post menopausal women was examined [Fantl et al., 1994]. Of 166 articles identified, which were published in English between 1969 and 1992, only six were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost, Maximum urethral closure pressure increased significantly but this result was influenced by only one study showing a large effect.

In the second meta-analysis Sultana and Walters [1990] reviewed eight controlled and 14 uncontrolled prospective trials and included all types of oestrogen treatment. They also found that oestrogen therapy was not an efficacious treatment for stress urinary incontinence but may be useful for the often associated symptoms of urgency and frequency. Oestrogen when given alone therefore does not appear to be an effective treatment for stress urinary incontinence.

Several studies have shown that oestrogen may have a role in combination with other therapies e.g. α-adrenoceptor agonists. However, phenylpropamalamine (the most widely used α-adrenoceptor agonist in clinical practice) has now been restricted or banned by the US Food and Drug Administration (FDA).

In a randomised trial Ishiko et al. [2001] compared the effects of the combination of pelvic floor exercise and oestriol (1 mg per day) in 66 patients with post menopausal stress urinary incontinence. Efficacy was evaluated every three months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress incontinent patients in both groups three months after the start of therapy and concluded that combination therapy with oestriol plus pelvic floor exercise was effective and could be used as first line treatment for mild stress urinary incontinence. A further study evaluating the effects of intravaginal oestriol and pelvic floor rehabilitation on urogenital aging in post menopausal women randomised 206 women with symptoms of urogenital aging into two groups of 103 women each. Subjects in the treatment group received intravaginal oestriol ovules 1 mg once daily for 2 weeks and then 2 ovules weekly for a total of six months together with pelvic floor rehabilitation. Subjects in the control group received only intravaginal oestriol. Prior to treatment 83 (80.6%) of the women in the treatment arm complained of stress urinary incontinence compared to 103 (100%) of the control women. At the end of the study only 22 (21.4%) of the treated patients suffered from stress urinary incontinence compared to 93 (90.3%) of the control group representing a significant improvement in stress incontinence as a result of this combination therapy [Capobianco et al., 2012]

Thus even prior to the more recently reported secondary analyses of the heart and oestrogens/progestogen replacement study (HERS) [Grady et al., 2001] and women's health initiative (WHI) [Hendrix et al., 2005] it was already recognised that systemic oestrogen therapy alone had little effect in the management of urodynamic stress incontinence [Al-Badr et al., 2003; Robinson and Cardozo, 2003].

1.3. Oestrogens for Urgency Urinary Incontinence and Overactive Bladder Symptoms.

Oestrogen has been used to treat post menopausal urgency and urge incontinence for many years but there have been few controlled trials to confirm that it is of benefit [Hextall, 2000]. A double blind multi centre study of 64 post menopausal women with "urge syndrome" failed to show efficacy [Cardozo et al., 1993]. All women underwent pre-treatment urodynamic investigation to ensure that they had either sensory urgency or detrusor overactivity. They were randomised to treatment with oral oestriol 3 mg daily or placebo for three months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Oestriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another randomised controlled trial from the same group using 25 mg Oestradiol implants confirmed the previous findings [Rufford et al., 2003], and furthermore found a higher complication rate in the Oestradiol treated patients (vaginal bleeding).

Symptoms of an overactive bladder increase in prevalence with increasing age and lower urinary tract symptoms and recurrent urinary tract infections are commonly associated with urogenital atrophy. Whilst the evidence supporting the use of oestrogens in lower urinary tract dysfunction remains controversial there are considerable data to support their use in urogenital atrophy and the vaginal route of administration correlates with better symptom relief by improving vaginal dryness, pruritis and dyspareunia, greater improvement in cytological findings and higher serum oestradiol levels [Cardozo et al., 1998]. Overall vaginal oestradiol has been found to be the most effective in reducing patient symptoms although conjugated oestrogens produced the most cytological change and the greatest increase in serum oestradiol and oestrone. The most recent meta anlysis of intravaginal oestrogen treatment in the management of urogenital atrophy was reported by the Cochrane group in 2012 (Cody et al., 2012) Overall 34 trials including 19676 incontinent women of whom 9599 received oestrogen therapy (1464 involved in trials of local vaginal oestrogen adinistratoin). The trials used varying combinations of oestrogen, dose, duration of treatment and length of follow up. The combined result of six trials of systemic administration (oral oestrogen) resulted in worse incontinence then placebo. However, there was some evidence that oestrogen used locally as vaginal creams or pessaries improved incontinence. Overall thefre was less frequency and urgency in those women treated with local oestrogen.

Thus, theoretically there could be a role for combination treatment with an antimuscarinic agent and vaginal oestrogen in post menopausal women. However, the three clinical trials which have been reported to date differ in their outcome. Tseng et al. [2009] showed superior efficacy in terms of symptom improvement for the overactive bladder when Tolterodine was used with vaginal oestrogen cream as opposed to Tolterodine alone. However, Serati et al. [2009] found no difference between Tolterodine with or without topical oestrogen in women with symptomatic detrusor overactivity. A further study compared the efficacy and safety of solifenacin succinate versus solifenacin succinate with local oestrogen for the treatment of overactive bladder in 104 post menopausal women randomised to receive either solifenacin 5 mg daily plus Promestriene vaginal capsules or solifenacin alone. The primary outcome measure was changed from baseline to end of treatment in the mean number of voids per 24 hours, quality of life was assessed using international prostate symptom score and overative bladder symptoms score questionaires. The median decreases in number of voids in 24 hours in the two groups were 5.4 and 4.3 respectively which was not statistically different. The median decrease in urgency episdoes was 2.0 and 2.5 resptively. In addition, the quality of life scores significantly changed in both groups (both the <0.05). The author

concluded that solifenacin with or without local oestrogen was effective and safe for overactive bladder treatment in post menopausal women. The addition of local oestrogen improved subjective feelings and quality of life [Jiang et al., 2016].

There has been one study comparing the oestradiol vaginal ring with oral oxybutynin for treatment of overactive bladder [Nelken et al., 2011]. Participants were randomised to receive either the ultra low dose oestradiol vaginal ring or oral oxybutynin for 12 weeks. The primary outcome was a decrease in the number of voids in 24 hours. Secondary outcomes were quality of life questionaires, vaginal ph levels and vaginal maturation index. 59 women were enrolled, 31 were randomised to receive oxybutynin whereas 28 received oestradiol vaginal ring. Women who received oxybutynin had a mean decrease of 3.0 voids per day and women who received the vaginal ring had a mean decrease of 4.5 voids per day with no significant difference between the groups. There was a significant improvement in urogenital distress infantry and incontinence impact questionnaire scores in both groups with no significant difference in improvement between the two groups, thus ultra low dose oestradiol releasing vaginal ring and oral oxybutynin seemed to be similarly effective in decreasing the number of daily voids in post menopauasal women with overactive bladder.

1.4. Evidence Regarding Oestrogens and Incontinence from Large Clinical Trials.

The HERS study included 763 post menopausal women under the age of 80 years with coronary heart disease and intact uteri [Grady et al., 2001]. It was designed to evaluate the use of oestrogen in secondary prevention of cardiac events. In a secondary analysis 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated oestrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (N=768) or placebo (N=757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared to 21% assigned to hormones whilst 27% of the placebo group worsened compared with 39% of the hormone group (P=0.001). This difference was evident by four months of treatment, for both urgency and stress urinary incontinence. The number of incontinence episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group ($p< 0.001$). The authors concluded that daily oral oestrogen plus progestogen therapy was associated with worsening urinary incontinence in older post menopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence. However, it is possible that the progestogen component may have had an influence on the results of this study.

The Women's Health Initiative (WHI) was a multi centre double blind placebo controlled randomised clinical trial of menopausal hormone therapy in 27347 postmenopausal women age 50-79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23296 participants at baseline and one year [Hendrix et al., 2005]. The women were randomised based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg per day of conjugated equine oestrogen (CEE) plus 2.5 mg per day of medroxyprogesterone Acetate (CEE+MPA), whereas those who had undergone hysterectomy received oestrogen alone (CEE). At one year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline. The risk was highest for stress urinary incontinence CEE+MPA: RR, 1.7 95% continence interval) CI (1.61-2.18); CEE alone RR 2.15 mg, 95% CI, 1.77-2.62, followed by mixed urinary incontinence CEE+MPA: RR 1.49 95% CI 1.10-2.01. On CEE alone RR was 1.79 95% CI, 1.26-2.53. The combination of CEE and MPA had no significant effect on developing urge urinary incontinence RR, 1.15; 95% CI, 0.99-1.34 but CEE alone increased the risk RR 1.32; 95% CI, 1.10-1.58. For those women experiencing urinary incontinence at baseline frequency worsened in both active groups CEE+MPA; RR, 1.38 95% CI 1.28-1.49; CEE alone: RR, 1.47 95% CI, 1.35-1.61. Quantity of urinary incontinence worsened at one year in both active groups, CEE+MPA: RR, 1.20 95% CI, 1.06-1.76; CEE alone: RR, 1.59 95% CI, 1.39-1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities CEE+MPA: RR 1.18 95% CI, 1.06-1.32. CEE alone: RR 1.29 95% CI, 1.15-1.45 at one year. Thus, based on this secondary analysis of data from a huge study conjugated equine oestrogen alone or in combination with Medroxyprogesterone Acetate was shown to increase the risk of urinary incontinence amongst continent women and worsen urinary incontinence amongst asymptomatic women after one year of therapy.

The Nurses Health Study [Grodstein et al., 2004] was a biennial postal questionnaire starting in 1976. In 1996 39436 post-menopausal women aged 50-75 years was reported no urinary leakage at the start of the study were followed up for four years to identify incident cases of urinary incontinence. 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased amongst post menopausal women taking hormones compared to women who had never taken hormones (oral oestrogen: RR1.54 95% CI 1.44, 1.65; transdermal oestrogen: RR1.68, 95% CI 1.41, 2.00; oral oestrogen with progestin: RR1.34, 95% CI 1.24, 1.44; transdermal oestrogen with progestin: RR1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping

hormones the risk was identical in women who had and who never had taken hormone therapy.

The most recent meta analysis of the effect of oestrogen therapy on the lower urinary tract has been performed by the Cochrane Group [Cody et al., 2012] and is notable as the conclusions are starkly different from those drawn from the previous review [Moehrer et al., 2003]. Overall 34 trials were identified including 19676 incontinent women (1464 involved in trials of local administration) of which 9599 received oestrogen therapy.

Systemic administration (of unopposed oral oestrogens – synthetic and conjugated equine oestrogens) resulted in worse incontinence than placebo (RR1.32; 95% CI: 1.17-1.48). Although this is heavily influenced by the size of the WHI study [Hendrix et al 2005]. When considering combination therapy there was a similar worsening effect on incontinence when compared to placebo (RR1.11; 95% CO: 1.04-1.08). There was some evidence suggesting that the use of local oestrogen therapy may improve incontinence (RR0.74; 95% CI: 0.64-0.86) and overall there were 1-2 fewer voids in 24 hours and less frequency and urgency.

The authors conclude that local oestorgen therapy for incontinence may be beneficial although there was little evidence of long term effect. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition they report that there are too few data to comment reliably on the dose type of oestrogen and route of administration.

2. GENITOURINARY SYNDROME OF MENOPAUSE

Following a consensus conference held in 2013 the Board of Directors of the International Society for the Study of Women's Sexual Health (ISSWSH) and the Board of Trustees of the North American Menopause Society (NAMS) acknowledged the need to review current terminiology associated with genitourinary tract symptoms related to menopause [Portman et al., 2014]. They agreed on the new term Genitourinary Syndrome of Menopause (GSM) as a more accurate all encompassing and publically acceptable term than vulvo-vaginal atrophy. As well as genital symptoms this covers the urinary symptoms of urgency, dysuria and recurrent urinary tract infections. It has long been appreciated that these symptoms respond well to low dose local (intravaginal) oestrogen therapy given long term to post menopausal women [Baber et al., 2016]. The most recent Cochrane review included 16 trials with 2129 women and intravaginal oestrogen was found to be placebo in terms of efficacy although there were no differences between types of formulation. Fourteen trials compared safety between the different vaginal preparations and found a higher risk of endometrial stimulation with conjugated equine oestrogens as compared to oestradiol [Suckling et al., 2003]. However, since then the traditional 25 microgram twice weekly dose of oestradiol vaginal tablets has been replaced by the ultra low dose 10 microgram twice weekly vaginal tablet [Simon & Maamari, 2013]. This has unfortunately led to reduced efficacy and does not appear to be adequate for the control of overactive bladder symptoms in post menopausal women, 50% of whom may suffer from genitourinary syndrome of the menopause if untreated.

3. OTHER HORMONES

Progesterone and progestogens are thought to increase the risk of urinary incontinence. Lower urinary tract symptoms especially stress urinary incontinence have been reported to increase in the progestogenic phase of the menstrual cycle [Hextall et al., 2001]. In similar studies, progesterone has been shown to increase beta adrenergic activity leading to a decrease in the urethral closure pressure in female dogs [Raz et al., 1973]. However, in the WHI there appeared to be no difference whether or not progestin was given in addition to oestrogen [Hendrix et al., 2005].

Selective oestrogen receptor modulators (SERMS) have been reported to have varying effects. Each of the SERMS has receptor ligand conformations that are unique and have both oestrogenic and anti oestrogenic effects. In the clinical trials of levormeloxifene there was a fourfold increase in the incidence of incontinence leading to cessation of the clinical trial [Hendrix et al., 2001]. However, raloxifene has not been shown to have any effect at all on urinary incontinence [Waetjen et al., 2004]. There are no reported clinical trials evaluating the effect of androgens, and in particular testosterone, on urinary incontinence in women.

Conclusions. Oestrogen has an important physiological effect on the female lower urinary tract and its deficiency is an aetiological factor in the pathogenesis of a number of conditions. However, the use of oestrogen either alone or in combination with progestogen has yielded poor results. The current level 1 evidence against the use of systemic oestrogen for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have only been based on self reported symptoms of urinary leakage without any objective data. Despite this all of these large randomised controlled trials show a worsening of pre-existing urinary incontinence both stress and urgency and an increased new incidence of urinary incontinence with both oestrogen and oestrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine oestrogen and this may not be representative of all oestrogens taken by all routes of administration.

In a systematic review of the effects of oestrogens for symptoms suggestive of an overactive bladder the

conclusion was that oestrogen therapy may be effective in alleviating OAB symptoms, and that local administration may be the most beneficial route of administration [Cardozo et al., 2004]. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency and urge incontinence may be a manifestation of genitourinary syndrome of menopause atrophy in older post menopausal women rather than a direct effect on the lower urinary tract [Robinson and Cardozo, 2003]. Whilst there is good evidence that the symptoms and cytological changes of urogenital atrophy may be reversed by low dose (local) vaginal oestrogen therapy there is currently no evidence that oestrogens with or without progestogens should be used in the treatment of urinary incontinence. The International Menopause Society (IMS) has produced new 2016 recommendations on women's midlife health and menpause hormone therapy (MHT) to help guide healthcare professionals in optimising their management of women in menopause transition and beyond. They have given a Grade A recommendation to the use of local oestrogens for urogenital symptoms and a Grade B recommendation for the long-term use of such treatment. They have also allocated a Grade B recommendation to the use of low dose local oestrogens in the management of recurrent lower urinary tract infection [Baber et al., 2016].

4. DESMOPRESSIN

The endogenous hormone vasopressin (also known as anti-diuretic hormone) has two main functions: it causes contraction of vascular smooth muscle and stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors of which there are two major subtypes, namely the V_1 and V_2 receptors. The V_2 subtype is particularly important for the anti-diuretic effects of vasopressin. A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V_2 receptor can cause nephrogenic diabetes insipidus [Insel et al., 2007]. Accordingly, decreased vasopressin levels are believed to be important in the pathophysiology of polyuria, specifically nocturnal polyuria, which can lead to symptoms such as nocturia [Matthiesen et al., 1996; Weiss et al., 2011a]. Nocturia is currently defined by the International Continence Society (ICS) as the complaint that an individual has to wake at night one or more times to void. It is, however, "an underreported, understudied, and infrequently recognized problem in adults" [Weiss et al., 2011b]. Nocturia leads to decreased quality of life [Kupelian et al., 2011], and has been associated with both increased morbidity and mortality [Nakagawa et al., 2010; Kupelian et al., 2012]. While it remains largely unknown in which fraction of patients nocturia can indeed be explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioural factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist. While it remains largely unknown in what fraction of patients nocturia is explained by too little vasopressin, the presence of nocturnal polyuria in the absence of behavioral factors that can explain it (e.g. excessive fluid intake) is usually considered to indicate decreased vasopressin levels [Bosch and Weiss., 2011, Weiss et al., 2011b]. Based upon these considerations, vasopressin receptor agonists have been used to treat nocturia, both in children and in adults. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for anti-diuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration [Rittig et al., 1998]. Because of symptomatic hyponatremia with water intoxication which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin [Thumfart et al., 2005; Robson et al., 2007; Van de Walle et al., 2010], the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate (MELT) formulation requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, cross-over study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children. A recent study confirmed the superior pharmacodynamic characteristics of desmopressin MELT to desmopressin tablets [De Guchtenaere et al., 2011].

The use of desmopressin in children with nocturnal enuresis was comprehensively reviewed by the Cochrane Collaboration in 2002 [Glazener et al., 2002]. These authors evaluated 47 randomized controlled trials involving 3448 children, of whom 2210 received desmopressin. According to their analysis, desmopressin was effective relative to placebo in reducing bed-wetting (e.g. a dose of 20 µg resulted in a reduction of 1.34 wets/night (95% CI 1.11; 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that desmopressin suppresses symptom enuresis but does not cure the underlying cause. The Cochrane Group have reviewed a total of 40 randomised or quasi-randomised controlled trials of 1780 children who were in enrolled receiving an active drug other than desmopressin or a tricyclic. Thirtyone different drugs or classes of drug were tested. For drugs versus placebo, when compared to placebo indomethacin, diazepam, mestorelone and atomoxetine appeared to reduce the number of children failing to

have 14 consecutive dry nights. Althogh indomethacin and diclofenac were better than placebo during treatment, they were not as effective as desmopressin and there was a higher chance of adverse effects [Desphande et a., 2012]. Additionally, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates [Alloussi et al., 2011]. The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates as well as a lower relapse rate than desmopressin alone [Austin et al., 2008; Alloussi et al., 2009). A recent Cochrane Review has shown that when Imipramine combined with Desmopressin was compared with Imipramine monotherapy there was no different in outcomes. However, when imipramine plus desmopressin was compared with desmopressin monotherapy the combination was more effective with 15% not achieving 14 consecutive dry nights at the end of treatment for imipramine plus demospressin versus 40% for desmopressin monotherapy [Caldwell et al., 2016]. For non-responders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic receptor antagonists may be ineffective in such children (De Guchtenaere et al., 2007; Neveus and Tullus, 2008). A study of enuresis patients thought to be resistant to desmopressin who were subsequently referred to a specialist centre showed that 1/3 of the children could become dry on desmopressin monotherapy under specialist care once their daytime symptoms had been addressed [Rittig et al., 2014]. This has led to recommendations for maximising the chances of treatment success in patients receiving desmopressin [Kamperis et al., 2016]

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms “desmopressin” and “nocturia” was performed and limited to clinical studies of *de novo* nocturia, i.e. those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis [Eckford et al., 1994;1995]. One study with single dose administration reported a reduction in nocturnal polyuria, but by design did not assess nocturia [Eckford et al., 1995]. Three placebo-controlled double-blind studies with a small patient number (16-33 patients total per study) reported a significant reduction in nocturia [Hilton et al., 1983; Eckford et al., 1994; Valiquette et al., 1996]. Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 h after desmopressin administration rather than nocturia as their primary endpoint. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious [Kinn and Larsson, 1990; Fredrikson, 1996; Hoverd and Fowler, 1998]. While desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment due to asymptomatic or minimally symptomatic hyponatremia [Valiquette et al., 1996]. Accordingly, desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients [Cvetkovic and Plosker, 2005]. In a small open-label study, desmopressin was also reported to reduce nocturnal polyuria in spinal cord injury patients [Zahariou, Karagiannis et al. 2007].

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurological damage. The recruited patient populations were based upon different criteria, including having at least two nocturia episodes per night or having nocturnal polyuria. Earlier studies mostly used a desmopressin dose of 20 µg given either orally [Asplund et al., 1999] or intranasally [Hilton and Stanton, 1982; Cannon et al., 1999], and tended to be very small (≤25 patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1-0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults [Mattiasson et al., 2002; Lose et al., 2003; van Kerrebroeck et al., 2007]. A total of 632 patients entered the dose-titration phase and 422 patients entering the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose titration phase, all patients in the NOCTUPUS trials were washed-out following the dose-titration phase and in order to be randomized, it was a requirement that the patients returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2 or 0.4 mg) is effective in both men and women aged ≥ 18 years with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared to 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as ≥ 50% reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo. In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

Weiss and colleagues reported outcomes on a four week multi centre randomised double blind placebo controlled trial to determine the efficacy of orally disintegrating sub-linguinal Desmopressin i.e., ” melt” formulation. The authors randomised patients to 10, 25, 50 and 100 micrograms. Approximately 90% of the subjects reported true nocturnal polyuria, 710 patients completed the study. A statisically significant difference in the number of nocturnal voids was seen for all patients with a 100 micrograms and 50 micrograms. Women responded to 25 micrograms as well, however for men there was only a statistically

significant difference with 100 micrograms. The proportion of patients with at least a 33% reduction in the number of nocturnal voids (primary outcome measure) increased with dosage for all patients but there was a stronger response seen in women at 25 micorgrams. A total of 24 patients (3%) experienced hyponatremia which was a more likely occurence in patients over the age of 65 years [Weiss et al., 2012].

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10-12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response [Lose et al., 2004]. An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects [Johnson et al., 2006].

Around 75% of community-dwelling men and women with nocturia (≥2 voids/night) have nocturnal polyuria (NP) [Rembratt et al., 2003; Swithinbank et al. 2004]. The key urological factors most relevant to nocturia are NP and OAB in women [Irwin et al., 2008], and NP and benign prostatic hyperplasia (BPH) in men. About 74% of women with OAB have nocturia and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP; 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or bladder outlet obstruction [Chang et al., 2006]. Therefore, desmopressin combination therapy with α_1- adrenergic blockers and/or anticholinergics should be considered for patients with treatment–resistant nocturia. Seventy-three percent of α_1- adrenergic blocker-resistant BPH patients experienced a ≥50% reduction in nocturnal voids with oral desmopressin [Rembratt et al., 2003; Yoong et al., 2005]. A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low dose (0.1 mg) oral desmopressin in elderly (≥ 65 years) patients reported that low dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH [Wang et al., 2011a].

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, non-randomized pilot study of men believed to have BPH, desmopressin was reported to improve not only nocturia, but also to reduce the overall international prostate symptom score (IPSS) [Chancellor et al., 1999]. An exploratory, placebo-controlled double-blind study in women with daytime urinary incontinence reported that intranasal administration of 40 μg desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg oral desmopressin reported a reduction in voids along with an improvement in quality of life (QoL) [Hashim et al., 2009]. While these data indicate that desmopressin may be effective in treating voiding dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared to placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side-effects of demopressin usage is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. The risk of hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume [Rembratt et al., 2003; 2006]. Based on a meta-analysis, the incidence is around 7.6% [Weatherall, 2004]. Increased age and female gender are well-known risk factors for the development of desmopressin-induced hyponatremia [Rembratt et al., 2006]. Bae et al. [2007] assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (greater than 3 voids nightly), who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration serum sodium should be assessed regularly, at least every 6 months.

There has been some research exploring gender differences in the antidiuretic response to desmopressin. Juul et al. [2011] found an increasing incidence of hyponatremia with increasing dose, and at the highest dose level of 100 μg decreases in serum sodium were approximately twofold greater in women over 50 yr of age than in men. A new dose recommendation stratified by gender was suggested in the treatment of nocturia: for men, 50- to 100 μg melt was suggested to be an efficacious and safe dose, while for women a dose of 25 μg melt was recommended as efficacious with no observed incidences of hyponatremia. Weiss and colleagues investigated the efficacy and safety of 50 and 75 micrograms Desmopressin orally disintegrating tablets in 385 men with nocturia. They showed that both doses increased the time to first void from baseline by approximately 40

minutes compared to placebo. The response to Desmopressin was seen within a week of treatment and was sustained producing signficant increases in health-related quality of life and sleep quality compared to placebo. Only 2 subjects aged 74 and 79 years respectively developed hyponatremia [Weiss et al., 2013]. A similar study carried out in women explored the efficacy and safety of 25 micrograms of desmopressin orally disintegrating tablets compared to placebo. 261 women with nocturia were randomised to either 25 micrograms of desmopressin or placebo. Desmopressin significantly reduced the mean number of nocturnal voids compared to placebo and increased the mean time to first noctunral void by 49 minutes compared to placebo. Once again response was seen within the first week of treatment and sustained throuhgout the 3-month trial. Desmopressin was well tolerated with only three transient decreases in serum sodium level [Sand et al., 2013].

Initiation of desmopressin is currently not indicated for patients aged ≥65 years. The mechanisms behind desmopressin-induced hyponatraemia are well understood, and serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk of developing the condition. Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to recommended dosing, should be followed to minimize the risk of hyponatremia [Vande Walle et al., 2007].

Desmopressin is useful for patients with nocturia as well as for children with nocturnal enuresis. The drug has been proven to be well-tolerated and effective by several randomized, placebo-controlled trials and is recommended as a first-line treatment (either as monotherapy or in combination with other agents) for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see Table 2.

VI. CONSIDERATIONS IN THE ELDERLY

The mainstay of pharmacological therapy for OAB in the elderly has been antimuscarinic agents. However, antimuscarinics may be associated with side effects that result in poor persistence and contribute to the anticholinergic burden of polypharmacie. Since antimuscarinics and β_3-AR agonists (mirabegron) are similarly efficacious, and mirabegron has a more favorable tolerability profile than antimuscarinics amongst older patients, this drug was suggested to provide an improved benefit-to-risk ratio and therefore should be considered as an alternative to antimuscarinics for older patients [Wagg et al., 2016]. Until recently, few studies had specifically evaluated the efficacy and safety of antimuscarinics in the treatment of OAB symptoms in elderly patients.

1. ANTIMUSCARINIC AGENTS – EFFICACY AND TOLERABILITY

The efficacy of antimuscarinic agents for treating symptoms of overactive bladder and urge urinary incontinence in older people is similar to that observed in younger and middle-aged adults. Age-related pooled results or sub-analyses from randomized controlled trials of tolterodine [Malone-Lee et al., 2001, Zinner et al., 2002], solifenacin [Wagg et al., 2006], darifenacin [Foote et al., 2007], fesoterodine [Kraus et al., 2010; Sand et al., 2012; see Wagg et al., 2015], and trospium chloride [Sand et al., 2011] indicate that reductions of 25-75% in urgency urinary incontinence episodes can be expected with use of these agents in older (65+) adults. Higher doses may be needed in those over age 75 [Kraus et al., 2010]. In a post-marketing surveillance study of darifenacin, Michel et al. [2010] found that increasing age was negatively associated with improvements in urgency episodes and incontinence, with a statistically significant, but non-clinically relevant effect (0.01 more urgency episodes per year of age). Older adults may derive greater benefit from use of a combined drug and behavioural therapy regime as compared to treatment with drug therapy alone [Burgio et al., 2000]. Dry mouth is the most frequently reported treatment-related adverse event, however overall tolerance has been reported as good to excellent with fewer treatment-motivated withdrawals in recent trials of older patients persisting on antimuscarinic therapy [Sand et al., 2012; Sand et al., 2011a;b]. Constipation is also common and may be particularly bothersome for older adults already suffering from chronic bowel dismotility [Meek et al., 2011, Gallegos-Orozco et al., 2012].

However, the therapeutic effectiveness and tolerability of antimuscarinic agents in the elderly in the real-world practice setting may differ from the results obtained in randomized controlled trials for several reasons. First, research trials generally exclude individuals with concomitant consumption of other anticholinergic agents. In practice, older adults are a heterogeneous group, often consuming many medications that may augment, desensitize or alter the response to antimuscarinic therapy. As well, there is a higher prevalence of comorbidity among the elderly, which can further reduce treatment efficacy and heighten the potential for side effects to occur (see the Section on Incontinence in the Frail Elderly). Failure to acknowledge the multifactorial nature of urinary incontinence in the elderly often leads to sub-optimal treatment. Urgency symptoms may be exacerbated by consumption of caffeinated beverages, pelvic floor muscle weakness, diuretics or other functional and systemic dysfunctions. Treatment should therefore address all possible etiologies, and not be limited to a solitary intervention.

2. ANTIMUSCARINIC AGENTS – COGNITIVE SAFETY

A growing body of literature has emerged to address the concern that antimuscarinic agents used to treat symptoms of overactive bladder may cross the blood-brain barrier and provoke subtle or not so subtle cognitive impairment [Callegari et al, 2011; Jakobsen SM et al., 2011; Wagg et al., 2010; Pagoria et al., 2011; Gray et al., 2015]. Higher cumulative anticholinergic use seems to be associated with an increased risk for dementia [Gray et al., 2015]. Large randomized controlled trials were not designed to adequately measure central nervous system adverse events [Paquette et al., 2011]. As a result, evidence on the relative risk of different antimuscarinic agents for crossing the blood brain barrier and inducing changes in cognitive comes primarily from in-vitro studies and experimental studies using detailed neuropsychological testing.

Early studies suggested that administration of anticholinergic agents such as scopolamine could impair memory and attention in older adults, and possibly induce hallucinations and confusion [Flicker et al., 1992; Sperling et al., 2002]. Oxybutynin, in particular, due to its small molecular size and increased propensity to cross the blood-brain barrier, has consistently shown potential to elicit cognitive impairment in new users after a single high dose of this agent or at steady state, and should be avoided in the elderly [Donellan et al., 1997; Katz et al., 1998; Kay et al., 2008, Wesnes et al., 2009]. Katz et al. [1998] used a double-blind, placebo-controlled cross-over design to test a convenience sample of 12 healthy continent older adults, and revealed cognitive decrements on seven of fifteen cognitive measures resulting from oxybutynin use. Impairments were observed in verbal learning, memory, reaction time, attention, concentration and psychomotor speed. In a sleep study, oxybutynin was found to significantly alter EEG patterns compared to placebo [Todorova et al., 2001]. Oxybutynin was compared to darifenacin and placebo in a 3-week randomized multicentre double-blind parallel-group study in 150 healthy volunteers aged 60-83 [Kay et al., 2006]. Darifenacin produced no impairments compared to placebo at 3-weeks, but oxybutynin caused significant memory deterioration in delayed recall compared to the other two groups. Darifenacin was associated with significantly slower reaction times than placebo in the Divided Attention Test, but not in other tests of information processing speed. Oxybutynin also reduced accuracy scores for immediate recall in one of three tests. Wesnes et al. [2009] showed in a single-dose crossover study with 12 healthy older volunteers that oxybutynin IR 10 mg induced significant deficits in attention and memory compared to placebo, whereas solifenacin 10 mg did not.

Studies with the antimuscarinic agents solifenacin, trospium chloride ER and darifenacin suggest that these agents confer significantly lower cognitive risk than oxybutynin. Administration of trospium chloride ER to 12 cognitively intact adults with overactive bladder aged 65-75 was found to have no effect on memory testing with the Hopkins Verbal Learning Test on day 10 post-administration compared to baseline, and was also found to be undetectable in the cerebral spinal fluid of participants [Staskin et al., 2010]. In a study of darifenacin among 129 older adults aged 65-84, no significant effects on cognition were observed (memory scanning sensitivity, speed of reaction time, and word recognition) compared with placebo [Lipton et al., 2005]. No data on fesoterodine and memory were found.

New onset delirium also does not appear to be a significant concern in patients taking antimuscarinic agents. Although several published case reports have documented the acute onset of delirium following initiation of tolterodine, in incontinent adults with and without dementia [Womack and Heilman, 2003; Salvatore et al., 2007; Williams et al., 2004; Tsao et al., 2003], these deficits resolved upon discontinuation or dose reduction of tolterodine. In a randomized controlled study of extended-release oxybutynin in nursing-home residents with mild to severe dementia, there was no incidence of delirium over the duration of the study [Lackner et al., 2008]. Furthermore, more recent evidence puts into question the traditionally held belief that new use of anticholinergic agents provokes incident delirium in hospitalized older patients [Campbell et al., 2011; Luukkanen et al., 2011].

Taken together, increasing evidence suggests that with the exception of oxybutynin, use of the other antimuscarinic agents poses little or no cognitive risk to otherwise healthy older adults with symptoms of overactive bladder [Esin et al., 2015]. However, two caveats apply. First, the integrity of the blood brain barrier may be compromised in many older adults with cerebrovascular disease, diabetes, or certain forms of dementia, with the results of studies in healthy older adults not generalizable to frailer individuals [Kay et al., 2005]. Second, long-term use of anticholinergic agents over months or years may yield more detrimental cognitive effects than single dose or short-term use. A number of large observational studies have linked chronic consumption of anticholinergic drugs with an increased risk of cognitive impairment, although most studies simultaneously examined the cumulative effect of drugs with any anticholinergic properties rather than each drug class alone [Ancelin et al., 2006; Campbell et al., 2009; Fox et al., 2011, Gray et al., 2015]. The Eugenia study of aging randomly recruited 372 adults 60 years and older from Montpellier, France, and showed that antimuscarinic drug users displayed significantly poorer reaction time, attention, immediate and delayed visuospatial memory, narrative recall, and verbal fluency than did non-drug users [Ancelin et al., 2006]. A 2-year longitudinal study of 13,000 participants enrolled in the Medical Research Council Cognitive Function and Ageing Study also showed that use of medication with anticholinergic effects was associated with a

0.33-point greater decline in the Folstein Mini Mental Status Exam score (95% confidence interval (CI)=0.03-0.64, P=.03) than not taking anticholinergics. Two-year mortality was also greater for those taking (OR=1.68; 95% CI=1.30-2.16; P<.001) anticholinergics. Many commonly prescribed medications in the elderly possess antimuscarinic properties [Chew et al., 2008], so the results may not be specific to bladder antimuscarinics. Other anticholinergic medication include, among others, amytriptyline, clozapine, olanzepine, paroxetine, furosemide, hydrocodone, lansoprazole, levofloxacin, and metformin.

Clinicians who remain wary of prescribing antimuscarinic agents for frail older adults with symptoms of overactive bladder are suggested to proceed with caution in prescribing these medications and fully weigh the risk-benefit ratio in light of other therapeutic options that can be equally effective for urgency and mixed incontinence in the elderly. If antimuscarinics are to be prescribed, a short cognitive screen (such as the Montreal Cognitive Assessment http://www.mocatest.org) or even a full neuropsychological test battery for those patients who are concerned or at risk, before and after initiating therapy might reveal whether subtle impairments have been induced. This is especially pertinent because patients are often unaware of their memory deficits [Kay et al., 2006]. A proxy informant, such as the patient's spouse or a relative, may be able to provide more reliable information on possible cognitive changes resulting from the drugs.

A frequently asked clinical question is whether antimuscarinic agents used to treat incontinence should be contraindicated in patients with dementia already taking cholinesterase inhibitors, as the mechanisms of these two medications are diametrically opposed. A number of small studies have shown that cholinesterase inhibitors used to improve cognition in Alzheimer's disease precipitate urinary incontinence [Hashimoto et al., 2000]. A Japanese study followed 94 patients with mild to moderate dementia treated with donepezil [Hashimoto et al., 2000]. Seven patients developed urinary incontinence, although the event was transient in most patients. In Scotland, among 216 patients with Alzheimer's disease initiating treatment with a cholinesterase inhibitor, incontinence was precipitated in 6.6%, and those with existing incontinence worsened [Starr, 2007]. Epidemiologic studies also show associations between cholinesterase inhibitors and incontinence [Gill et al., 2005; Roe et al., 2002]. In a large population-based cohort study of 44,884 adults with dementia carried out in Canada, those who were dispensed cholinesterase inhibitors were more likely to subsequently receive an antimuscarinic drug for incontinence compared to those not receiving cholinesterase inhibitors (hazard ratio 1.55, 95% confidence interval 1.39-1.72) [Gill et al., 2005]. This finding was confirmed by a separate study in the U.S. documenting a two-fold risk of taking oxybutynin in dementia patients treated with donepezil compared to those not treated with donepezil [Roe et al., 2002]. A Japanese study examined the addition of a 3-month trial of propiverine 20 mg/day to donepezil in twenty-six cognitively impaired older adults, and found improved dryness rates with no deleterious effect on cognition [Sakakibara et al., 2009]. A 6-month study also compared the effects of trospium, galantamine, or trospium plus galantamine in 178 older adults with urge incontinence (n=99), dementia (n=43) or dementia and incontinence (n=36) respectively (Isik et al., 2009). Treatment with 45-60 mg/day of trospium chloride and combined use of trospium with galantamine 24 mg/day was found to have no adverse effect on cognitive or physical function scores in this group of patients. A larger observational study of 3,563 long-term care residents with dementia also failed to document an increased rate of cognitive decline with combined use of a cholinesterase inhibitor and anticholinergic therapy (oxybutynin or tolterodine) compared to cholinesterase therapy alone [Sink et al., 2008]. However, a 50% faster rate of physical function decline was observed in higher-functioning participants on dual therapy compared to cholinesterase inhibitor therapy alone. This evidence suggests the competing mechanisms of the antimuscarinics and cholinesterase inhibitors may indeed have clinical consequences in some, but not all patients.

It has been stated that a dementia diagnosis does not preclude management of incontinence, but it was emphasized that treatment options may be more limited in those with advanced dementia who are unable to retain information and modify behaviors [Orme et al., 2015]

3. ANTIMUSCARINIC AGENTS – CARDIAC SAFETY

Another serious side effect of antimuscarinic drugs in the elderly is the risk of cardiac adverse effects and increased mortality, particularly due to increases in heart rate, prolongation of the QT interval, and induction of polymorphic ventricular tachycardia. These have been previously discussed, and it has been noted that studies specific to the elderly are lacking [Andersson et al., 2011]. Only one study prospectively examined the effect of anticholinergic drug use in 400 community-dwelling older people (aged 75-90 years) with stable cardiovascular disease in Helsinki, Finland [Uusvaara et al., 2011]. Bladder antimuscarinic agents were not examined individually, but were considered in a cumulative assessment of all drugs with anticholinergic properties being taken by the same individual. The unadjusted follow-up mortality was 20.7% and 9.5% among users and non-users of anticholinergic drugs, respectively ($p = 0.010$). However, the use of drugs with anticholinergic properties was not a significant predictor of mortality in multivariate analysis after adjustment for age, sex and other comorbidites (hazard ratio 1.57; 95% CI 0.78, 3.15).

4. ANTIMUSCARINIC AGENTS – DRUG/DRUG INTERACTIONS IN THE ELDERLY

Rates of polypharmacy (> 5 drugs per patient) are high in the geriatric population, and cause potential for drug-drug interactions that increase toxicity or reduce the efficacy of antimuscarinic agents [Chancellor and Miguel, 2007]. The relationship between the number of drugs and potential drug-drug interactions in the elderly is alarming. Consumption of 5 to 7 and 8 to 10 drugs places older adults at a 4-fold and 8-fold increased risk of potentially serious drug-drug interactions respectively, compared with consumption of 2 to 4 drugs [Johnell and Klarin, 2007]. Drug drug interactions frequently involve isoenzymes of the hepatic cytochrome CYP450 system [Zakrzewski-Jakubiak et al., 2011]. Of the antimuscarinic drugs, tolterodine, darifenacin, solifenacin, and oxybutynin are extensively metabolized by CYP450 and are at greater risk of having altered drug metabolism due to hepatic-based drug-drug interactions. Trospium is eliminated renally as unchanged drug, suggesting that it has lower potential for CYP450 drug-drug interactions [Sand et al., 2011]. Trospium may therefore represent a safer treatment option in the context of polypharmacy in the elderly.

5. B_3-AR AGONISTS (MIRABEGRON)

Wagg et al. [2014) performed a prospective subanalysis of individual and pooled efficacy and tolerability data from three 12-week, randomised, Phase III trials, and of tolerability data from a 1-year safety trial in order to evaluate the efficacy and tolerability of mirabegron in subgroups of patients aged ≥65 and ≥75 years. Mirabegron 25 mg and 50 mg once-daily reduced the mean numbers of incontinence episodes and micturitions/24 h from baseline to final visit in patients aged ≥65 and ≥75 years. The drug was well tolerated. In both age groups, hypertension and urinary tract infection were among the most common adverse effects over 12 weeks and 1 year. The incidence of dry mouth, was up to sixfold higher among the older patients randomised to tolterodine than any dose of mirabegron.

Combined treatment for severe symptoms of OAB in elderly men and women with standard doses of solifenacin and mirabegron provided satisfactory therapeutic effect within short period of time without increasing the risk of side effects, and improved the quality of life and self-esteem of patients [Kosilov et al., 2015a]. In elderly men (≥65 years), combination of mirabegron as additional therapy to treatment with α-AR antagonists was effective, particularly if OAB was not controlled with α1-AR-blocker monotherapy. Mirabegron did not have negative effects on voiding function [Matsuo et al., 2016]. The combination of mirabegron with tamsulosin did not seem to cause clinically relevant changes in cardiovascular safety or safety profiles [van Gelderen et al., 2014].

6. DESMOPRESSIN – EFFICACY AND SAFETY IN THE ELDERLY

Desmopressin (DDAVP) (0.1–0.2 mg) reduces nocturia in older persons [Rezakhaniha et al., 2011; Fu et al., 2011; Johnson et al., 2006], but has been associated with significant dose-related hyponatremia in 2-20% of older patients [Fu et al., 2011; Johnson et al., 2006; Weatherall, 2004]. Both female sex and increasing age are risk factors for the development of hyponatremia [Callreus et al., 2005; Rembratt et al., 2006; Juul et al., 2010]. A lower starting dose (0.025 mg) for the melt form has been suggested for older women [Juul et al., 2010] but requires further study. Caution is recommended for the initiation of desmopressin in adults aged 65 years and older at the current time.

7. BONT/A IN OLDER ADULTS

To date no studies have stratified the results of trials using BoNTA/A for the treatment of urinary incontinence in patients with neurogenic bladder according to age. The risk of catheterization due to high post-void residual urine volumes following treatment with botulinum toxin may be higher in older adults, as they are at higher risk of elevated residuals, but this requires systematic investigation.

8. OTHER

None of the other drug classes have undergone rigorous evaluation in the elderly, however a number of general guidelines apply. Use of α-AR agonists and tricyclic antidepressants are discouraged in the elderly due to blood pressure considerations. Uncontrolled systolic hypertension could occur with the former agents and orthostatic hypotension leading to falls with the latter. There is no evidence that hormonal agents are of benefit for urgency or stress incontinence in older women, although local estrogens may be indicated to treat symptomatic vaginal atrophy. Finally, removal of any offending agents that could be contributing to incontinence should be considered.

Thus, proper patient selection for antimuscarinic and any other drug treatment requires careful assessment of underlying physical status including cognitive function, mobility, and comorbidities.
