I. INTRODUCTION

In this chapter the diagnostic and treatment modalities of urinary incontinence in childhood will be discussed. In order to understand the pathophysiology of the most frequently encountered problems in children, we shall also consider the normal development of bladder and sphincter.

Underlying pathophysiology will be outlined and the specific investigations for children will be covered but for general information on epidemiology and urodynamic investigations their respective chapters should be consulted.

1.1. Normal development of bladder and sphincter control

Normal bladder storage and voiding involve low-pressure and adequate bladder volume filling followed by a continuous detrusor contraction that results in bladder emptying, associated with adequate relaxation of the sphincter complex. This process requires normal sensation and normal bladder outlet resistance. The neurophysiological mechanisms involved in normal bladder storage and evacuation include a complex integration of sympathetic, parasympathetic and somatic innervation which is ultimately controlled by a complex interaction between spinal cord, brain stem, midbrain and higher cortical structures (1,2).

Achievement of urinary control is equally complex and as yet not fully understood: various developmental stages have been observed (2,3).

In new-borns, the bladder has been traditionally described as “uninhibited”, and it has been assumed that micturition occurs automatically by a simple spinal cord reflex, with little or no mediation by the higher neural centres. However, studies have indicated that even in full-term fetuses and new-borns, micturition is modulated by higher centres and the previous notion that voiding is spontaneous and mediated by a simple spinal reflex is an oversimplification (4). Fetal micturition seems to be a behavioural state-dependent event: intrauterine micturition is not randomly distributed between sleep and arousal, but occurs almost exclusively while the fetus is awake (4).

During the last trimester the intra-uterine urine production is much higher than in the postnatal period (30ml/hr) and the voiding frequency is approximately 30 times every 24 hours (5).

Immediately after birth voiding is very infrequent during the first few days of life. The first void may only take place after 12 to 24 hours. After the first week frequency increases rapidly and peaks at the age of 2 to 4 weeks to an average of once per hour. It then decreases and remains stable after 6 months to about 10 to 15 times per day. After the first year it decreases to 8 to 10 times per day, while voided volumes increase by three-to-fourfold.

During the postnatal period, micturition control mechanisms undergo further changes and extensive modulation. Using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings it has been shown that even in new-borns the bladder is normally quiescent and micturition does not occur during sleep (6).

This inhibition (or lack of facilitation) of detrusor contractions during sleep is also observed in infants with neurogenic bladder dysfunction who have marked detrusor overactivity while they are awake. In response to bladder distension during sleep, an infant nearly always exhibits clear electro-encephalographic evidence of cortical arousal, facial grimaces or limb movements, or actual awakening. Sleeping infants are always seen to wake up before the bladder contracts and voiding occurs. This arousal period may be transient and the infant may cry and move for a brief period before micturition and then shortly af-

terward go back to sleep. Because this wakening response is already well established in new-borns, it follows that the control of micturition probably involves more complicated neural pathways and higher centres than has been appreciated. There is also strong evidence that a pronounced reorganisation of pre-existing synaptic connections and neural pathways involved in bladder control occurs during the early postnatal period.

In new-borns micturition occurs at frequent intervals and may have an intermittent pattern although bladder emptying efficiency is usually good. In over 80 percent of voids the bladder empties completely (7).

During infancy voiding pressures are much higher than in adults. It has also been noted that these pressures are higher in boys than in girls (mean pdet max of 118 vs. 75 cm H2O, respectively) (8,9).

These higher detrusor pressures decrease progressively with increasing age. In up to 70 percent of infants (up to the age of 3 years) with normal lower urinary tracts, intermittent patterns of voiding were observed. They tend to disappear with increasing age, and are thought to represent variations between individual infants in the maturation of detrusor and sphincteric co-ordination during the first 1 to 2 years of life. Videourodynamic studies have confirmed these findings (6,8-11).

Between the age of 1 and 2, conscious sensation of bladder filling develops. The ability to void or inhibit voiding voluntarily at any degree of bladder filling commonly develops in the second and third years of life. Central inhibition is crucial to obtain continence.

During the second and third year of life, there is progressive development towards a socially conscious continence and a more voluntary type of micturition control develops. The child becomes more aware of the sensation of bladder distension and the need to urinate, as well as social norms and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time, then actively initiate urination even when the bladder is not completely full, and allows urination to proceed to completion. During the first years of life, gradual development to an adult type of voluntary micturition control that conforms to the social norms depends on an intact nervous system, in addition to at least three other events occurring concomitantly:

a) a progressive increase in functional storage capacity,
b) maturation of function and control over the external urinary sphincter,
c) and most importantly, achievement of volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit a micturition reflex (12).

The final steps are usually achieved at the age of 3 to 4 years when most children have developed the adult pattern of urinary control and are dry both day and night. The child has learned to inhibit a micturition reflex and postpone voiding and voluntarily initiate micturition at socially acceptable and convenient times and places. This development is also dependent on behavioural learning and can be influenced by toilet training, which in turn depends on cognitive perception of the maturing urinary tract.

It is understandable that this series of complex events is highly susceptible to malfunction. Various functional derangements of the bladder-sphincter-perineal complex may occur during this sophisticated course of early development of normal micturition control mechanisms. These acquired “functional” disorders overlap with other types of bladder functional disturbances that may have a more organic underlying pathophysiological basis.

2. NORMAL VALUES

2.1. Normal bladder capacity

Bladder capacity increases during the first 8 years of life roughly with 30 ml per year, so with an average capacity of 30 ml in the neonatal period, a child's bladder volume can be calculated as Y = 30 + 30 X, where Y = capacity in ml and X = age in years (Fig 1) (13).

Hjälmås described a linear correlation that could be used up to 12 years of age: in boys, Y = 24.8 X + 31.6, in girls Y = 22.6 X + 37.4, where Y is capacity in ml, and X is age in years (14).

It should be noted that these data were obtained during cystometric investigations. Cystometric capacity is generally less than normal bladder volumes. Obviously, the relation between age and bladder capacity is not linear for all ages, nor is the relation between body weight and bladder capacity (15).

Another formula to calculate bladder capacity in infants is: bladder capacity (ml) = 38 + (2.5 x age (mo)) (11).

Kaefer and co-workers demonstrated that a non-linear model was the most accurate for the relation between age and bladder capacity, and they determined two practical linear equations:

Y = 2 X + 2 for children less than 2 years old, and Y = X/2+6 for those 2 years old or older; Y = capacity in ounces, X = age in years (Fig. 2) (16).

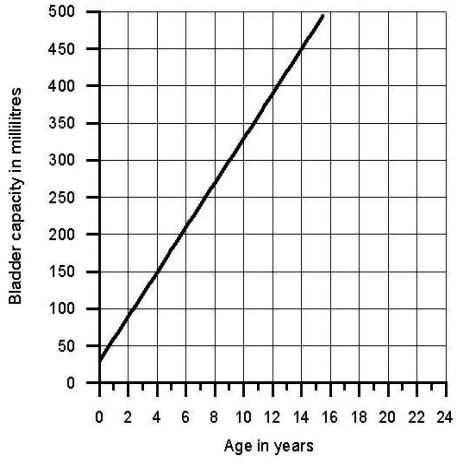

Fig 1. Bladder capacity using the formula

Y = 30 + 30 X

(Y= capacity in ml, X = age in years)

None of these formulae have been acquired from a population based study and do not reflect normal bladder capacity. Normal bladder capacity should be regarded as the maximum voided volume of urine and shows huge variation. Recent work of Rittig et al looked at Maximum Voided Volumes (MVV). The Koff Formula showed a reasonably good correlation with 2836 daytime voids, if first morning voids were neglected (17).

Girls were found to have a larger capacity than boys, but the rate of increase with age was not significantly different between them. Data on 'normal' bladder capacity have been obtained in continent children undergoing cystography, with retrograde filling of the bladder.

Data obtained from the International Reflux Study indicate that there is not a linear relation between age and capacity and that there is a huge variability. (Fig. 3) (18).

2.2. Normal voiding

The micturition frequency of the fetus during the last trimester is approximately 30 per 24 hours. It decreases to 12 during the first year of life, and after that it is gradually reduced to an average of 5±1 voidings per day (11, 16). The normal range for the micturition frequency at age seven is 3 to 7 (19).

By age 12, the daily pattern of voiding includes 4-6 voids per day (20). Mattson and Lindström emphasize the enormous variability of voiding frequencies in children: also in individual children, the weight-corrected diuresis could vary up to 10-fold (21).

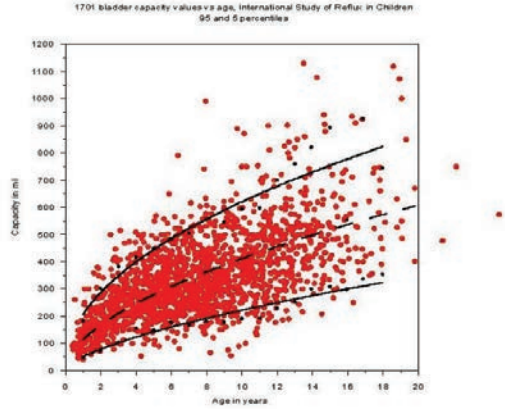

Fig 3. Bladder capacities determined by VCUG in the International Reflux Study

2.3. Normal voiding pressures

Bladder dynamics in children have demonstrated developmental changes with age. Detrusor pressures at voiding in children after the age of 2 years are similar to adults, with a mean maximum pressure of 66 cm H_2O in boys, and 57 cm H_2O in girls (22).

These pressures are lower than those reported in infancy by Yeung et al, who found boys having pressures of 118 cm H_2O and girls 75 cm H_2O (6).

2.4. Normal urinary flow rates

Urinary flow rates in normal children have been only minimally described. Szabo et al published nomograms for flow rates vs. age in normal children (23).

As in adults, flow rates are clearly dependent upon voided volume, and normal values can only be applied to flow rates that have been registered when

Normal urinary flow rates

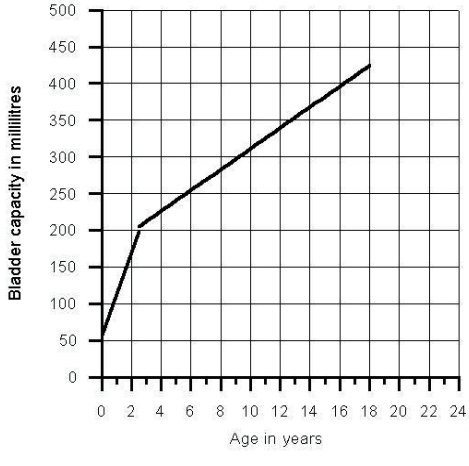

Fig 2. Bladder capacity using the formula

Y = (2 X + 2) x 28.35 ml < 2 years

Y = (X/2+6) x 28.35 ml > 2 years

(Y = capacity in ml, X is age in years)

voiding at a bladder volume approximating the normal capacity for age (21,24).

II. EVALUATION IN CHILDREN WHO WET

Even with clear definitions, the approach to history-taking and physical examination should be structured. The child's complaints at presentation are not synonymous with the signs and symptoms that have to be checked to arrive at a diagnosis. Also, sociocultural aspects and psychomotor development will distort the presentation. The International Children's Continence Society has provided two standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the evaluation of and treatment for monosymptomatic enuresis (1,2). Standardisation reports on urodynamic studies of the lower urinary and on initial diagnostic evaluation, follow-up and therapeutic intervention in congenital neurogenic bladder and bowel dysfunction in children are available (3,4)

Validated questionnaires are very helpful in structuring the history-taking; they at least provide checklists (5). With a structured approach the diagnosis of monosymptomatic nocturnal enuresis can be made with confidence.

When ultrasound imaging of kidneys and bladder, recording of urinary flow, and measurement of post-void residual are added to history and physical examination, the clinical entities caused by functional disturbances of the bladder and sphincter mechanism (non-neurogenic detrusor and pelvic floor dysfunction) can be diagnosed accurately in the majority of cases, and a high level of suspicion can be maintained towards incomplete bladder emptying in both neurogenic pelvic floor dysfunction and structurally caused incontinence. This is important in view of the potential these conditions have to cause irreversible loss of kidney function.

In a minority of incontinent children the non-invasive assessment yields equivocal results, or results suggesting gross deviations from normal function. Only in these situations is there an indication for invasive investigations, such as:

- Voiding cystourethrography.
- Invasive urodynamics (cystometry, pressure/flow/EMG studies, videocystometry).
- Renal scans or intravenous urography.
- Cystourethroscopy.

1. HISTORY TAKING

For the paediatric age group, where the history is jointly obtained from parents and child, and where the failure to develop bladder control generates specific problems, a structured approach with a questionnaire is recommended (5,6).

Level of evidence: 3

Grade of recommendation: B

Many signs and symptoms related to voiding and wetting are new to the parents, and they should be specifically asked for, using the questionnaire as checklist. If possible the child should be addressed as the patient and questioned directly, as the symptoms prompting the parents to seek consultation may be different from those are problematic for the child.

A voiding diary is mandatory to determine the child's voiding frequency and voided volumes. Checklists and frequency volume chart can be filled out at home, and checked at the first visit to the clinic. History-taking should also include assessment of bowel function; a similar proactive process using a questionnaire should be followed for defaecation and faecal soiling (7).

The general history-taking should include questions relevant to familial disorders, neurological and congenital abnormalities, as well as information on previous urinary infections, behavioural problems, relevant surgery and menstrual and sexual function (in pubertal and older children). Information should be obtained on medication with known or possible effects on the lower urinary tract.

The ICCS recommends to screen all children with incontinence with validated questionnaire forms such as CBCL (Achenbach) or Strengths and Difficulties Questionnaire (SDQ) (8,9).

A short screening instrument for psychological problems in enuresis (SSIPPE) and a disease specific quality of life questionnaire for children with LUTD called PinQ are also validated tools available to the clinician (10,11). If a clinically relevant behavioural or emotional disorder is suspected, a full child psychological or psychiatric assessment is recommended (8).

Sexual abuse can be signalled first by symptoms of the lower urinary or gastrointestinal tract (12). However, other more specific symptoms of abuse predominate (13).

Level of evidence: 4

Grade of recommendation: C

2. PHYSICAL EXAMINATION

Apart from a general paediatric examination, the physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 (standing on toes, bulbocavernosus) and anal sphincter tone and control. Special attention should be paid to inspection of the male or female genital region, and of the urethral meatus. Asymmetry of buttocks, legs or feet, as well

as other signs of occult neurospinal dysraphism in the lumbosacral area (subcutaneous lipoma, skin discoloration, hair growth and abnormal gait) should be specifically looked for (14).

In examining the abdomen for the presence of a full bladder, a full sigmoid or descending colon is a significant finding with a history of constipation.

Detailed questioning of the parents' observation of the child's voiding habits is essential as is direct observation of the voiding, if possible. Children may have their voiding dysfunction ameliorated or even eliminated by correcting anomalies of body position detected when observing the child's micturition. Children may void in awkward positions, e.g. with their legs crossed or balancing on the toilet without proper support of the legs, thereby preventing the pelvic floor relaxation and obstructing the free flow of urine (15) (Fig. 4).

Level of evidence: 4

Grade of recommendation: D

3. URINALYSIS

In order to be comprehensive, physical examination should include urinalysis to identify patients with urinary tract infection, diabetes mellitus, diabetes insipidus and hypercalcuria if iindicated (16).

4. NON-INVASIVE TECHNIQUES

The frequency/volume chart is a detailed diary recording each void by time and urine output over 24-hour periods. The chart gives objective information on the number of voidings, the distribution of day and night voids, along with the voided volumes and episodes of urgency and leakage, or dribbling. In order to obtain a complete picture, defaecation frequency and/or soiling are often also recorded: this becomes termed as bladder-bowel diary due to its complexity.

For a complete picture of the child's elimination habits, a 14-day defaecation diary that includes frequency, soiling and stool consistency based on the Bristol Stool Form scale and Rome III criteria should be documented (17).

Fig 4. Improper position for voiding: the feet are not supported (unbalanced position) and the boy is bent forward. Support of the feet will correct this and will allow the pelvic floor muscles to relax properly.

The frequency volume chart provides the maximum storage capacity as the largest voided volume, exclusive of the first morning micturition which reflects overnight urine production and capacity, and is termed maximum voided volume (MVV) (18). MVV should be referenced during cystometry to prevent overfilling. Whenever possible, filling out the chart is the responsibility of the child: the parents provide assistance and support. Ideally the chart should cover 3 complete days, but in reality completion over a weekend restricts the record to 2 days (19). The frequency volume chart is a reliable non-invasive measure of maximum bladder storage capacity and can be used as an outcome measure in children with bladder dysfunction if care is taken to minimise confounding factors and sources of error during chart completion (19). The amount of urine voided by a non-supervised child during the day varies considerably since the child's voidings are dictated more by social circumstances and /or bladder activity rather than by bladder capacity. Children with bladder symptoms void smaller volumes of urine than may be expected from traditional estimates (19). This is unrelated to either gender, type of presenting incontinence or a positive family history of bladder dysfunction. The only significant influence upon voided volumes recorded on a frequency volume chart is the age effect, and voided volumes, even in incontinent children, increase incrementally with age. The frequency volume chart is useful when comparing the mean voided volume and standard deviation by a child's age (20,21).

Validation and test/retest data on frequency/volume charts whilst scarce indicate that voiding interval is the most variable parameter. Data in normal children and in children with different categories of incontinence are available for comparison (19,22,23).

In order to obtain a complete picture it is better to ask for a bladder diary: fluid intake as well as voiding frequency, voided volumes, incontinence episodes and defaecation frequency and/or soiling are recorded.

Test/retest evaluation is not available; trend analyses of frequency/volume charts can be extracted from currently available data.

Grade of recommendation: B

5. QUANTIFICATION OF URINE LOSS

Subjective grading of incontinence may not indicate reliably the degree of dysfunction. For objective grading, 12-hour pad test and frequency/volume charts are validated instruments (23-25).). One should be aware that children tend to do their utmost best when filling out diaries and doing pad tests: underestimation is more the case than overestimation (26).

In children, the 12-hour pad test should also give information about fluid intake. The pad test is complementary to the bladder diary, which denotes more the frequency of incontinence and the distribution of wetting episodes than the quantities of urine lost.

The amount of urine lost during sleep can be determined by weighing diapers or absorbent pads, before and after sleep. To obtain a measure of the total nocturnal urine output, the volume of the early-morning voiding should be added to the amount lost during sleep.

6. SCORING SYSTEMS

At present three scoring systems, based on validated questionnaires have been described. Specific scores correlated with lower urinary tract dysfunction with a specificity and sensitivity of about 90% (27-29).

The value of these scoring systems to determine the cause of incontinence seems to be of limited value to the individual patient, but can be very useful in studies to determine and compare treatment outcome.

Level of evidence: 3

Grade of recommendation: C

6.1. Quantification of constipation

Scoring a plain X-ray of the abdomen (Barr score) yields inconsistent results in grading constipation. (17,30-32) Reproducibility seems to be best using the method described by Leech (33-35). A better way to match clues from the medical history with signs and symptoms is the measurement of colonic transit time. As many children with an overactive bladder habitually use their pelvic floor as an “emergency brake”, anomalous defaecation frequency and constipation have a high prevalence in this group.

Diagnosing constipation is important: we recommend using the Rome III criteria listed in the table below (36).

The Rome III paediatric criteria for functional constipation

Functional constipation

Must include ≥ 2 of the following in a child with a developmental age of ≥ 4 years with insufficient criteria for diagnosis of IBS:

- ≤ 2 defaecations per week
- ≥ 1 episode of faecal incontinence per week
- History of retentive posturing or excessive volitional stool retention
- History of painful or hard bowel movements
- Presence of a large faecal mass in the rectum
- History of large diameter stools that obstruct the toilet

For a complete picture of the child’s elimination habits, a 14-day defaecation diary that includes frequency, soiling and stool consistency based on the Bristol Stool Form scale and Rome III criteria is documented (17).

A non-invasive way to determine faecal retention is the estimation of rectal diameter on ultrasound. In children without constipation the mean diameter was 2, 2.1 and 2.4 cm in three different studies respectively (37-39). In children with constipation the rectal diameter was on average 3.4 cm in the first, 4.9 in the second and 4.2 cm in the third study, significantly different from the non-constipated children. Joensson et al. also re-measured constipated children 4 weeks after treatment with laxatives finding the rectal diameters in the constipation group were significantly reduced ($p < 0.001$) (40).

Finding a dilated and filled rectum on ultrasound while the child feels no need to defaecate probably can replace a digital rectal examination and a distended rectum in ultrasound of 35 mm or more may be one of the signs indicative of constipation.

Overt constipation should be dealt with before embarking on treatment of incontinence or bladder and pelvic floor dysfunction (41,42).

Grade of recommendation: B

7. URINARY FLOW

Voiding should be analysed in detail in all incontinent children, with the exception of monosymptomatic bedwetting, where voiding, as far as we know, is normal. Graphic registration of the urinary flow rate during voiding is a standard office procedure. Flow patterns and rates should be repeated to allow for evaluation, and several recordings are needed to obtain consistency. Afterwards, parents are asked if their child’s flowmetry pattern was representative of their voiding.

Approximately 1% of school children have a voiding that can be labelled abnormal with flattened or intermittent flow curves. The remaining 99% have a bell-shaped flow curve (43). It should be noted that a normal flow does not exclude a voiding disturbance, nor does an abnormal flow pattern automatically means a bladder or voiding dysfunction, as in asymptomatic normal schoolchildren abnormal patterns were also found (44,45).

Flow recordings with a voided volume of less than 50% of the functional capacity are not consistent: they represent voiding on command, and many children will try to comply by using abdominal pressure. On the other hand, overdistension of the bladder can result in abnormal uroflow recordings also (46).

A helpful tool in this respect is the use of trans-abdominal ultrasound (e.g. bladder scan) before micturition in order to assess the bladder volume (47,48). If the bladder is still nearly empty the child should be asked to drink some water until the bladder is full enough for a reliable flow. Urinary flow may be described in terms of rate and pattern and may be continuous, intermittent (in fractions), or staccato (fluctuating). An intermittent flow pattern shows a interrupted flow, whereas in staccato voiding the flow does not stop completely, but fluctuates due to incomplete relaxation of the sphincter.

Measurement of urinary flow is performed as a solitary procedure, with bladder filling by diuresis (spontaneous or forced), or as part of a pressure/flow study, with bladder filling by catheter. Patterns and rates should be consistent to allow for evaluation, and several recordings are needed to obtain consistency (49,50).

The same parameters used to characterise continuous flow may be applicable, if care is exercised, in children with intermittent, or staccato flow patterns (Fig. 2 - 5). In measuring flow time, the time intervals between flow episodes are disregarded. Voiding time is total duration of micturition, including interruptions. (Figures 5 – 8)

Sonographic estimation of Post Void Residual volume completes the assessment. In children >6 years, a repetitive PVR of >20 ml or >10% bladder capacity is considered elevated. In children > 7 years, repetitive PVR>10ml or 6% bladder capacity is regarded as elevated (51). Ideally 3 uroflows are representative but 2 will suffice as this maintains accuracy and consistency.

First morning uroflows should be avoided as they may exceed normal voided volumes

Level of evidence: 3

Grade of recommendation: B

8. ULTRASOUND IMAGING OF UPPER AND LOWER URINARY TRACT

In most clinical settings, ultrasound-imaging techniques are routinely used in children with incontinence. Upper tract abnormalities such as duplex kidney, dilatation of the collecting system, and gross reflux nephropathy can be readily detected, but detection of the more subtle expressions of these abnormalities requires urological expertise on the part of the ultrasound operator (52).

Lower urinary tract abnormalities are even more difficult to assess for the inexperienced, aside from bladder wall thickness: a bladder wall cross-section of more than 3-4 millimetres, measured at 50% of expected bladder capacity, is suspicious of detrusor overactivity (53,54). Because only a few studies have been conducted to compare bladder wall thickness in normal children without complaints and in children with lower urinary tract dysfunction, more studies need to be performed to validate these non-invasive techniques (55,56).

Another possibility is to assess bladder volume and bladder wall thickness to calculate the Bladder Volume / Bladder Wall Thickness index. In children with nocturnal enuresis this index correlated well with response to treatment (57).

8.1. Post-void residual volume

Except in small infants, the normal bladder will empty completely at every micturition (58).

The identification or exclusion of post-void residual is therefore an integral part of the study of micturition. However, an uneasy child voiding in unfamiliar surroundings may yield unrepresentative results, as may voiding on command with a partially filled or overfilled bladder. When estimating residual urine, voided volume and the time interval between voiding and estimation of post-void residual should be recorded. This is of particular importance if the patient is in a diuretic phase. In patients with gross vesicoureteral reflux, urine from the ureters may enter the bladder immediately after micturition and may falsely be interpreted as residual urine. The absence of residual urine is an observation of clinical value, but does not exclude bladder outlet obstruction or sphincter / pelvic floor overactivity with absolute certainty. An isolated finding of residual urine requires confirmation before being considered significant, especially in infants and young children.

8.2. Ultrasound-flow-ultrasound

This combination of imaging and non-invasive urodynamics is a standardised procedure used to obtain representative data on flow rate and flow pattern, as well as post-void residual volumes. With ultrasound, bladder filling is assessed and when the bladder capacity is equal to the functional or expected bladder capacity for age, the child is asked to void into the flowmeter. After recording the flow, post-void residual is assessed again.

This procedure avoids the registration of flow rates at unrealistic bladder volumes.

Alternatively, children can be asked to use a flowmeter at home: a special flowmeter has been designed to use at home (59). For those children who have difficulty voiding in a strange environment, this option can be useful.

9. INVASIVE DIAGNOSTIC TECHNIQUES

The important question (for the incontinent child) "whether invasive diagnostic procedures are necessary" is decided by the results of the non-invasive procedures.

At present, there are no studies indicating that a videocystourethrogram (VCUG) is useful in children with incontinence, but without urinary tract infections.

In general urodynamic studies will only be done if the outcome will alter the management, and this will also depend on whether the possible treatments being considered are invasive. The diagnostic information needed is that which is necessary to find the correct treatment. Indicators include, straining or manual expression during voiding, a weak urinary stream, previous febrile urinary tract infection, continuous dribbling incontinence or pronounced apparent stress incontinence, or previously identified dilating vesicoureteral reflux.

The finding of genitourinary abnormalities or signs of occult spinal dysraphism at physical examination also indicate the need for further diagnostics. Urinary flow registration will detect the plateau-shaped flow curve typical for structural bladder outlet obstruction, and an intermittent flow suggesting detrusor –sphincter- pelvic floor dys-coordination (48).

A clinically significant post-void residual on repeated occasions clearly points to incomplete bladder emptying. The pad test will detect the cases with obvious stress and urgency incontinence, or continuous dribbling. Ultrasound imaging will raise suspicion of an ectopic ureter.

In short, invasive diagnostics are indicated when the non-invasive testing raises suspicion of neurogenic detrusor-sphincter dysfunction (occult spinal dysraphism), obstruction (especially posterior urethral valves), genitourinary abnormalities (e.g. epispadias), advanced non-neurogenic detrusor-sphincter- pelvic floor dysfunction (as in children with vesicoureteral reflux and upper tract dilatation and/or febrile urinary tract infections), or significant post void residuals.

To diagnose the complex of non-neurogenic detrusor-sphincter dysfunction, recurrent urinary tract infections and vesicoureteral reflux, urodynamic studies are needed in only a minority of all children.

9.1. Technique of VCUG in children

Cleanse and rinse the external genitalia with lukewarm water: do not use detergents. Use a feeding tube with side holes and a rounded tip (Ch 06-08) or balloon catheter to catheterise the bladder; check the urine for infection. Empty the bladder completely before filling. Use a radio-opaque dye of maximum 30% concentration, at body temperature, and fill the bladder by slow-drip infusion, with a hydrostatic pressure of not more than 40 cm H2O. Note the volume of the contrast medium instilled. Use fluoroscopy during filling at regular intervals.

Take spot-films (70mm or 90mm camera) with the child in supine position, with partial filling and at the end of filling, in AP projection, of the complete urinary tract. Upper and lower tract should be visible.

When voiding is imminent, change the position of the child so that spot films of bladder and urethra in 3/4 projection can be taken during voiding. Also take a spot film of the upper urinary tract during voiding, as the degree of vesicoureteral reflux (VUR) may change with the pressure generated by the detrusor muscle during voiding. Post-void residual volumes vary very considerably with VCUG. The voiding phase is critically important to VCUG, both for reflux detection and for assessment of voiding dynamics. Without a voiding phase the VCUG is incomplete.

Prophylactic antibiotics are indicated in all children, to minimise the risk for post-VCUG urinary tract infection especially in children with an anatomic abnormality.

9.1.1 Indications for VCUG

A VCUG is an invasive procedure and should only be done if the outcome will influence the management. It is indicated in children with recurrent urinary tract infections to detect reflux, in children with a dilated system on ultrasound and in children with an abnormal flow pattern to detect bladder outlet abnormalities (like valves, strictures or a syringocoele).

In children with incontinence the lateral projection during voiding is the most important part of the study. Especially in children with stress incontinence or a neurogenic bladder the position and configuration of the bladder neck during filling and voiding should be noted.

In children with non-neurogenic detrusor-sphincter-pelvic floor dysfunction as well as in children with neurogenic detrusor-sphincter dyssynergia, the proximal urethra may show the so-called 'spinning top' configuration, during filling and during voiding. With detrusor and pelvic floor muscles contracting at the same time, the force of the detrusor contraction will dilate the proximal urethra down to the level of the forcefully closed striated external sphincter. The resulting 'spinning top' configuration used to be seen as a sure sign of distal urethral stenosis, a concept held responsible for recurrent urinary tract infections in girls, with urethral dilatation or blind urethrotomy as the obvious therapy. However, urodynamics made it clear that the 'spinning top' will only appear when detrusor and pelvic floor contract synchronously, which makes it a functional anomaly, not an anatomical one (60,61).

Women often recall their experience with VCUG as young girls in terms bordering on abuse. The use of

VCUG in children should be limited to the absolutely necessary.

9.1.2 (Video)-Urodynamics

In children urodynamic investigations should only be performed if the outcome will have consequences for treatment (62-64). Furthermore like VCUG it may be considered when invasive or surgical interventions are planned. The main question is whether the urodynamic study will provide new information that cannot be obtained otherwise and will influence the further management. From the few studies that have addressed this issue it can be concluded that urodynamic studies in the majority of cases do not provide significant additional information to justify this type of investigation as a routine procedure in children (65-67).

Both children and parents need careful preparation and adequate information before the study is done. It is an invasive procedure and artefacts may occur. Because of the invasiveness of the investigations all children are anxious and this may be reflected in the outcome of the study. Especially during the first filling cycle, when the child does not know what to expect, detrusor overactivity may be seen and the voiding phase can be incomplete due to contraction or incomplete relaxation of the pelvic floor muscles during voiding. Once the child knows that filling and voiding are not painful a subsequent filling and voiding cycle may show a completely different pattern. The study should be repeated at least 2 or 3 times. Only if during the first filling cycle, no detrusor contractions are seen and also the voiding phase is in accordance with history and uroflow, it is probably sufficient to do only one complete filling and voiding cycle (68).

Still the results may not always be reproducible and it should be stressed that the primary objective is to treat the child and not a "urodynamic abnormality" *per se.*

Special attention should be given to a pleasant surrounding for the child: one or both parents should be present and young children may be given a bottle. Older children may be distracted by watching a video movie. The child should be awake, non-anaesthetised and neither sedated nor taking any drugs that affect bladder function. Intranasal midazolam may be administered in certain situations where high anxiety levels cannot be mollified, as this drug appears to be innocuous regarding outcome of the study (69).

During the study the investigator has the opportunity to observe the child and discuss various findings and correlate them to what the child feels and/or normally would do in such circumstances.

Because UDS is an invasive procedure artifacts may influence accurate interpretation of results (70)

In children, the transition from filling phase to voiding phase is not as marked as in adults. To avoid missing this important transition, cystometry and pressure-flow/EMG measurements are performed as one continuous study in paediatric urodynamics.

Electromyography of the pelvic floor muscles is assumed to evaluate the activity of the striated urethral sphincter, in the filling phase and in the voiding phase. Surface skin electrodes are usually used to record the EMG. In children the pelvic floor EMG is probably of much more importance than in adults as it helps to differentiate the different voiding disorders.

Filling the bladder can be achieved by diuresis (natural fill cystometry) or retrograde by catheter. For retrograde filling by catheter, saline 0.9% or contrast medium at body temperature is recommended in children. Especially in young children some urodynamic parameters, such as capacity and detrusor activity are influenced by the temperature of the filling fluid. Although the clinical relevance is as yet unknown, it is recommended to fill the bladder with fluid of body temperature (71).

When filling by catheter, slow fill cystometry (5 – 10 percent of expected bladder capacity per minute (based on the voiding diary), or < 10ml/min) is recommended in children.

Involuntary detrusor contractions may be provoked by rapid filling, alterations of posture, coughing, walking, jumping, and other triggering procedures.

The presence of these contractions does not necessarily imply a neurological disorder. In infants, detrusor contractions often occur throughout the filling phase (Figure 9).

Bladder sensation is difficult to evaluate in children. Only in toilet-trained cooperative children is it a relevant parameter. Normal desire to void is not relevant in the infant, but can be used as a guideline in children of 4 years and older. Normal desire to void should be considered the volume at which some unrest is noted, e.g. wriggling the toes; this usually indicates voiding is imminent. In the older child, the volume may be small with the first cystometry, for fear of discomfort. Also involuntary detrusor contractions occur more often during the first filling cycle (71). This is the reason that in paediatric urodynamics at least two cycles of filling are recommended.

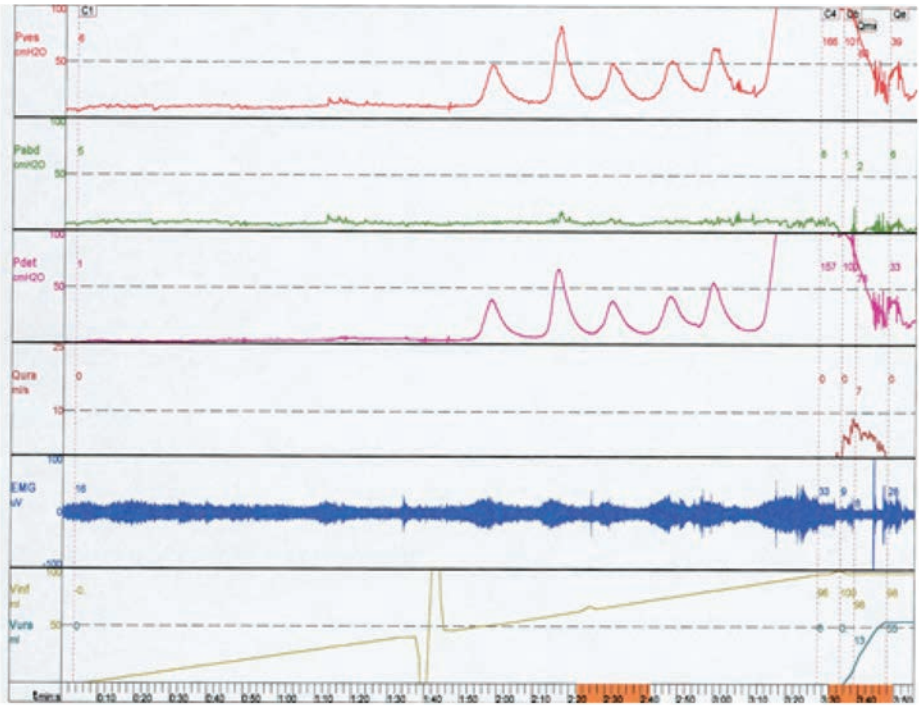

Fig. 9.Urodynamic study illustrating involuntary detrusor contractions, counter action of pelvic floor muscles (guarding reflex) and incomplete pelvic floor relaxation during voiding resulting in post void residual urine (detrusor overactivity + dysfunctional voiding) (72).

Maximum cystometric capacity (MCC) is the volume in the bladder at which the infant or child starts voiding. The value for maximum cystometric capacity is derived from volume voided plus residual volume. Values for MCC should be interpreted in relation to normal values for age.

Compliance indicates the change in volume for a change in pressure. For children with neurogenic detrusor-sphincter dysfunction, data are available relating poor compliance to the risk of upper urinary tract damage (73).

The usual notation for compliance is a single value, but a full characterisation of compliance may be helpful, as some children have varying compliance factors throughout filling (74). This variability depends on several factors: rate of filling, which part of the curve is used for compliance calculation, shape (configuration) of the bladder, thickness, and mechanical properties of the bladder wall, contractility, relaxability of the detrusor, and degree of bladder outlet resistance (68).

The urethral closure mechanism during storage may be normal or incompetent. The normal urethral closure mechanism maintains a positive urethral closure pressure during filling, even in the presence of increased abdominal pressure or during detrusor overactivity (guarding reflex) (72). An incompetent closure mechanism is defined as one that allows leakage of urine in the absence of a detrusor contraction.

In urodynamic stress incontinence, leakage occurs when Pves exceeds Purethra (intraurethral resistance) as a result of an increase in intraabdominal pressure, often in conjunction with low Purethra (72). Although common in multiparous females, it is exceedingly rare in paediatrics but may be noted in athletically active teenage girls (77). Immediately prior to micturition the normal closure pressure decreases to allow flow.

Bladder outlet obstruction, recorded with a pressure / flow study, may be anatomical or functional in nature. An anatomical obstruction may be present at the bladder neck or in the urethra as a stenosis or a stricture when there is a small and fixed urethral diameter that does not dilate during voiding. As a result, the flow pattern is plateau shaped, with a low and constant maximum flow rate, despite high detrusor pressure and complete relaxation of the urethral sphincter. In a functional obstruction, it is the active contraction of the urethral sphincter or pelvic floor during passage of urine, that creates the narrow urethral segment as a constant or intermittent obstruction. To differentiate anatomical from functional obstruction, information is needed about the activity of the urethral sphincter during voiding. This information can be obtained, and recorded together with pressure and flow, by monitoring the urethral pressure at the level of the urethral sphincter, or by recording a continuous electromyogram of the pelvic floor, as in clinical practice the urethral sphincter is not readily accessible, and the electromyogram of the external anal sphincter is

often used to monitor activity of the striated urethral sphincter. This corresponds to activity of the pelvic floor muscles. Also the use of video urodynamics can be very helpful in this respect, as contractions of the pelvic floor muscles can actually be seen during the voiding phase (Fig 5 and 6).

In infants and small children, pelvic floor muscle overactivity during voiding (with post-void residuals) is not uncommon: in all probability, it is a normal developmental feature (75,76).

9.1.3 Cystoscopy

In the majority of children cystoscopy is not indicated. In boys with therapy resistant incontinence, an abnormal flow pattern, especially in combination with a history of (recurrent) urinary tract infection is suspicious of infra-vesical obstruction such as bladder neck obstruction, urethral valves, syringocele etc. A VCUG may not always show these abnormalities and pressure flow curves may be equivocal (78).

In girls the flow may be directed upward, indicating an abnormal meatal position or stenosis. A dorsal meatotomy generally solves this problem. It has been postulated that in girls the abnormal direction of the stream triggers the bulbocavernosus reflex resulting in dysfunctional voiding (79).

III. CHILDREN WITH NIGHT TIME INCONTINENCE

Nocturnal enuresis is a complex disorder, with multiple pathogenetic factors, treated by multiple disciplines but seldom in a multidisciplinary setting, leading to confusing terminology. To avoid further confusion, this an update to previous ICI-papers, largely keeping the same definitions and structure [1], integrating with recent ICCS standardisation papers [2].

1. DEFINITION

Nocturnal enuresis (NE) is involuntary voiding of urine during sleep a week, in children over 5 years of age in the absence of congenital or acquired defects of the central nervous system [3]. Parental concern and child distress affect the clinical significance of the problem [4], and is to some extent country and culture dependent. Most children who wet at night after age five should be considered as patients with enuresis, although decision to start diagnostic and therapeutic approach must take in account that several factors including the child's development level play a role. The age criterion of five is not only epidemiology driven, but reflects the natural course of achieving bladder control [5-7], as well the maturation of the circadian rhythm of diuresis. Epidemiology demonstrates that girls acquire earlier continence than boys, a gender difference that disappears after the age of 10 years [5,8,9]. Research on pathophysiology has demonstrated that both diuresis-rate and bladder dysfunction might play a role in this sex difference.

NE is bedwetting without daytime symptoms. Non-monosymptomatic or polysymptomatic NE describes children with both day and night-time wetting [10], but further finetuned by including also patients with other daytime symptoms (LUTS) than incontinence [2,11].

This subtyping is essential for appropriate diagnostic and therapeutic approach in first line, but there is a large overlap in pathogenesis between both groups. Where all patients with NMNE have underlying bladder dysfunction

2. SEVERITY

Nocturnal enuretics vary in wetting frequency. Although fifteen percent wet each night, most children wet less frequently [2, 12]. In a population survey of nearly 1,800 Irish children aged 4 –14 years, Devlin found the frequency of wetting as follows: less than once per week in 33 percent, once per week in 11 percent and 2 to 4 times per month in 25 percent [13]. Some children and parents are concerned about an occasional wet bed, while others accept regular wetting.

Various definitions have complicated the literature and research. Applying the criteria set forth by the DSM-5 and ICD-10, enuresis and daytime urinary incontinence is a significant condition if it occurs >1 episode per month and a frequency of 3 episodes over 3 months. We propose in the future to follow the ICCS definition to qualify the significance of enuresis as frequent (>4 per week) or infrequent (<4 per week), to homogenise literature and future studies [2]. Severe bedwetters at the age of 5 years have a poor prognosis, with a spontaneous regression-rate of only 50-60% [9].

3. PREVALENCE

Bedwetting is common. In the United Kingdom, estimates approximately 750,000 children and young people over 7 years regularly wet the bed. In the United States 5 to 7 million children regularly experience primary NE [14-16]. The prevalence of bedwetting might vary regionally, although self-reporting might underestimate the real problem, because of the taboo in several cultures. In China, where parents take children out of diapers earlier, bedwetting seems to resolve more quickly. For example, in a large survey from Shandon, the proportion of children attaining nocturnal urinary control before age 2 was 7.7%; by age 3, this had increased to 53.1%, and by age 5 to 93%. The overall prevalence of NE was 4.3%, with a significantly higher prevalence in boys than girls. There was no additional decrease in the prevalence of enuresis between 6 and 16 years [17]. This can suggest that structured awakening and toileting is effective treatment for monosymptomatic NE, even in

small children, although the observation of CK Yeung suggests that in Hong Kong a progressive increase of self-reported enuresis rate could be explained by increased awareness and less taboo, but probably also because of changing lifestyle and nutritional habits [8, 9, 18].

Bedwetting becomes less common with advancing age. In the West, 15 per cent of children each year develop nocturnal bladder control [3]. By adulthood, bedwetting is rare. Hirasing *et al* sampled over 13,000 adults [18-64 years] and found only two decades ago an overall prevalence rate of NE at 0.5% [19]. Of these, 12 percent of men and 29 percent of women had daytime incontinence. Despite persistence of wetting into adulthood, 50 percent of men and 35 percent of the women never seek help for their problem. The enuresis prevalence of 0.5% in otherwise healthy adults in Hirasing's study refers to a largely untreated population. Fifty percent of the men had primary enuresis and had never been consistently dry at night. Assuming a prevalence of enuresis of 8 percent in 7-year-old boys, the risk for an enuretic boy to remain so for the rest of his life is 3 percent. CK Yeung documented that the severe cases had only a spontaneous regression-rate of 50-60 % [18].

Adults with enuresis represent a "hard core" group with worse symptoms. These individuals are likely to have associated LUTS during daytime%. Goessaert documented that in patients with long-term follow up 1/3 patients persisted to have symptoms into adulthood, especially in a subgroup with nocturia ($p<0.01$) [22].

4. INHERITANCE

Bedwetting runs in the family of many children who suffer from bedwetting. In one study, A positive family history was found in 94 families (23%) of 411 probands with PNE, including 49% of fathers, 9% of mothers, 6% of both parents, 6% of the siblings and 30% of grandfathers or (and) mothers. Among the probands the ratio of male to female was 1.3:1 excluding sex-linked inheritance. Family studies indicated autosomal dominant inheritance in 15%, and autosomal recessive inheritance consistent in 1.46% of families. Thus, the mode of inheritance is usually autosomal dominant; if both parents were nocturnal enuretics as children, the risk for their children is from 65 to 85 % [3,23]. If only one parent has NE the risk is about 45 percent [24].

Molecular studies have clearly shown that NE is a complex disease with locus heterogeneity and no clear genotype-phenotype association.

Linkage studies to determine the location of the genetic changes have suggested foci on several genes. Linkage studies to markers on chromosomes 4p, 8q, 12q and 13q and 22s demonstrate both clinical, as well as genetic heterogeneity in nocturnal enuresis [25-29]. So far, there has been no reported association of the genotype with a phenotype of enuresis [29]. The weak indications from genetic studies might indicate only autosomal monogenetic inheritance in a minority of cases, where in many families the predisposition might be multifactorial.

5. SEX AND MONOSYMPTOMATIC NE

Boys suffer nocturnal enuresis more frequently. In a population survey in London of 706 families, a higher prevalence was found for boys than girls, at age 3 years, with 56 percent of boys and 40 percent of girls being wet at night more than once a week [30]. More recent studies are consistent [31]. Surveys of monosymptomatic NE undertaken in Great Britain, Holland, New Zealand and Ireland suggest that the prevalence for boys is 13-19% at 5 years, 15-22% at 7 years, 9-13% at 9 years and 1-2% at 16 years. For girls, the prevalence rates are about half: 9-16% at 5 years, 7-15% at 7 years, 5-10% at 9 years and 1- 2% in the late teenage years [5, 6, 13]. Although monosymptomatic NE is more common in young boys, by adolescence the incidence in males is the same as in females [9, 32]. This might be explained by gender difference in maturation of the bladder, but also in renal sensitivity to vasopressin, not only in the elderly but also in children [33,34,35,36].

6. CLASSIFICATION

6.1. Primary versus secondary nocturnal enuresis

Children who have never been free of bedwetting for 6 months have primary NE. Secondary NE is the re-emergence of wetting after a period of being dry for at least six months. A birth cohort of 1265 New Zealand children studied over 10 years by Fergusson et al found an increased risk of secondary nocturnal enuresis with age [37]. The proportion of children who developed secondary enuresis was 3.3 percent at 5 years, 4.7 percent at 6 years, 6.2 percent at 7 years, 7.0 percent at 8 years, 7.5 percent at 9 years and 7.9 percent at 10 years. But all studies failed to document how many patients with secondary enuresis, were totally symptom free, including absence of LUTS during daytime and nocturia. In the past, major attention was given to the psychological comorbidities: Secondary NE is associated with a higher incidence of stressful events particularly parental separation, disharmony between parents, birth of a sibling, early separation of the child from parents and psychiatric disturbance in a parent [24, 37, 38]. Von Gontard and colleagues found children with secondary enuresis had significantly more emotional difficulties compared to those with primary NE. Their evidence also suggests children with secondary enuresis, compared to those with primary enuresis, are more likely to have behavioural problems, a finding which corresponds to that of McGee *et al* [1, 39, 40].

Both Jarvelin and Fergusson *et al* argue that primary and secondary enuretics are similar [37, 41]. They believe the two share a common organic aetiological basis. The rate the child acquires primary control influences his or her risk of secondary enuresis. The primary form is the consequence of a delay in maturation of the physiological mechanisms. The child's capacity to sustain and maintain nocturnal bladder control is manifest in the rate at which he or she acquires control. On the other hand, this capacity determines the child's susceptibility to lapsing back to night wetting when exposed to stress. Psychological factors should be considered as comorbidities.

Other sources of secondary enuresis must be excluded prior to proceeding with treatment for enuresis. These include sleep apnoea from obstructive airway disease, obesity, constipation and infrequent or dysfunctional voiding. Treatment of sleep apnoea from an obstructed airway has been shown to improve or eliminate NE in some children following surgery or medical management [42, 43]. Obesity has been associated with nocturnal enuresis both independently [44-47] and in the context of sleep apnoea [48-51].

6.2. Mono-symptomatic versus non-mono-symptomatic NE

Mono-symptomatic NE refers to those children who report no other bladder or voiding problems associated with wetting. Non-mono-symptomatic NE refers to bedwetting, that is associated with overt detrusor overactivity or voiding problems such as urgency, frequency and bladder holding during the day [52, 53].

This classification becomes important when considering the most appropriate treatment intervention. Many parents are unaware of daytime symptoms when seeking help for bedwetting and when identified these symptoms should be treated prior to intervention for the NE. Between 10-28% of children with NE have associated daytime wetting, and were considered according to the old ICCS standardisation [54] as NMNE. If so, these children should be considered day and night incontinent. In these cases, night time incontinence is not any longer an isolated phenomenon but part of the symptomatology of day and night time incontinence. These children are more resistant to treatment and more vulnerable to relapse [55]. These boys and girls are more appropriately managed in the context of the primary bladder problem.

7. PATHOPHYSIOLOGY OF MONOSYMPTOMATIC NE

NE stems from a mismatch of functional bladder volume overnight and, nocturnal urine output and the ability for the child to arouse during sleep. Night wetting is considered normal/ acceptable until age 5. Delayed maturation in one or more of the following systems results in NE: overactive bladder (OAB), or decreased arginine vasopressin (AVP) release are considered to play a major role. In desmopressin refractory nocturnal polyuria, more complex pathogenetic mechanisms are involved, such as abnormal circadian rhythm of different renal functions resulting in a relative increased solute excretion during the night [56-60]. The third parameter is an inability to wake from sleep to full bladder sensations [61, 62]. Combinations of all three problems may be present.

A unifying and simplistic concept with important clinical implications, is that NE is caused by a mismatch between nocturnal bladder capacity and the amount of urine produced during the night, combined with delayed or incomplete arousal response to the afferent neurological stimulus of the full bladder (Figure 1 and 2).

7.1. Increased nocturnal urine output

In normal children, the circadian rhythm of urine production results in a nocturnal reduction in diuresis to approximately 50% of daytime levels [63, 64]. In children, this is the result of nocturnal release of hormones that regulate free water excretion (arginine vasopressin, (AVP) [65, 66] or solute excretion (angiotensin II and aldosterone) as well [67, 68] as haemodynamic homeostasis [69] and may result from circadian changes in glomerular filtration [70-72]. In the normal child, this results in increased urine concentration and reduced urine volume during sleep, in presence of decreased osmotic excretion. Therefore, children who are not enuretic sleep through the night without being wet and do not need to rise to void.

Two thirds of patients with mono-symptomatic NE [2] have been found to have a lack of circadian rhythm of vasopressin, resulting in high nocturnal urine production, which exceeds bladder capacity [65, 73, 74]. Rittig *et al* and Norgaard *et al* demonstrated abnormalities in the circadian rhythm of AVP secretion resulting in increased nocturnal urine output that exceeded bladder capacity in children with nocturnal enuresis [65] [66, 73]. These children make more urine at night, and often overcome their bladder capacity and wet early in the night. Abnormalities can also be intrinsic, related to reduced nocturnal circadian changes in glomerular filtration rate (GFR) [70, 72] or in sodium and calcium excretion [59, 75-78].

Detection of low plasma vasopressin levels, GFR assessments or specific sodium and calcium excretion are too difficult to measure as first line investigation. Instead, we look for clinical signs of low vasopressin during the assessment interview. Weighing the diapers and adding the first morning void provides the total nocturnal urine output. if this total exceeds the child's functional bladder capacity this may indicate nocturnal polyuria. Nocturnal polyuria is defined as nocturnal diuresis >130% of expected bladder capacity for age, this is based on expert opinion [79]. If we would indicate the diuresis volume that might predict desmopressin response, >100%EBV seems to be more appropriate [80]. Nocturnal urine output varies appreciably from night to night [36, 81], but seems

larger in children with NE who respond best to desmopressin (dDAVP) [82].

By the time the child becomes an adolescent, the circadian rhythm is less prominent. In adolescents and adults with nocturnal enuresis, there is no diurnal rhythm of plasma vasopressin concentration. The changes in urine production at night occur from a decrease in the urinary sodium excretion that is not due to differences in concentration of AVP but due to a lack of sensitivity to AVP [64, 83] [84] with resultant increased urine output [56, 85].

There may be a small sub-group of children with impaired renal sensitivity to vasopressin or desmopressin [57, 81, 86]. Recent work by Devitt *et al* suggests that 18 percent of children have 'normal' levels of plasma vasopressin release but remain enuretic [74, 87]. These children all failed to respond to a therapeutic dosage of desmopressin. This finding could indicate renal insensitivity to vasopressin but could also be indicative of detrusor overactivity or a small functional bladder capacity. Total urine output during the night could be helpful in differentiating between the two conditions. The archetype of patients with NE and increased nocturnal urine output generally has a normal functional bladder capacity and a favourable response to dDAVP [88] [11, 80, 82], while the archetype of patients with OAB, will reduce fluid intake as compensatory mechanism, and have low diuresis volumes overnight, but the combination exists.

7.2. Detrusor overactivity during the night

The detrusor, to function appropriately, needs to be relaxed during filling and allow an appropriate functional capacity. Detrusor overactivity usually causes small voided volumes resulting in a decreased functional bladder capacity [89].

Watanabe and his colleagues, employing EEG and cystometry recording during sleep, discovered that 32 percent of children with NE had involuntary detrusor contractions that resulted in enuresis [90-93]. These children had smaller functional bladder capacities at the point of wetting, than children with enuresis who did not have detrusor overactivity. Functional bladder capacity – defined as the largest daytime void on a frequency- volume (F/V) chart, after excluding the first morning void, may give a reasonably accurate assessment of daytime functional bladder capacity (FBC). Reduced functional bladder capacity, when below 70% of predicted FBC for age, is likely to result in poor response to dDAVP treatment [80, 94]. Daytime bladder capacity is smaller than night time capacity in children without NE [95].

The pattern may be different at night. Yeung *et al* reported that 44 percent of treatment failures [with desmopressin or the enuresis alarm] have normal daytime bladder function but marked detrusor overactivity during sleep resulting in enuresis [96]. Almost none of these children had nocturnal polyuria. Ultrasound studies of the bladder furthermore revealed an increased bladder wall thickness in these children [97] [98].

When further segregated prior to treatment, increased bladder wall thickness and bladder volume predicted the response to therapy in children with their primary nocturnal enuresis (more than three nights weekly). In one study, Yeung, *et al*. [97], correlated ultrasound measured parameters and urodynamic findings. Of 35 children with frequent NE, bladder wall thickness index was normal in only eight patients. It was less than 70% of predicted in 24, and more than 130% in three. When bladder volume and wall thickness index was correlated with ultrasound, 87% of the patients with a normal index exhibited a normal bladder pattern on imaging and 96% of patients with an index less than 70 exhibited detrusor over activity on ultrasound. All the children with a normal index either had a complete or good response to conventional treatment for nocturnal enuresis, whereas 62% of those with an index less than 70 % did not respond to treatment. With longer follow-up, bladder dysfunction had resolved in 38% of the children with an initial index of less than 30, all of whom had a good response to treatment. The bladder dysfunction persisted in the 63% of children who had partial or no response to treatment. What this means is that ultrasound measured bladder parameters may segregate children, prior to management of primary nocturnal enuresis, into groups that have a favourable outcome and those that do not, following conventional treatment. These studies will become more and more important in helping to predict response of various treatment regiments in the future.

This approach may be even more important in adults with refractory monosymptomatic nocturnal enuresis. Bower, *et al.* [99] found that in 56 consecutive adolescents and adults compared with 293 normal adults, there were significantly higher childhood scores of urgency, frequency, urgency incontinence, infrequent voiding and small volume voids than their normal non-enuretic counterparts. This suggests that adolescents and adults with persistent nocturnal enuresis may have a more significant bladder component, particularly since the majority of patients with adult type nocturnal enuresis do not seem to exhibit the nocturnal polyuria problem seen more commonly in the smaller children.

7.3. Lack of arousal

The fundamental mechanism resulting in nocturia or NE is that the bladder fills to its capacity during sleep and needs to empty (Figure 1). Bladder fullness is due to nocturnal polyuria and/or a reduction of the bladder capacity due to detrusor overactivity during sleep. The arousability differentiates patients with diuresis/ bladder volume mismatch into enuresis versus nocturia, but does not reflect underlying / associated sleep disturbances neither CNS dysfunction.

From an adult patient point of view, these factors do not fully explain why the enuretic child does not wake

up during the night to the sensation of a full or contracting bladder. Regardless of whether the child has detrusor overactivity or nocturnal polyuria, the enuresis event results from the child's inability to awaken from sleep to empty prior to the wetting episode. However, we must admit that the majority of children become dry, without nocturia, what might indicate that nocturia is a defence against diuresis/mismatch only present in children with high arousability.

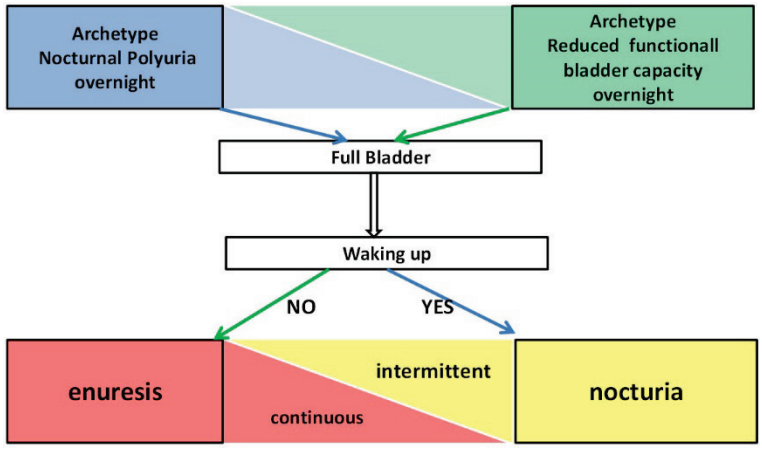

Figure 1: Basic pathophysiology of NE or nocturia. When the bladder is full because of (relative) polyuria and/or a reduced bladder capacity, the child either wakes up to void (nocturia) or voids while sleeping (NE). The two archetypes nocturnal polyuria and overactive bladder are well defined, but combination of both factors might be present. In additional it should be stressed that the enuresis and/or nocturia might be continuous or intermittent.

Recent findings suggest that the issue of decreased arousability is not the same as deep sleep.

There is a widely-held belief amongst parents and some clinicians that enuretics are deep sleepers. This is logical, since many of the children exposed to alarm therapy sleep through the alarm while family members awaken. Nevéus reviewed by questionnaire 1413 schoolchildren between the ages of six and ten and noted that enuresis was associated with subjectively high threshold arousal and significant confusion upon awakening from sleep [100]. Wolfish, in a study of 15 enuretic and 18 control boys and girls found that enuretics wet most frequently during the first two-thirds of the night and that arousal attempts were less successful in enuretics than in normals [101, 102]. This might explain why the most heavily endorsed view of both children and parents, regarding the aetiology of NE is a belief in deep sleep [103]. The recent findings of Dhont and Van Herzeele favour a disrupted sleep, with increased arousals, rather than a deep sleep [104-110].

Enuretic episodes occur during all stages of sleep in proportion to the amount of time spent in that stage and appear to occur independent of sleep stage but occur when the bladder is at a volume equivalent to the maximal daytime functional capacity [111-114]. Bedwetting children sleep normally but are unable to suppress nocturnal detrusor contractions or awaken in response to them or to bladder fullness.

Waking becomes easier as the night progresses. However, several authors have found that children with NE are also more likely to wet in the first third of the night, often in the first two hours following sleep [101, 102, 113, 115-119]. Thus, the point of bladder fullness for most enuretic children coincides with a time of night where they find it most difficult to wake from sleep, and not always when there is already an apparent diuresis / bladder mismatch: maybe diuresis-rate is more important than absolute volume, or OAB overnight is unidentified [120].

7.4. Comorbidities

There is increasing interest in comorbidities, not only coinciding with enuresis, but with common pathways in pathogenesis and/or interfering with therapy response.

7.4.1 Sleep disturbance

There is increasing evidence that sleep disturbance alone, or in combination with disrupted homeostasis play a role in the pathogenesis of nocturnal enuresis.

Recently it was documented that enuretic children did not exhibit deep sleep, but rather a disturbed sleep with increased PLMS, cortical arousals, and awakenings [104, 107-110], both in patients with refractory enuresis and in children with monosymptomatic + nocturnal polyuria. Polysomnography studies documented a significant difference in PLMS index, arousal index, and awakening index compared with healthy control subjects. The presence of sleep fragmentation does not exclude a high sleep pressure or high arousal threshold. The role of sleep fragmentation in children with NE was earlier emphasised using sleep actigraphy [121]. Obstructive airway syndrome

(OSAS) causes nocturnal polyuria in both children and adults, eventually resulting in enuresis. The prevalence of this NE subtype in patients primarily consulting for enuresis is not known, but the anti-enuretic response to OSAS therapy suggests that in refractory cases this might be considered [48-51].

In conclusion, albeit there is little doubt that sleep and/or arousal plays a role in the pathophysiology of NE the clinical relevance and possible implications are still unclear and, so far, sleep investigation is not part of routine evaluation of enuretic children.

Dhont and van Herzeele published evidence that the superficial sleep, was coinciding with neurocognitive dysfunctions, thereby undermining earlier opinions that sleep patterns of children with NE are no different from control children [107, 110]. These neurocognitive dysfunctions were already documented in the past. In patients with enuresis. treatment of the enuresis resulted in amelioration of sleep quality and neurocognitive functioning [110].

7.4.2 Neurocognitive comorbidities.

Several neurocognitive comorbidities, coincide with nocturnal enuresis and might play a role, not only in pathogenesis but certainly in therapy resistance, such as psychological / behavioural problems; and attention deficit, neurocognitive dysfunction.

Psychological comorbidity among children with functional urinary incontinence is high: 20-30% of children with nocturnal enuresis (NE), 20-40% of children with daytime urinary incontinence (DUI), and 30-50% of children with faecal incontinence (FI) have clinically relevant comorbid disorders [1, 122-134]. Both internalising and externalising characteristics are represented [131, 135-137]. The best documented comorbidity conditions are attention deficit/hyperactivity disorder (ADHD) and oppositional defiant disorder (ODD). Attention deficit disorders coincide with higher prevalence of enuresis (both MNE and NMNE), where the prevalence of ADHD in the enuresis population is up to 4 times higher than the background population. The association of abnormal prepulse inhibition (Startle reflex) in both ADHD and enuresis patients, might suggest a common central nervous pathogenic pathway but this is far from fully understood [138-141].

Frietag *et al* studied brainstem evoked potentials in 37 children with nocturnal enuresis and compared these aged 8 to 14 years, with 40 controls, mean age 10 years, and found that interpeak latencies of the brainstem evoked potentials were increased in children with nocturnal enuresis, suggesting that a maturational deficit of the brainstem was present in children with nocturnal enuresis. Differences in visually evoked potential latencies might point to a reason behind functional cortical differences in children with family history of nocturnal enuresis [142].

Freitag's study would suggest that a maturational effect is present [143]; however, overnight studies in enuretic children with simultaneous sleep electroencephalographic and cystometry have revealed marked detrusor overactivity, only occurring after sleep at night and not during wakeful periods during the day [143]. Because this pattern has not been observed in normal non-enuretic subjects, even during the new-born period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area near the pontine micturition centre, the posterior hypothalamus (responsible for secretion of antidiuretic hormone) or the locus coeruleus which may be the cortical arousal centre [144] [145].

Another interesting study by Baeyens *et al.* [138] showed a convincingly significant difference between children with enuresis and control groups, and the startled eye blink reflex which improved with maturation but did not seem to correlate with resolution of enuresis. Clearly there is considerable work that is required to further unravel the mechanisms behind perceived differences in arousal between enuretic and non-enuretic children.

7.4.3 Constipation

The coexistence of LUT symptoms and functional constipation and/or faecal incontinence in children is not uncommon and was previously identified as Dysfunctional Elimination Syndrome' [146-148] and more recently as 'Bladder and Bowel Dysfunction' (BBD) [147].

Although the association with dysfunctional voiding, decreased voiding frequency and underactivity is obvious, there is also a clear comorbidity between bladder overactivity (urgency), increased voiding frequency, bladder underactivity and constipation. It is a well-established clinical experience that treatment of defecation problems in children with BBD enhances successful management of lower urinary tract disturbances such as daytime urinary incontinence (DUI), enuresis, and urinary tract infections (UTIs) [40, 147, 149, 150]. Treatment of the bowel dysfunction gives amelioration of the voiding disorder and should be first line treatment [151].

7.4.4 Mentally and motor disabled

It is evident that many of these children have underlying or associated bladder-dysfunctions. These children may also suffer from typical enuresis nocturna, but we should consider their maturation level, and, if this is delayed, initiate appropriate therapy which takes this into account [152].

Children who do wake up but are afraid to go to the bathroom [63], and therefore wet their bed should be identified as their treatment, for obvious reasons, is completely different [153].

8. MANAGEMENT OF NOCTURNAL ENURESIS

The age at which the child and his or her parent begins to be concerned about bedwetting varies. Hjalmas *et al*. noted that, "for successful treatment of nocturnal enuresis, the child must be brought to the physician by the parents who are concerned and the physician must have the necessary knowledge about the condition and be motivated to start treatment [63]. To fulfil these requirements, parents, teachers, and nurses in primary care need to understand nocturnal enuresis and be ready to treat the child, regardless of age according EBM based guidelines, against "Dr. Google" directed information. There remains a big task for demystification not only for patients/parents but also care givers in primary care.

Nocturnal enuresis is thought of as a social problem and less of a medical problem; therefore, since most children stop wetting as they mature and since no ill health follows bedwetting in most cases, there is a tendency for many practitioners to take a "wait and see" approach despite the fact that the family and the child in many cases are quite disturbed. In one study, 3803 French school children aged between five and ten years noted the prevalence of primary nocturnal enuresis to be 9.2%. The majority of the children noted that bedwetting bothered them and hoped that a doctor could help them. In this survey, a questionnaire was addressed to mothers of enuretic children, 100 school teachers and 100 school doctors. The mothers had a relatively tolerant attitude but two-thirds had consulted a doctor. Most of the doctors had proposed no solution or a "wait and see" attitude or treatment with a drug rather than an alarm. From this study, we may conclude that considerable work needs to be done to help educate not only parents but teachers and even physicians about the importance of treatment of nocturnal enuresis as well as supportive care [154].

The actual timing of treatment for nocturnal enuresis may vary depending on the needs of the child and the parent. Toilet training age may be different in different societies [155]. For example, toileting in Asia may begin earlier than in North America or other parts of the world [61, 154, 156, 157]. Toilet training should be started when both the child and parents are ready. Most studies appear to show that children start training between 24 and 36 months of age with a current trend toward later completion than in previous generations. This is markedly different than noted in some Asian cultures where training appears to begin much earlier. Toilet training should occur in an environment that is comfortable for the child. Unfortunately, toilets in most household bathrooms are adult sized, making it difficult for the child who needs to climb to the top of the toilet to relax. In these cases, a potty chair to toilet train the child, and once the child is old enough, he or she should be transitioned to an over-the-toilet seat with a footstool to allow optimal posture for voiding. Parents should encourage children to relax and take time to completely empty the bladder [63].

It is essential that both the child and his or her parents understand bedwetting pathophysiology and treatment philosophy. The clinician should give the child general advice such as what to eat and drink and to void regularly during the day, abstain from drinking too much during the late afternoon and evening and have relaxed routines at bedtime. The clinician should stress that NE is common and usually represents a delay in maturation without any psychopathological undertone. Up to 19 percent of children will become dry within the next 8 weeks without any further treatment besides good counselling [63, 156, 158].

8.1. Evaluation / intake

Over past decades several attempts have been made to standardise qualitative intake of patients, although still limited translated into primary care. Hjalmas recommended a careful history which will be summarised in these next few paragraphs. (Figure 2, table 1). This approach, which has been recommended by the International Children's Continence Society, provides an excellent guide toward the taking of a history for a child with nocturnal enuresis, with a few adaptations over time [11, 63, 159-161].

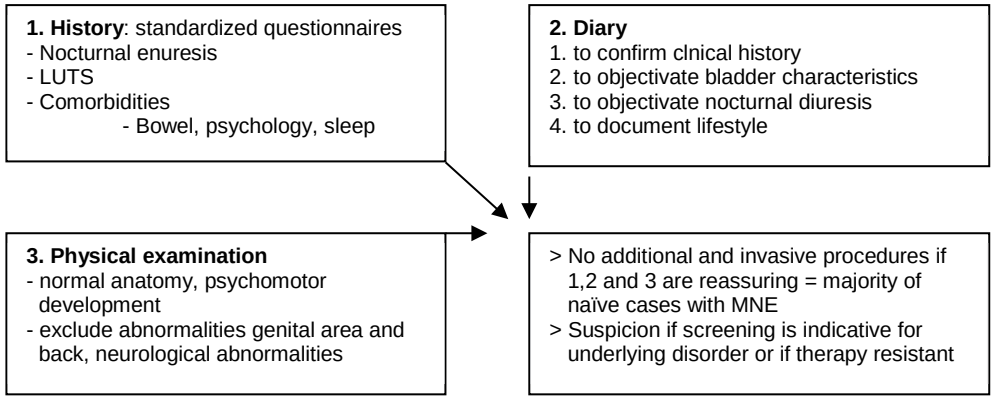

Figure 2: Schematic work-up in patients presenting with night-time wetting

8.2. frequency volume chart (FVC).

Parents are asked to record a two-day three-night record. This includes recording the child's fluid intake and urine output, frequency of micturition and the frequency and pattern of voiding. The largest single micturition is considered the functional bladder capacity. This chart can be performed beginning on a Friday evening and concluding on Sunday on any weekend [11].

Symptoms of nocturnal enuresis [11, 53, 161]. A careful history should include questions about the age of onset of nocturnal enuresis, length and circumstances of dry spells, number and time of episodes of nocturnal enuresis or nocturia, presence of daytime voiding symptoms or urinary tract infection, posture while voiding, daytime and evening fluid intake, sleep habits, frequency and consistency of bowel movements and psychosocial situation. One must establish whether, or not, symptoms represent primary or secondary nocturnal enuresis. It is critical to search for new psychological problems that might cause secondary nocturnal enuresis, particularly when the child presents with nocturnal enuresis after a prolonged period of dryness. The personality of the child, family situation, school environment, and presence of alternative caregivers might have an appreciable impact on voiding habits and will influence management options (43). Children may drink large volumes of fluid in the hours before sleep and this may result in nocturnal enuresis or nocturia.

It is helpful to determine the number of hours of sleep and to compare this to standard charts of average duration of sleep by age. Morning fatigue may be the result of obstructive sleep apnoea or restless legs syndrome. Other symptoms of sleep apnoea include mouth breathing, snoring, and restless sleep [11, 63]. More attention should be given to sleep hygiene: is the child drinking, eating prior to sleep? Is the child voiding just before bedtime? Is the light turned off immediately after going to bed?

It is important to rule out symptoms of anatomical or physiological urological conditions that may lead to nocturnal enuresis. Many of these conditions are covered in other parts of this section, and include a failure to store urine or failure to empty urine. Storage symptoms include increased frequency, urgency, and urgency incontinence including squatting behaviour, daytime incontinence and the sensation to need to void again. The clinician must carefully assess daytime wetting, particularly in older children. In many cases, the child may hide these symptoms from the clinician and the family.

Table 1, simple overview of items to be investigated in children with enuresis.

	history	**diary**
Enuresis nocturna		
night time episodes only	Y/N n = /w	Y/N n = /w
nocturia	Y/N n = /w	Y/N n = /w
Exclusion daytime symptoms		
Daytime incontinence: timing before or after void? Very wet pants? Frequency of leakage, Intermittent versus continuous leackage	Y/N Y/N Y/N Y/N n = /w Interm /cont.	Y/N Y/N Y/N Y/N n = /w Interm /cont.
Urgency	Y/N	
Frequency >8 or < 3 x/day	 Y/N Y/N	 Y/N Y/N
Voiding postponement	Y/N	Y/N
Interrupted stream	Y/N	Y/N
Urinary tract infections	Y/N	Y/N
History uropathy	Y/N	Y/N
Comorbidities		
Sleep disorders: restless legs, arousals, sleepwalking, snoring	Y/N	Y/N
Psychological comorbidity	Y/N	
ADHD, ADD, autism	Y/N	

	history	diary
Mentally and motoric disabled	Y/N	
Constipation, soiling	Y/N	Y/N
Lifestyle		
Sleep hygiene: Hours + timing of sleep + waking up Voiding prior to bedtime Once in bed immediately sleeping	/ Y/N Y/N	/ Y/N Y/N
Fluid intake Enough, spread over the day No drinking before sleeping time or overnight	Y/N Y/N Y/N	Y/N Y/N Y/N

Children void four to seven times a day or about every two to three hours [11, 80, 162]. If the child is voiding significantly more frequently than eight or more times a day, this may suggest incomplete emptying or overactive bladder. Urgency is present in many children and posturing, including squeezing or crossing the legs, squirming while standing or sitting, or physically compressing the genital area with a hand is all suggestive of overactive bladder due to detrusor overactivity which may or may not be associated with dysfunctional voiding. Other causes include urinary tract infection, polyuria from diabetes mellitus or diabetes insipidus, which can also cause more frequent voiding [63]. Treatment for these symptoms is covered in other sections within this chapter.

Additional symptoms during the daytime include continuous dribbling between voids that can come from an ectopic ureter bypassing sphincter mechanisms, from failing to empty the bladder or from sphincter incompetence. Also, continuous leakage can result from neurological causes or anatomical causes such as epispadias, or a closed bladder exstrophy or urogenital sinus.

Lastly, children may have incomplete emptying from true dysfunctional voiding which results from the sphincter or pelvis floor contracting at the same time as the detrusor contracts during micturition. In addition, detrusor underactivity may result from neuropathy from diabetes mellitus and in some cases conditions such as the prune belly syndrome will result in detrusor underactivity. Lastly, urethral strictures may result in incontinence due to detrusor overactivity with poor bladder emptying. Boys with posterior urethral valves or Cobb's collar may also have incomplete emptying. Lastly, the clinician should be alert for symptoms of constipation and faecal incontinence [163]. It is a common misconception that if a child is stooling once per day then he or she is not constipated. In fact, the best symptom of constipation is the infrequent or painful passage of hard small pellet-like stools. Faecal incontinence may also be present, the principal sign of this being faecal material in the underwear. Excessive stool retention may result in bladder dysfunction. In these cases [164], this may result in increased urethral sphincter and pelvic floor activity and explain the association of voiding dysfunction with incomplete voiding. Treatment of constipation may result in improvement in enuresis [151].

8.3. Physical examination

Anatomical and behavioural causes for enuresis may be identified through a careful physical examination. Evidence of improper gait, spinal deformities, and foot abnormalities including asymmetry, high-arched feet, or hammer toes are signs of sacral neuropathy. Physical signs of occult spinal abnormalities such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks and gluteal clefts are also important. A careful abdominal examination with emphasis on the left lower quadrant may identify the colon full of firm stool. In most cases, a rectal examination is not performed but in some cases this may also be indicated. Occult faecal impaction, poor perineal sensation and reduced anal sphincter tone can be indicative of neuropathy.

In boys, marked narrowing of the urethral meatus (when the meatal lips are separated and no mucosa is seen), must be identified and carefully noted. If these signs are present, the boy should be asked to void so the clinician can witness and record the flow rate and residual urine. Narrowed or displaced urinary stream is suggestive of meatal stenosis.

In girls, the introitus should be identified for the position of the urethra. Evidence of wetting or irritation of the labia or vagina should be identified, as this could be suggestive of post-void dribbling or incomplete emptying with incontinence due to either detrusor overactivity or sphincter weakness [2, 146].

8.4. Laboratory examination

There is very little laboratory examination that is required in patients with nocturnal enuresis other than a urinalysis to rule out UTI and evidence of glycosuria and a urine culture if the urinalysis is suggestive of infection [63].

Urodynamics and imaging have no place in the initial intake and therapeutic approach of a child with monosymptomatic nocturnal enuresis. If there is any suggestion, however, that daytime wetting is occurring,

and then a full evaluation of the daytime problem should precede the evaluation for nocturnal enuresis.

9. THERAPY

The management of NE depends on:

- the child's motivation to participate in treatment
- exclusion of confounding psychosocial factors
- providing information and instruction about daily habits, underlining the importance of having regular fluid intake, regular voidings, and relaxed routines at bedtime
- regular review of the new intervention

The therapist should convey a sense of understanding and compassion to both the child and the family. Education about the problem and a realistic discussion about the prognosis will help instil competence in the treatment offered which may improve both compliance and outcome [82, 165-167].

9.1. Evidence based recommendations for treatment.

First line treatment and preliminary steps: primary and secondary forms of nocturnal enuresis are treated the same. If faecal incontinence, constipation or daytime wetting is present, these should be treated first [146, 151, 164].

All guidelines advocate urotherapy as first line therapy, although the evidence in children with NMNE is low, and efficacy is questioned [161, 168]. However, it is rational to initially normalise lifestyle and to give first urotherapy-advice.

However, treatment modalities like lifting, fluid restriction, dry-bed training, retention control training, psychotherapy, acupuncture, and hypnosis all have insufficient data in the literature to recommend any of them. However, non-invasive behavioural modifications such as resisting over-hydration in the evening are appropriate recommendations at the initiation of therapy. Normal fluid intake, but spread over the day should be advocated, to reduce osmotic excretion overnight [59]. The child must void before bed. Excessive protein or sodium intake should be avoided in the evening, since it will result in osmotic diuresis [59, 75, 76, 78]. During the day, the child should be instructed to void regularly, not to hold urine until the last minute, and to relax and take time to completely empty. If deemed important by the parents, a letter should be sent to the school to explain this.

Timing of treatment for the child who wets is dependent on the family's desire and the child's desire. As a good rule of thumb, children should be six to eight years of age. Some children, however, may want to wait until later. Others may be ready closer to age six. It is important for the parents to know that relapses can occur. The successful treatment of children with nocturnal enuresis has a foundation of realistic expectations and a motivated family [63].

Before starting treatment, a "baseline" meeting with counselling, provision of information, positive reinforcement, reassurance that 15% of children with mild enuresis (<4/7d) resolve each year, and increasing motivation should occur first. Children are asked to fill out a calendar or chart depicting the wet and dry nights. Children became significantly drier in two non-randomised trials associated with fewer wet nights simply by focusing them more on record keeping and true reward charts [121].

It is also important to be realistic about parental expectations, including the next steps of EBM, the alarm and desmopressin, where success-rates after 1 year do not exceed 60%, relapse free.

9.2. Enuresis alarm

The underlying mechanism of action of the alarm remains uncertain [169], and interpretation of the data in the literature when using the new ICCS definitions, unknown, since almost all studies have been performed with poor differentiation of MNE from NMNE, according to the new standards [2, 54, 63, 79, 170].

In unselected or poorly subtyped patients with enuresis, the enuresis alarm is the most effective means of facilitating arousal from sleep and remains the most effective way to treat NE [171-174]. There is an average success rate of nearly 68% with efficacy increasing with the duration of therapy. Relapse rates in the 6 months following treatment are in the order of 15 - 30 %, significantly lower than for desmopressin in unselected populations. Alarm therapy has been shown in a meta-analysis to have a 43% lasting cure rate [175-178].

Better results occur with optimal motivation of the child and family and higher frequency of wet nights. Reduced efficacy is associated with the lack of concern shown by the child, lack of supervision, inconsistent use, family stress, abnormal scores on behaviour system checklists, psychiatric disorder of the child, failure to awaken in response to the alarm, unsatisfactory housing conditions and more than one wetting episode per night. Enuresis alarms require several months of continuous use and are, therefore, unsuitable for some families [11, 179, 180].

For optimal results, alarm therapy should be individualised; it requires a motivated family and child with significant commitment to time and effort. The impact on other family members should be considered. In some families, alarm therapy may wake other members of the family and may increase parental annoyance and place a child at increased risk for physical or emotional abuse. Be aware of the burden, if the alarm is activated early in the night or several times per night, especially because these are predictive of resistance. Close follow-up is important to sustain motivation, troubleshoot technical problems, monitor the therapy [63], and identify the burden. The exact

mechanisms of action for alarm treatment are unknown. The effects are not due to classical conditioning, as stimulus awakening occurs after and not before wetting. Instead it is clearly an operant type of behavioural approach, i.e. a learning programme with positive reinforcement that includes aversive elements. Dryness is reached either by waking up leading to "nocturia" in 35% of children or by sleeping through the night with a full bladder in 65%. Body worn (vibrating) alarms are at least as effective as bedside alarms [121].

The family should continue alarm therapy for at least 14 consecutive dry nights – or a maximum of 16 weeks before discarding it as ineffective [11]. Compliance remains a problem: dropout rates are rarely disclosed in reported studies. Proper guidance and instructions are mandatory.

The key to success is not the stimulus intensity of the alarm triggering, but the child's preparedness to awake and respond to the signal. Comparison of the different types of alarm did not show significant outcomes.

In general, alarm treatment is more effective than other forms of treatment and the lasting cure rate about twice as high.

Level of evidence 1

Grade of recommendation A

In some cases, alarm therapy can be enhanced using the alarm in addition to other behavioural components. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm) and avoiding penalties may further reduce the relapse rate [171].

9.3. Dry bed training

This is a package of behavioural procedures used in conjunction with the enuresis alarm first described by Azrin *et al* [181, 182]. It incorporates:

- the enuresis alarm
- cleanliness training (encouraging the child to take responsibility for removing of wet night clothes and sheets, re-making the bed and resetting the alarm),
- waking schedules – to ease arousability from sleep as described above and involving:
    - for the first night, waking the child each hour, praising a dry bed, encouraging the child to decide at the toilet door whether he or she needs to void, and on returning to bed the child is encouraged to have a further drink
    - On the second night, the child is awakened and taken to the toilet 3 hours after going to sleep. For each dry night, the waking time is advanced by 30 minutes. If the child is wet on any night, the waking time stays at the time of the previous evening. The waking schedule is restarted if the child begins wetting twice or more in any week, stating again 3 hours after sleep.

High success rates and low drop out have been reported although relapse rates are no different than enuresis alarm treatment alone. Modifications are advocated to remove some of the more punitive elements of the programme but at best, it is a complex, time consuming and a demanding technique [171, 183, 184].

Hirasing *et al* found 80 % success with group administered dry bed training. Girls responded better than boys [185]. Most parents were satisfied with the programme but opinions of the children were divided. Factors related to failure were the child's age, bedwetting frequency, secondary enuresis or family history. In another study, they found a positive effect on behavioural problems [186].

An important component analysis by Bollard & Nettelbeck found that the enuresis alarm accounted for most of the success achieved through dry bed training. They believe that a large proportion of the components of the procedure can be eliminated without sacrificing much of its overall effectiveness and that the waking schedule coupled with the enuresis alarm is as effective as the complete dry bed-training programme [187, 188].

Level of evidence: 2

Grade of recommendation D (no more effective than alarm treatment alone)

9.4. Arousal training

Arousal training entails reinforcing appropriate behaviour [waking and toileting] in response to alarm triggering. The aim is to reinforce the child's rapid response to the alarm triggering, not on 'learning to keep the bed dry'.

The instructions involve: setting up the alarm before sleep

- when the alarm is triggered the child must respond by turning it off within 3 minutes
- the child completes voiding in the toilet, returns to bed and re-sets the alarm
- when the child reacts in this fashion he is rewarded with 2 stickers
- when the child fails to respond in this way the child pays back one sticker

Van Londen *et al* first described this procedure with a group of 41 children, aged 6-12 years, with predominantly primary enuresis [189]. They reported 98 percent success [14 consecutive dry nights] compared to 73 percent success with alarm monotherapy. The difference was significant [$p<0.001$]. Ninety-two per cent remained dry after 2 ½ years: a very low relapse rate. An extraordinary aspect of this study was the lack of

contact between therapist and parents. All those included were parents who had ordered an alarm from a rental agency and were given the instructions with the alarm. The authors conclude that arousal training is 'definitely the treatment of choice for enuretic children between 6 and 12 years'. Compared with other studies, and considering experience of daily practice, one may question the very high success rate in this group of patients.

Recommendation: grade C

9.5. Pharmacological treatment

Based on the three main causes of enuresis, namely nocturnal polyuria, detrusor overactivity, and disorder of arousal, the pharmacological treatment is designed to address these three areas. Table 2 shows rates of efficacy.

9.5.1 Desmopressin therapy [190-198]

Arginine vasopressin (AVP) or antidiuretic hormone (ADH) is normally produced in the hypothalamus and released in the pituitary in response to hyperosmolality or hypovolaemic conditions. Vasopressin acts on the collecting ducts and distal tubules to enhance water absorption. AVP, by virtue of an independent vasoconstrictor effect, is also a potent vasopressor. Desmopressin (or dDAVP) is an analogue of vasopressin created by deaminating the cystine residue at position 1 and substituted D-arginine for L -arginine at position 8. These changes result in significantly increased antidiuretic activity but loss of vasopressor activity. The half-life of Desmopressin is 1.5 to 3.5 hours. In a larger portion of children with monosymptomatic nocturnal enuresis, the normal circadian variation in urine production with nocturnal rise of vasopressin is absent. In these cases, dDAVP would seem to be particularly appropriate. Desmopressin is easy to administer and the clinical effects appear within 1 hour.

Several formulations are on the market: rhinyl nasal solution, desmopressin nasal spray, desmopressin oral tablet and the desmopressin oral lyophysilate (sublingual), all characterized by rather low bioavailability, with large intra-individual variability (0.08-0.16% in adults); only the last 2 formulations have a licence for enuresis in children [196, 197]. The intranasal form is no longer recommended for nocturnal enuresis, because of concern about water-intoxication, because of unpredictable nasal reabsorption in children.

The low bioavailability is largely related to the peptide structure, making oral /intestinal reabsorption very difficult, although pharmacodynamic effects remains very predictable, and when used *lege artis*, is rarely associated with serious adverse effects. It is available as a tablet (dosage, 0.2–0.6 mg) or a fast-melting oral lyophilisate (Melt; dosage, 120–240 µg). The latter is a recommended formulation for all children and is preferred by children under 12 years [197, 199-201]. It is not affected by nasal congestion or gastrointestinal transit and does not require fluid intake. Since tablets require up to 200 ml of fluid intake, which is ~25% of a 7-year-old's bladder capacity, the Melt formulation is more suited to the antidiuretic indication of desmopressin. Good pharmacodynamic data are available for the Melt and its dosing in children with enuresis [197, 202] [58].

Some patients have a delayed response and a small group of children who do not respond to desmopressin in ordinary dosage will become dry when the dose is increased, but this off-label use should be restricted to expert centres [203, 204]. Desmopressin may be particularly beneficial in the child with limited numbers of wet episodes per week. Often advice is given to use it as added security on special nights such as a sleepover. There is no sound medical evidence for this advice as intermittent regimens have never been proven to be beneficial [80].

Nocturnal polyuria is a characteristic of children that respond the best to desmopressin [56, 80, 205]. ICCS defines nocturnal polyuria >130% of expected bladder capacity for age, but the DRIP study showed that diuresis lower than 60%EBV is likely desmopressin resistant, where diuresis>100% has a 60% response-rate.

The efficacy of desmopressin in the treatment of enuresis is well documented [57, 192, 193, 206]. In a Cochrane Library, meta-analysis 17 controlled trials all showed superiority of desmopressin compared to placebo regardless of the route of administration [194, 207]. An estimated 70% of the enuresis population has full or partial response to the drug [110] and the response to desmopressin is highly dependent on factors such as nocturnal urine production and bladder capacity. The few studies that have tried to compare different doses of the drug reveal comparable efficacies [191, 208-210]. Several key issues should be taken into consideration, when the drug is prescribed. 200 to 400 mg tablets are considered bioequivalent to 120-240 µg Melt and are the therapeutic range for children with MNE between 7 - 18 years. The recently documented size relationship could mean that higher dosages might be needed in some of the larger children [200].

Medication should be taken 1 h before the last void before bedtime to allow timely enhanced concentration of urine to occur. Fluid intake should be reduced from 1 h before desmopressin administration and for 8 h subsequently to encourage optimal concentrating capacity and treatment response, as well as to reduce the risk of dilutional hyponatraemia/ water intoxication [82, 194, 197, 199].

Desmopressin is only effective on the night of administration; therefore, it must be taken daily. Full adherence is required to avoid wet nights. Desmopressin acts immediately, but in our expert opinion, the initial duration of treatment should be for 2–6 weeks, to ascertain its anti-enuretic effect [11]. If a sufficient degree of improvement is experienced, then treatment

can be continued for an additional 3 months—where appropriate. Country-specific regulations regarding treatment breaks should be followed. If patients are dry on treatment after this initial period, breaks are recommended to ascertain whether the problem has resolved and therapy is no longer necessary. If the child does not achieve complete dryness, or if wetting resumes once treatment is withdrawn, it should be continued or resumed. There is some evidence that structured withdrawal of medication may reduce relapse rates following its discontinuation [211,212]. Desmopressin is well tolerated, but clinicians should be aware that it is a potent antidiuretic and families must be educated regarding the rare possibility of patients developing hyponatraemia/water intoxication with symptoms including headache, nausea, and vomiting [196]. Self-titration of medication should be avoided (opinion).

Adherence to the drug is important. It is estimated that ~30% of non-responders are not taking medication correctly [166, 167, 213]. Non-adherence to recommendations regarding timing of medication, voiding before bed time, and limitation of evening fluids can increase treatment success [214]. Moreover, compliance is often overestimated, both by patients and clinicians; therefore, it should be documented in a diary. Regular contacts between caregiver and patient are necessary to keep up compliance. Patients who appear treatment-resistant should be advised of the importance of full adherence and asked if they have had any difficulty with complying with recommendations. We may also neglect that in divorced families, information must be given to both parents, so that the treatment is appropriately given on daily basis

Desmopressin has higher success rates in children with large bladder and nocturnal polyuria [35, 80, 215]. The response rated of the initial studies of >70% have been decreasing in more recent studies to 20-30%, since the prevalence of occult OAB patients with small bladder volume and low nocturnal diuresis volume was high in these populations [216]. There are several unanswered questions regarding desmopressin therapy. It is still unclear whether desmopressin treatment leads to better long-term outcome than the spontaneous cure rate. The long-term cure rate of 15- 30% annually is higher than the spontaneous cure rate [193, 206, 217]. Long-term follow up showed persistent LUTs symptoms in the patients with NMNE and not in the MNE patients [22]. The suggestion that tapering of the dose and the structured withdrawal programme should be beneficial is still unproven [211, 218].

Desmopressin: Tolerability and Safety

Considering the worldwide prescription-rate, desmopressin, is an extremely safe product, if correctly dosed and fluid intake is withheld after administration. There are no reports of water-intoxication with the melt or the tablet, at correct doses, since the spray was withdrawn. On the other hand, we cannot stress enough that the drug should be correctly administered, since every year there are reports of children taking it in the morning.

We reinforce the ICI-advice that a rigid regimen of water restriction must be enforced for two hours prior to bedtime and to allow one eight-ounce (300 ml) glass of water at dinner and nothing for two hours prior to bedtime. In a survey on hyponatraemia in patients with nocturnal enuresis, by Robson and Noorgard in 1996, it was found that in most children water intoxication was due to considerable intake of water during the time the child was taking the desmopressin [219-221].

The results of numerous clinical trials have shown that desmopressin is well tolerated even during long-term treatment and associated with a low risk of adverse events. In the SWEET study, only six of 242 children (2.5%) withdrew during the long-term treatment because of very mild adverse events following the administration of intranasal desmopressin.

Predictors of Response:

Translating results from historical studies with no, or old ICCS standardisation of enuresis-patients remains difficult. The SWEET study found that those who improved or became dry during desmopressin were older (greater than 8 years), had fewer wet nights during baseline, and had only one wet episode during the week and responded initially to the smallest dose of desmopressin used in the study [52, 206, 208, 222, 223]. The DRIP study documented that the highest response rate was in older children, with less severe bedwetting, nocturnal polyuria and larger functional bladder volumes. A low diuresis-volume, <60% of EBV overnight, is highly predictive of desmopressin resistance; this is logical, since low diuresis-volume coincides with already presence of maximal concentrating activity of the kidney, where desmopressin cannot have additional value [80, 201].

There is considerable evidence that desmopressin works better than placebo. In one study, patients on desmopressin were 4.6 times more likely to achieve 14 consecutive dry nights compared with placebo [207]. However, relapse after short-term treatment is common. Sixty-one percent of 399 patients six to 12 years of age recruited from a primary care in one study responded to desmopressin initially [206]. Using intention to treat analysis 19% (77 of the 399) remained dry off medication and 18% were dry while still on desmopressin, thus not significantly better than the spontaneous cure rate. This suggests that desmopressin, by reducing the urine output overnight, reduces nocturnal enuresis but does not significantly affect the resolution rate over time above the spontaneous rate.

Although several studies have shown that dDAVP is a well-tolerated and safe drug, even during long-term usage, one must be aware that dDAVP is a potent antidiuretic drug and that there have been reports of

severe water retention with hyponatraemia and convulsions, but these are infrequent [204, 208, 219, 220, 224-231].

Level of evidence: 1

Grade of recommendation: A

9.5.2 Combined treatment with alarm and desmopressin

Combined treatment may be superior to use of the alarm alone, especially for non-responders of each individual treatment. In this approach, treatments are started at the same time: the rapid action of dDAVP is believed to facilitate the child's adaptation to the alarm [232-237]. After 6 weeks, the dDAVP is discontinued while the alarm treatment is continued until the child becomes completely dry. Compared with either therapy alone, the combination is particularly effective in children with high wetting frequencies and behavioural problems. Combination with full-spectrum therapy may even yield higher success rates [232, 238].

van Kampen *et al* reported their results of 'full-spectrum' therapy in 60 patients: they were treated for 6 months with a combination of alarm, bladder training, motivational therapy and pelvic floor muscle training: 52 patients became dry. The combination of alarm with six weeks of 40ug Desmopressin intranasally was better than alarm treatment alone, especially with high micturition frequency and comorbid behavioural symptoms [239]. In a Chinese study comparing alarm, desmopressin and a combined therapy, the latter had the highest rate of sustained response (40.6%). However, there was a high relapse rate after discontinuing medication [240].

In another randomised-controlled, double blind study, the addition of 3 weeks of 40ug and 3 weeks of 20ug Desmopressin to alarm use, lead to temporary, short-term reduction of wet nights compared to controls on alarm and placebo [237]. The long-term success rate did not differ between the two groups and were low (36% and 37%, respectively). In the subgroup of Desmopressin non-responders, the combination of alarm plus Desmopressin was not more successful (51.5% remission) than alarm plus placebo (48.1% remission), so that this cannot be recommended as a routine strategy [241].

Theoretically, the combination of alarm and desmopressin makes little sense: alarm treatment is an operant type of behavioural therapy that requires a certain number of wet nights to be effective: by reducing the number of wet nights through desmopressin, the child will have less opportunity to 'practice' and 'learn' continence by the alarm therapy.

9.5.3 Antimuscarinic drugs for OAB

Antimuscarinic drugs should not theoretically be efficacious in children with monosymptomatic nocturnal enuresis. However, because there is considerable misdiagnosis of monosymptomatic nocturnal enuresis, some children with mild daytime symptoms of overactive bladder may have symptoms of overactive bladder at night. Moreover, it has been shown that on urodynamics, 73% of adults with primary nocturnal enuresis have some form of functional bladder outlet outflow obstruction classified as (1) "primary bladder neck dysfunction" or "detrusor sphincter dyssynergia" [242]. That would suggest then that antimuscarinic drugs might be a useful alternative in some children who are unresponsive to DDAVP. Antimuscarinic therapy is also indicated in combined day and night-time incontinence [86, 243, 244].

In general, antimuscarinic drugs are well tolerated but there are some side effects, namely vasodilation, dryness of the mouth, constipation and vertigo (rare), and symptoms of hyperactivity and concentration disorders, especially in a population of children with ADHD. These side-effects are more predominant with oxybutynin, than with the newer anticholinergics. Constipation can also pose a problem since the development of constipation may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Antimuscarinics may also result in increased residual volumes which may make it difficult for the child to empty prior to bedtime. Antimuscarinic treatment in conjunction with desmopressin may have a role in cases with suspected day and night time detrusor overactivity.

The combination of alarm and anticholinergics should be considered if overactive bladder is suspected. If the alarm is set off several times per night, indicative of overactive bladder, this combination has been proven to be successful. For example, 5 mg of oxybutynin in the evening, combined with an alarm could be tried in these cases. If higher levels of anticholinergics are required, several doses should be given over the day. Other programmes such as 'full spectrum treatment' remain treatment forms that are reserved for therapy-resistant cases.

Level of evidence: 2

Grade of recommendation: B.

In those children who have NE due to detrusor overactivity during the night, treatment with an antimuscarinic drug should be considered [245, 246]. Because it is difficult to perform a night time cystometry in these children, it may be tried in children who have more than 2 wetting episodes per night and who do not respond to dDAVP or be given in combination with alarm or dDAVP [244] [247]. At present, no studies have been performed to demonstrate its efficacy in this circumstance.

Level of evidence: 3

Grade of recommendation: C

9.5.4 Tricyclic antidepressants

Although tricyclic antidepressant drugs, particularly imipramine, have worked in many children, most of

the studies that recommend this drug are relatively old. The major drawbacks to imipramine therapy are cardiotoxic side effects, in some cases even with therapeutic doses, and the possibility of death with overdose.

Because imipramine and other drugs of the same family have potential cardiotoxic side effects they cannot be generally recommended for treatment of this non-lethal disorder [248]. Although treatment with tricyclic drugs is associated with a decrease of one wet night per week, the lasting cure rate of only 17 percent restricts the use of these drugs [249].

Only in selected cases (like adolescent boys with Attention Deficit Hyperactivity Disorder and persistent NE) or refractory cases should it be considered [250], and use restricted to expert centres. The need to perform an *a priori* ECG remains open for discussion, but obtaining a clinical history to exclude familial sudden death in adolescents and adults is mandatory.

Level of evidence: 1

Grade of recommendation: C (due to potential cardiotoxicity)

Table 2: Response and cure rates of different treatment modalities. Full response (while on medication) and Cure rates (6 months after cessation of treatment) of Nocturnal Enuresis

	Full response	Cure
Alarm treatment	65%	43%
Desmopressin	31%	22%
Dry-bed training	40%	18%
Imipramine		17%

9.5.5 Alternative regimens:

Several other drugs, such as carbamazepine and NSAIDS (indomethacin, ibuprofen) have also been investigated: based on study design as well as study outcomes, these drugs are not recommended [251-256].

Acupuncture, laser acupuncture and neurostimulation have also been suggested, but none has demonstrated a convincing positive effect in primary care enuresis patients [257-262].

In one randomised controlled trial that examined acupuncture, 40 children were allocated either to dDAVP or acupuncture, 75% of children were dry after 6 months of therapy (while still on medication), while 65% of patients were completely dry after a mean of 12 sessions. The evidence from these alternatives is too weak to recommend them as a first line approach. It is concluded that as an alternative, cost-effective and short-term therapy, acupuncture should remain among available treatment options. Another meta-analysis provides some evidence for the efficacy of acupuncture for the treatment of childhood nocturnal enuresis. Comparison of treatment outcome and cure rates is difficult because of the inconsistent use of definitions, the inclusion of children with daytime symptoms, and the variable follow-up periods in most studies. For a pragmatic approach, see Figure 3.

Level of evidence: 4

Recommendation: grade D

9.6. Conclusion

Based on current evidence, the enuresis alarm remains the most effective means of facilitating arousal from sleep in unselected patients. The key to success is not the stimulus intensity of the alarm triggering, but the child's preparedness to awake and respond to the signal. As an adjunct programme, arousal treatment is easy to perform and effective. But this evidence is obtained from meta-analysis comparing the use of alarm and desmopressin in poorly characterised enuresis populations, mixing up MNE with non-MNE, if we use the recent ICCS standardisation criteria.

A second therapy regimen involves individualising the treatment to the characteristics of nocturnal diuresis and functional bladder volume overnight.

The ideal therapy regimen for children with a large bladder volume, a high diuresis volume with low urinary osmolality overnight will most likely be desmopressin responsive, and would only respond to the alarm by acquiring nocturia.

The 2nd archetype is children with a small bladder volume, low diuresis volume, with already maximal concentrating capacity who are likely to be desmopressin resistant, and where the alarm is the first choice. But there are many patients who overlap between these two types, where combination therapy will be necessary, even with associated anticholinergics.

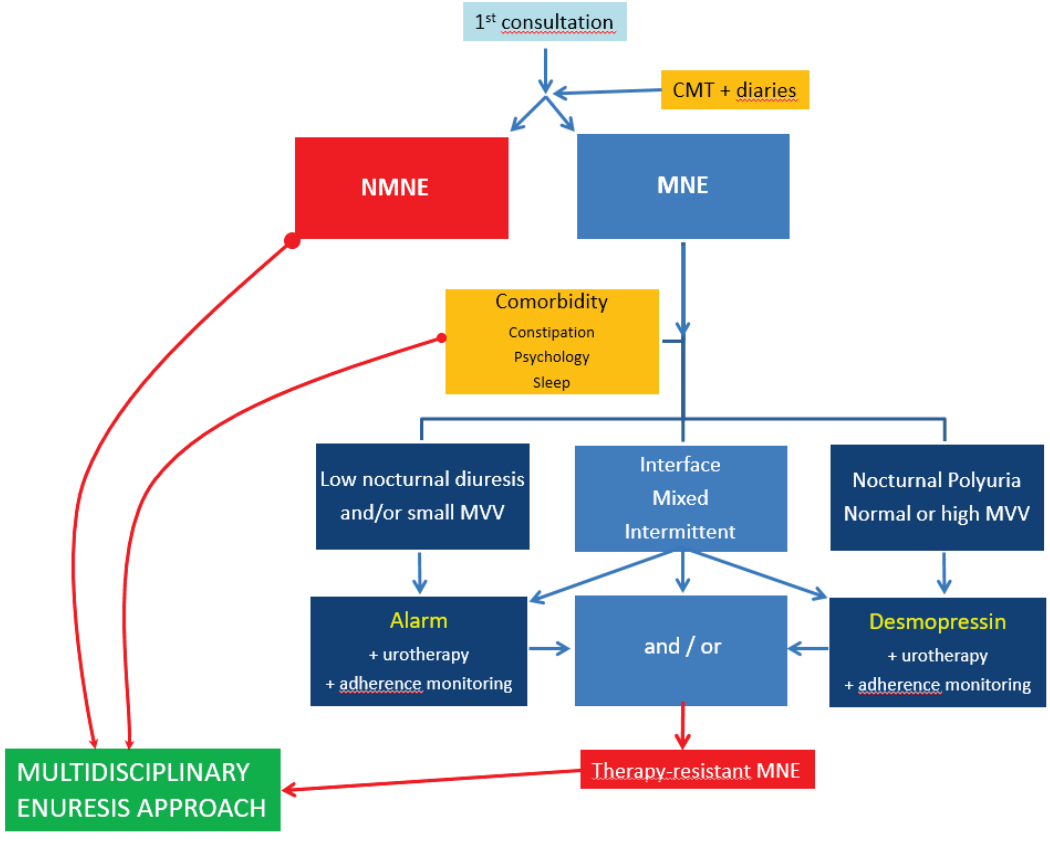

Figure 3: Treatment algorithm for enuresis.

10. REFRACTORY MNE:

About one third of children do not respond to treatment with alarm and/or dDAVP. The majority of these children are likely to have a small nocturnal bladder capacity and suffer from “detrusor dependent NE”.

Most patients with MNE who are non- or partial responders are likely to have underlying bladder dysfunction, missed during the initial assessment, because 1) it was not performed appropriately, or 2) patients were classified according to the old ICCS standardisation, when according to the new ICCS-standardisation they should be considered as NME. The full screening should be redone, with history of incontinence diurna (ID), diurnal symptoms after the age of 3,5 years, high / low frequency, postponing during normalised fluid intake as well as small enuresis volumes early in the night are very suggestive for bladder dysfunction. Spontaneous low fluid intake is suggestive of a defence mechanism, and may mask OAB symptoms. These symptoms are often not mentioned by parents, and deserve repeated questioning or documentation in a bladder diary during standardized fluid intake 1,5ml/1.73m²/day: this can give additional information. Uroflow and bladder ultrasonography may also be useful. These children benefit from a multidisciplinary approach and should not be treated in a primary care [264, 265].

But, in the absence of any bladder dysfunction we should concentrate on the desmopressin effect in differentiating different pathophysiological characteristics that may be involved 1) anti-enuretic effect = number of wet nights, 2) the anti-diuretic effect (= nocturnal diuresis rate 3) concentrating capacity (= urinary osmolality). Partial response to desmopressin in MNE (anti-enuretic effect) is related to persistent nocturnal polyuria on the wet nights [81].

Poor compliance should be excluded [167], including not taking the drug (consider letting the patient fill out a drug-diary and register the number of prescriptions /compliance):

1. the child forgets to void before going to bed, and already starts the night with a filled bladder
2. exclude drinking overnight, because fluid intake overnight or even the hour before desmopressin administration reduces both maximum and duration of anti-diuretic effect and concentrating capacity significantly.

3. intermittent polyuria might as well be related to the PK/PD characteristics of desmopressin [82, 199-202, 213]:

a. The 3 formulations (tablet, melt and spray) have poor bioavailability, ranging respectively 0,2 - 2% - 4%, but with a rather large SD = intra-individual variability. Only for the melt are dose-response-data and proper pharmacodynamic and kinetic data in children available. The melt showed superior PK and PD profile, better compliance and some indication of higher response rates. Before considering desmopressin resistance, a switch to the melt should be considered.

b. The child takes the drug just before sleeping time (the time to reach maximum concentrating capacity and anti-diuretic effect is 1-3 hours, and therefore the drug should be taken at least one hour before the last void before sleeping). Interference with nutrition (the tablet should be given on an empty stomach (= at least 2 hours after the last meal [85, 199, 200, 266].

   But 2 hours after the last meal, and 1 hour before sleep is not realistic in most children: a consideration that favours the melt above the tablet.

c. The melt study has demonstrated that, even in the therapeutic range of 120-240µg there is a large variation in maximal concentrating capacity and antidiuresis, as well as duration of action. Better understanding of these PK/PD dynamics, can lead to more personalised medicine, with individualised dosing. The PK/PD data demonstrate that at least 25% of patients might benefit from higher doses, patients that can be identified by a pharmacodynamics test in an ambulatory setting in the individual patient (24h concentration-profile), especially in the older patients. Increasing the dose without this test is indefensible, because of the risk for toxicity.

In desmopressin refractory nocturnal polyuria with low urinary osmolality, diabetes insipidus should be excluded. X-linked DI in boys does not present as enuresis, but female carriers might have a more *forme fruste* pattern with enuresis as major symptom. Many renal diseases (CKD, tubulopathies, renal dysplasia, uropathy) present with enuresis. Hypertension, and especially night time hypertension, coincides with nocturnal polyuria, and should be considered in refractory patients. Although there might be some anti-diuretic effect of desmopressin, these patients never reach maximum concentrating capacity. A desmopressin / vasopressin concentration test may be helpful if conventional diagnostic tests (ultrasound, lab) fail. It should be noted that the majority of studies on desmopressin in children with MNE demonstrate that up to 25% of patients do not reach >850 mOsmol/L after desmopressin therapy. Although these patients do not fulfil the criteria of DI, there is an increased prevalence of patients at the lower end of the normal range of concentrating capacity in these children. A 20% decrease in concentrating capacity will result in 20% increase in diuresis, and this may be the difference between continence and enuresis in many patients.

Desmopressin resistant nocturnal polyuria, with high urinary osmolality overnight might be associated / correlated with high urinary osmolality overnight. This can be caused by an increased solute load only in the evening or during 24 h [59, 60]. Sodium is the major osmotic agent [59, 72, 76, 267]. Although nutritional intake plays a major role, abnormalities of several circadian rhythms like prostaglandins [268-270], GFR [70, 72], blood pressure [69] and sleep pattern [104, 105, 108] have a significant impact in selected tertiary care patient populations. Extrapolation of these findings to primary care enuresis patients is premature. But these findings offer indications of future treatment options. Some pilot studies have promising results, such as sodium restricted diet, diuretics (Furosemide) [76, 251, 271, 272], NSAID, and treatment of sleep disturbances, (OSAS and melatonin) [48, 50, 273-276]. In the past much attention was put on the role of calcium, and a calcium restricted diet might be effective [77, 78, 277], but hypercalciuria might be a secondary phenomenon due to differences in diet [75, 84, 278].

Symptoms resistant to conventional therapy cannot only be related to underlying bladder dysfunction and renal response to desmopressin, but also to associated comorbidities. Identifying these, and addressing them if possible might increase the response rate. Constipation and faecal incontinence should be treated before the treatment of MNE but are often underestimated and underreported. Psychological comorbidities, as well internalising as externalising are more frequent in enuresis-patients. Attention deficit disorders, and autism are well studied and seem to have common pathways. A structured therapeutic approach is mandatory. Renal dysfunction, hypertension, diabetes mellitus and sleep disturbances should be treated appropriately. Many drugs interfere with the circadian rhythm of biorhythms, including diuretics, steroids, cyclosporine A, and neurotropic drugs and may be a possible trigger to offset enuresis in a sub-set of children: this is largely speculative, as good studies are lacking.

Conclusion [11, 82]

In children with MNE two first-line treatment options are available - desmopressin and the enuresis alarm. Without further individualised treatment, success rates of monotherapy may not exceed 30%, with a relapse rate up to 50%.

Optimally;

1. the initial treatment selection should be guided by the family's level of motivation and their preference.

2. and be based on the information from diaries: this will identify subtypes of MNE allowing further fine-tuning of treatment according to the child's characteristics and family motivation.

- Children with a normal urine output during the night and normal bladder capacity can be given either the alarm or desmopressin.
- Children with smaller than expected bladder capacity for age will likely be desmopressin-resistant and more sensitive to the alarm.
- Children with NP and normal bladder volume will be more sensitive to desmopressin.
- Children with both excessive urine output and reduced bladder capacity may find combined therapy of alarm and desmopressin to be successful. This strategy lessens the burden of alarm treatment as the alarm is triggered several times per night.

Despite best efforts, up to 30% of enuretics will be therapy resistant. We advocate to individualize therapy based upon the identification of the most likely pathophysiological mechanisms, bladder, kidney; sleep and comorbidities, in a multidisciplinary setting.

IV. CHILDREN WITH BOTH DAY AND NIGHT TIME INCONTINENCE

Urinary incontinence in children may be caused by a congenital anatomical or neurologic abnormality, such as ectopic ureter, bladder exstrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the inconti-nence and they are referred to as having “func-tional incontinence.”

Becoming continent is a complicated process: there is a progressive development towards nor-mal storage and emptying of the bladder at a so-cially accepted place and time, mostly achieved by age 3-4.

Bladder control is believed to be under the influ-ence of the central nervous system. The pontine region is considered to be responsible for detrusor sphincter coordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition (detrusor overactivity control). Formerly it was believed that bladder maturation followed maturation of cortical inhibition processes, However, recent work of CK Yeung suggests bi-directional maturation of both the coordinating influence on the bladder and the pons may be implicated. This implies that a condi-tion such as detrusor overactivity would be the result of loss of cortical control or of deficiency in cortical control, while dysfunctional voiding would be the result of non maturation of the coordination.

With the emergence of functional MRI, future stud-ies will be able to illuminate this enigma.[1,2] This opens an era of corticocentric thinking on lower urinary tract dysfunction, moving away from the current trend of vesicocentric thinking. Detrusor overactivity may be a symptom of a centrally locat-ed dysfunction affecting bladder, bowel, sexual function and even mood and behaviour.[3] Indeed many studies indicate that there exists a link be-tween lower urinary tract dysfunction and behav-ioural disorders such as ADHD (attention deficit / hyperactivity disorder) [4-5].

The desire to void is a sensation which, in the developing child, is incorporated into daily life so that voiding takes place at an appropriate time and place. Problems with training or psychological difficulties possibly have a great impact on the results of training: some parents send their child to the toilet many times, though his/her bladder may be empty [6,7]. Voiding in these circumstances can only be achieved by abdominal straining. The pos-itive reinforcement that the child receives by void-ing even a small amount may lead to the develop-ment of an abnormal voiding pattern. The same is true when children receive negative feedback relat-ed to voiding [8-10]. At present no evidence exists to prove these assumptions.

Urinary incontinence in children may be due to disturbances of the filling phase, the voiding phase or a combination of both. In the ICCS termi-nology document, these conditions are termed functional bladder disorders or Lower Urinary tract (LUT) conditions. They are divided into either overactive bladder (OAB) or dysfunctional voiding [11]. While the former condition is a filling disor-der the latter is considered an emptying disorder. They can of course coincide and one may even be causative of the other. No evidence exists however for this last assumption. It has been postulated that detrusor overactivity may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detru-sor, sphincter and pelvic floor. However, the natural history of many of these children does not con-firm this hypothesis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have differ-ent primary diseases, but all have a common risk of incontinence, UTI, VUR [15%] and constipation [17%] [12].

Detrusor overactivity may lead to disturbances in the filling phase characterized by urgency, fre-quency and at times urgency incontinence. Girls present with OAB symptoms more often than boys. In addition to the urinary symptoms, children with functional urinary incontinence may also have recurrent urinary tract infections (UTI) and consti-pation.

Incomplete relaxation or tightening of the sphinc-teric mechanism and pelvic floor muscles during voiding results in an interrupted or staccato void-ing pattern, that may be associated with elevated bladder pressures and post-void residuals. Such individuals with dysfunctional voiding are also prone to constipation and recurrent UTIs [13]. Bladder function during the filling phase in these children may be essentially normal, alternatively OAB may be present. In children with a underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals, and incontinence is a characteristic symptom.

1. PREVALENCE

For more detailed information on the prevalence of daytime incontinence the Chapter on Epidemiolo-gy should be consulted. The main problem is that it is impossible to draw any conclusions from the presented data as different studies have used dif-ferent definitions and criteria. Furthermore, it is virtually impossible to identify the prevalence of detrusor overactivity or dysfunctional voiding as the studies tended to look primarily at daytime versus night-time incontinence and made no effort to evaluate the type of daytime incontinence.

Daytime or combined daytime and night-time in-continence at least once a week seems to occur in about 2-4 percent of 7-year old children and is more common in girls than in boys [14]. Overall the rates of prevalence vary from 1 to 10 percent, but in general for 6 to 7-year-old children the prevalence is somewhere between 2 and 4 percent, and rapid-ly decreases during the following years [15-19]. Sureshkumar et al in a population based survey of over 2000 new entrant primary school children [age 4-6 years] in Sydney, Australia noted an over-all prevalence of daytime wetting of 19.2% defined as at least one daytime wetting episode in the prior 6 months with 16.5% having experienced more than one wetting episode and only 0.7% experi-encing wetting on a daily basis [20]. Multivariate analysis showed that recent stress, a history of daytime wetting along the paternal line, and a his-tory of wetting among male siblings were inde-pendent risk factors for moderate to severe daytime wetting. Because this was a cross-sectional study recall bias may have resulted in an overestimate of risk of daytime wetting being caused by such factors as emotional stress and family histo-ry. In addition, urine cultures were not obtained so occult UTIs could not be identified. Chung comes to the same percentage of OAB (16,6%) in 19,240 Korean children. In this study OAB was differenti-ated in 'dry' OAB and 'wet' OAB: children with OAB do not always have incontinence (21).

In a questionnaire based study, supplemented by telephone calls, Hellstrom assessed the preva-lence of urinary incontinence in 7 year old Swe-dish school entrants [22]. Diurnal incontinence was more frequent in girls than boys, 6.7% vs 3.8%, respectively. Wetting every week was report-ed in 3.1% girls and 2.1% of boys. The majority of children with diurnal incontinence had concomi-tant symptoms: urgency was reported in 4.7% girls and 1.3% boys. Nocturnal incontinence combined with daytime wetting was equally common in males versus females, 2.2% versus 2%, respectively. At the age of 17 years daytime wetting, at least once a week, was found in 0.2 % of boys and 0.7% of girls. A limitation of this study is its dependency on re-call. Children with daytime or mixed wetting were found to suffer from urgency in 50.7 %, with 79.1 % wetting themselves at least once in 10 days [23]. Urgency symptoms seem to peak at age 6–9 years and diminish towards puberty, with an assumed spontaneous cure rate for daytime wetting of about 14% per year [24].

In a, cross sectional sample of 594 individuals 4 to 26 years old Kyrklund describes in 2012 4% of respondents with frequent UI, most < 12 years. Prevalence decreases enormously with age (25).

Most children are toilet-trained by the age of 3 years, although the mean age may range from 0.75 to 5.25 years, with girls being trained earlier [2.25 years] than boys (2.56 years) [26]. A 2008 Turkish study reported day dryness at a mean age of 28 months (27). This is confirmed by a 2015 Turkish study in 1500 children whose mean age of dryness was 29 months (28). The age of commencing toilet training has increased [29]. This is thought to be associated with higher education levels in parents and the popularity of the child-oriented approach rather than parent-initiated methods [26]. Children who exhibited elimination signals for voiding be-came dry sooner than those who did not show such signs. There is huge social and cultural varia-tion in toilet training practices with some of the implicated issues being, availability of inside toilet, washable versus disposable diapers, working or home-based mothers, rural or urban location and use or not of punishment methods (22). It ap-peared that initiating toilet training after 24 months of age may be associated with problems attaining and maintaining bladder control and that early training is not associated with bladder dysfunction (29,30). A prospective study in 112 patients pub-lished in 2014 however showed problems in early training (<2 years) and in late training (>3 years) alike (31). Da Fonseca found no association be-tween children with combined bladder and bowel dysfunction and the time of toilet training com-pared to healthy children (32).

Swithinbank et al found a prevalence of day wetting [including also "occasional" wetting] in 12.5% in children age 10-11 years which decreases to 3.0% at age 15-16 years [33]. Based on these findings, it seems that the prevalence of all kinds of daytime incontinence diminishes by 1-2% per year from age 10-11 to age 15-16 years, while daytime incon-tinence, at least once a week, seems to diminish by 0.2% per year from age 7 to age 17 years. Because of treatment interventions the studies may not re-count the true natural history.

A cohort study of all school children in the first and fourth grades in the city of Eskilstuna (Swe-den), published in 2004, daytime urinary inconti-nence (at least once a month) was reported in 6.3% of the first graders and 4.3% of the fourth graders, while bedwetting (at least once a month) was reported in 7.1% and 2.7% and faecal inconti-nence in 9.8% and 5.6%, respectively. This study demonstrates that soiling and daytime urinary in-continence often coexist [34].

The natural history of detrusor overactivity in chil-dren is not well understood. It is no longer held that detrusor overactivity in children is idiopathic or due to a maturational delay but more likely to be associated with feed forward loops from the gen-eration of a high

pressure system during voiding or filling. Both the interplay of neural drive with motor control and the dynamic nature of the grow-ing bladder could be causative. This is in contrast to the adult population, where detrusor overactivity is considered a chronic condition whose origin is unrelated to functional use. There is no long-term data to determine if childhood detrusor overactivity predicts detrusor overactivity as an adult. There is evidence that genetic influences affect adult urinary symptoms and that suffering lower urinary tract conditions in childhood increases the risk for these conditions in adult woman (35-39). Recent research points to a link between deficits in the brain and functional urinary problems (5).

By the age of 5 years, unless organic causes are present, the child is normally able to void at will and to postpone voiding in a socially acceptable manner. After this age, night-time and daytime in-voluntary wetting become a social problem and a cause for therapeutic intervention. In children who present with a change in voiding habits, such as a new onset of voiding dysfunction, one should consider the possibility of child sexual abuse [37]. A more recent study found no significant differ-ences in the presence of lower urinary tract symp-toms between children and adolescents who had experienced sexual abuse and controls [31]. Never-theless this should be kept in mind, especially when invasive diagnostic and therapeutic proce-dures are contemplated. One may want to simply ask the parent or caregiver if there were any pre-cipitating events or concerns that they feel may have led to the changes in the child's voiding hab-its. The appropriate individuals should be contact-ed if there is a high index of suspicion. Of adult women with complex urinary symptoms, a signifi-cant proportion report sexual abuse as a child.

2. INTRODUCTION TO CLINICAL ASSESSMENT

The International Children's Continence Society has published standardisation documents on the diagnostic evaluation of children with daytime incontinence as well as on the management of daytime urinary incontinence in general and dys-functional voiding in children. They also assessed psychological and psychiatric issues in urinary and faecal incontinence (39-41).

The evaluation of daytime wetting is based on the medical and voiding history, a physical examina-tion, a urinalysis, bladder diaries and uroflowmetry with post void residual. The upper urinary tract should be evaluated in children with recurrent in-fections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyogra-phy to demonstrate overactivity of the pelvic floor muscles. Urodynamic studies are usually reserved for patients with therapy resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [42-46].

Treatment is usually a combination of 'standard therapy' (see below), behaviour therapy, bladder training, physiotherapy and medical treatment. Surgery is rarely needed for the management of daytime wetting in the absence of a structural ab-normality. The roles of neurostimulation, botulinum toxin and intravesical therapies in the management of paediatric urinary incontinence are less well-defined. Clean intermittent self-catheterisation is sometimes necessary in children with poor blad-der emptying, due to underactivity of the detrusor and subsequent large residuals, who do not re-spond to a more conservative approach.

The importance of treatment during childhood was pointed out in a general population study of 1333 adult women. Fifty percent reported symptoms of stress incontinence and 22 percent reported symptoms of urgency incontinence. Eight percent noted severe symptoms. Women who at age six years had wet episodes during the day or were wet several nights per week, were more likely to suffer from severe incontinence and report urgency symptoms: occasional bedwetting was not associ-ated with an increased risk in adult life [47].

3. CONFOUNDING FACTORS: LOWER URINARY TRACT DYSFUNCTION, RECURRENT URINARY TRACT INFECTION AND VESICOURETERIC REFLUX (VUR)

The relationship between detrusor dysfunction and VUR associated with a urodynamic anomaly was first described by Allen and Koff and has been con-firmed by several authors [48-51]. Koff demonstrat-ed that treatment of detrusor overactivity reduced the incidence of infection and resulted in a 3 fold increase in the rate of reflux resolution. In a study by Sillen of children with gross bilateral reflux, extreme detrusor overactivity without signs of bladder outlet obstruction was found in boys. Infant girls with gross bilateral reflux did not show the same degree of detrusor overactivity [51]. Other investigators assessing high grade VUR in new-borns noted similar findings. Van Gool et al noted that 40% of 93 girls and boys evaluated for urgency incontinence and recurrent UTIs had reflux [52].

These studies in infants and the association of combined bladder and bowel dysfunction with reflux and infection in older children support the suggestion that, in some individuals, vesicoureter-al reflux is a secondary disorder related more to abnormal detrusor function than to a primary ana-tomical defect at the ureterovesical junction. It has been shown that increased intravesical pressure, without reflux, may be detrimental for the upper tracts: renal scarring without reflux was recently described by Vega et al [53].

In support of this concept is the common finding of vesicoureteral reflux in children with neuro-pathic bladders and detrusor-sphincter dyssyner-gia. In such children, the institution of clean inter-mittent catheterisation and anticholinergic therapy leads to the resolution of VUR in a large number of cases. It is believed that the decrease of detrusor overactivity and restoration of functional capacity in combination with regular and complete empty-ing of the bladder are the responsible co-factors [54]

Koff et al. evaluated the effects of antimuscarinic therapy in 62 children with a history of recurrent UTIs, VUR and detrusor overactivity, and com-pared these children with an age-matched control group with a normal urodynamic study [55]. The overall small sample size and the small number of compliant patients limit the study, however, it did demonstrate a statistically significant difference in the resolution rate of VUR between the treated group and the control group. The overall infection rate was lower in the treated group [16%] compared to the non-medically treated group [63%] and the age-matched control group [71%]. Several authors have documented the relationship between detru-sor overactivity and dysfunctional voiding with recurrent UTIs .

Proposed aetiologies for the increased incidence of UTIs in these patient populations include a milk back phenomenon whereby bacteria in the proxi-mal urethra are “milked back” into the bladder dur-ing contraction of the pelvic floor muscles. Alterna-tively, decreased blood flow and relative hypoxia during periods of increased detrusor pressure such as during involuntary detrusor contractions and voiding against functional obstruction, may induce transient bladder mucosal injury.

Constipation is prevalent among children with bladder symptoms, but often poorly identified by parents [56]. It is a risk factor for recurrent UTIs. Contrary to expectations, findings from the Euro-pean Bladder Dysfunction Study suggested that symptoms of disordered defaecation did not influ-ence the cure rate of treatment for bladder symp-toms [57]. In a prospective non-randomised clini-cal series of day wetting children, a strong correla-tion was found between recurrent urinary tract in-fections, detrusor overactivity and detrusor-sphincter dysfunction [58]. In a study by Hansson et al, symptoms of detrusor overactivity, such as urgency and daytime incontinence were found in a high percentage of girls with asymptomatic bacte-riuria [59].

In the majority of children with dysfunctional void-ing the recurrent infections disappeared following successful treatment of the voiding dysfunction. This finding confirms the hypothesis that dysfunc-tional voiding is the main factor responsible for the infections [and to a lesser extent vice versa] [60,61]. Additionally, since such children typically have coexistent constipation, attempts at restoring normal bowel habits will also contribute to decreas-ing the risk of UTIs.

At present, current opinion is that vesicoureteral reflux as such does not predis-pose to UTI: however it may facilitate renal in-volvement [causing pyelonephritis] once bacteriu-ria has been established in the bladder. This con-cept has not been scientifically validated and the incidence of renal scars as a consequence of pye-lonephritis is reportedly the same, regardless of whether reflux has been documented or not [62]. Those children with VUR in association with de-trusor overactivity and/or voiding dysfunction may be at increased risk for upper tract damage given their increased risk of developing UTIs. With this in mind, aggressive treatment of the underlying filling/voiding disorder, the addition of prophylac-tic antibiotics, and attention to their bowel habits should be given in an effort to decrease the risk of UTIs in this higher risk group [63-66].

In a recent study evaluating retrospectively a large group of children with LUT conditions it was shown that in patients who had urinary tract infec-tion the presence of reflux increased the rate of renal cortical abnormalities. [67].

4. CLASSIFICATION

Numerous classifications have been used for children who present with varying degrees of ‘func-tional’ urinary symptoms, unrelated to apparent disease, injury or congenital malformation. In 2016, the International Children’s Continence Society (ICCS) released a standardised terminology to provide guidelines for the classification and com-munication about LUTS in children [11].

Symptoms are classified according to their relation to the voiding and or storage phase of bladder function.

In addition to gaining a comprehensive history, observing micturition and examining the child forms the basis of assessment: the information derived from a 48 hour bladder diary, stool record, voiding uroflowmetery and lower urinary tract ul-trasonography is also essential in making the ini-tial diagnostic classification (39,68).

Screening for psychological symptoms with questionnaires is recommended, as 30-40% of children with daytime urinary incontinence are affected by comorbid emotional of behavioural disorders [69].

Urodynamic investigations elucidate the basis of clinical findings but are first line evaluation tech-niques only in tertiary referral centres where chil-dren have not responded to previous treatment or have symptoms suggestive of neural involvement or anatomical anomalies.

The ICCS has classified daytime LUT conditions into groups that currently align with understanding of underlying pathophysiology. The groups com-monly overlap and allocation is based on the 4 symptoms of urinary incontinence, frequency of volitional voiding, micturition volumes and fluid intake.

- Over active bladder (OAB) including urgency incontinence
- Dysfunctional voiding
- Underactive bladder

The symptom-specific conditions of

- Voiding postponement
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency
- Elimination syndrome

The term 'non-neurogenic dysfunction' is com-monly encountered in the literature and describes the whole spectrum, from simple bladder overactiv-ity to severe cases with deterioration of the upper tracts. The fact that a neurologic deficit is not demonstrated at the time of evaluation, does not, however exclude the possibility that a neurological abnormality was present at the onset of the prob-lem. It has been postulated that detrusor overactivi-ty may eventually lead to poor bladder emptying due to underactivity of the detrusor or severe dyscoordination between detrusor, sphincter and pelvic floor. However, the natural history of many of these children does not confirm this hypothe-sis, nor the early onset of severe pathology in some of them. Hoebeke et al found no evidence for this dysfunctional voiding sequence: children with functional incontinence have different primary diseases, but all have a common risk of inconti-nence, UTI, VUR [15%] and constipation [17%] [12].

4.1. Overactive bladder in children

The term bladder overactivity is used to describe the symptom complex of urgency, which may or may not be associated with urgency incontinence and is not a direct result of known neurological damage. Recent suggestions describe OAB as a symptom of cortico-central dysfunction that affects multiple systems rather than a dysfunction isolated to the urinary bladder [70]. Urgency syndrome is characterised clinically by frequent episodes of an urgent need to void, countered by contraction of the pelvic floor muscles (guarding reflex) and holding manoeuvres, such as squatting and the Vincent curtsey sign. The term urgency refers to a sudden compelling desire to void that is often difficult to defer, unlike the need to void which is experienced by all individuals and may be intense if one holds one's urine for a prolonged period. The symptoms are thought to arise from detrusor overactivity during the filling phase, causing urgency. These detrusor contractions are countered by voluntary contraction of the pelvic floor muscles to postpone voiding and minimise wetting. Where present, the detrusor contractions can be demon-strated urodynamically, as can the increased ac-tivity of the pelvic floor muscles during each con-traction.

The voiding phase is essentially normal, but detru-sor contraction during voiding may be extremely powerful. The flow rate reaches its maximum quick-ly and may level off ('tower shape'). Such strong bladder and pelvic floor muscle contractions have been postulated to result in damage to the bladder mucosa increasing the risk of UTIs. In addition, these children may note suprapubic or perineal pain. A cohort of patients presenting with night-time pain syndromes based on pelvic floor spasms was described by Hoebeke et al. Good response to pelvic floor relaxation biofeedback is described in this study [71].

Overactive bladder (OAB) should also be consid-ered in "continent" children with recurrent UTI and vesicoureteral reflux. Depending on fluid intake and urine production, the complaints of inconti-nence become worse towards the end of the day, due to loss of concentration and fatigue and may also occur during the night. Children usually di-minish their fluid intake to minimise wetting, and therefore incontinence may not be the main com-plaint or symptom, but on careful questioning ur-gency becomes apparent.

Frequent voluntary contractions of the pelvic floor muscles may also lead to postponement of defae-cation. Constipation and faecal incontinence (soil-ing) are often found in children with detrusor over-activity [72]. The constipation is aggravated by the decreased fluid intake. Constipation contributes to an increased risk of UTIs and may exacerbate the detrusor overactivity. An investigation of the natu-ral history of combined emptying dysfunction of bladder and bowel, using an elimination score in women with and without urogynaecological prob-lems, demonstrated that childhood lower urinary tract dysfunction may have a negative impact on bladder and bowel function in later life [73]. Urinary symptoms and faecal problems often go hand in hand, epidemiological data show that urinary con-tinence is found more often in girls, where defae-cation problems are more often found in boys. A clear explanation is not yet found.

A careful history, physical examination and scruti-ny of the child's bladder diary will identify symp-toms of detrusor overactivity. Urine flow rate regis-tration and post-void residual urine measurement help to identify co-existing dysfunctional voiding. Thus, in most children, invasive studies such as urodynamic studies are not indicated as part of the initial evaluation. Such studies are reserved for those children with a question of an underlying neurological defect and those who fail to improve with medical and behavioural therapy, if invasive therapies are being considered. Those children with a history of recurrent UTIs should undergo assessment with a renal/bladder ultrasound and depending on the age of the child, and the severity of the UTI(s), a voiding cystourethrogram (VCUG) to assess reflux is occasionally performed [74,75]. By adopting a structured approach to his-tory and physical examination, the diagnosis can be made in most children without the need for in-vasive diagnostic procedures.

Treatment:

Treatment involves a multimodal approach, involving strategies such as behavioural modification, antimuscarinic medication and neurostimulation. Underlying and potentially complicating conditions such as constipation and UTI are managed prior to intervention.

Level of evidence: 3

Grade of recommendation: C

4.2. Dysfunctional voiding

Dysfunctional voiding refers to an inability to fully relax the urinary sphincter or pelvic floor muscles during voiding. There is no identified underlying neurologic abnormality. Children with dysfunc-tional voiding usually present with incontinence, urinary tract infections and constipation and demonstrate an intermittent, or fluctuating pattern referred to as staccato flow (by ICCS definition) during repeated uroflowmetry.

No clear data are available on the possible causes of dysfunctional voiding. It may be that detrusor overactivity eventually leads to overactivity of the pelvic floor muscles, with subsequent insufficient relaxation during voiding [75]. Alternatively, poor relaxation of the pelvic floor muscles during void-ing may be a learned condition during the toilet training years, adopted following episodes of dys-uria due to UTI, or constipation or occurring sec-ondary to sexual abuse [77]. The child's environ-ment, in particular toilet conditions and privacy issues, can trigger or exacerbate voiding anoma-lies [78]. In some girls, anatomical anomalies of the external urethral meatus seem to be associated with a higher incidence of dysfunctional voiding. The urine stream may be deflected anteriorly and cause stimulation of the clitoris with subsequent reflex activity of the bulbocavernosus muscle causing intermittent voiding [78]. Since no true structural obstruction can be identified the intermittent in-complete pelvic floor relaxation that occurs during abnormal voiding is termed a functional disorder.

Abnormal flow patterns seen in children with dysfunctional voiding:

- Fluctuating (Staccato) voiding: continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity. Voids are commonly prolonged and incomplete.
- Interrupted voiding: characterized by unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in separate fractions. Bladder volume is usually larger than age-expected capacity. Residual urine is often present. Detrusor overactivity may be seen but it may also be absent [61, 73, 80]

Sustained alteration of voiding is associated with subsequent filling phase anomalies such as phasic detrusor overactivity and inappropriate urethral relaxation [81]. Urinary tract infections and kidney damage are common sequelae [82]. Over time, rou-tine incomplete bladder emptying may possibly progress to detrusor over-distension associated with chronic urinary retention and poor bladder emptying due to detrusor underactivity.

Urinary symptoms associated with dysfunctional voiding range from urgency to complex inconti-nence patterns during the day and night [78]. Chil-dren with dysfunctional voiding have a higher rate of recurrent urinary tract infections than children with no voiding abnormality and demonstrate in-creased incidence of higher grades of VUR [67, 84]. Symptoms are significantly more common in children with Attention Deficit Disorder than in 'normal' children [85].

Signs of dysfunctional voiding reflect initial "com-pensatory" overactivity of the detrusor along with poor emptying ability. They may include small bladder capacity, increased detrusor thickness, decreased detrusor contractility, impaired relaxa-tion of the external urinary sphincter/ pelvic floor during voiding, weak or interrupted urinary stream and large post-void residual volumes of urine. There may also be ultrasound abnormalities, sec-ondary vesicoureteric reflux, faecal incontinence or constipation [67, 86,87].

Treatment:

Symptoms are often refractory to standard therapy of hydration, bowel management, timed voiding and basic relaxed voiding education. Effective intervention requires combination therapy, generally with a sizeable investment of time over a long period. Treatment is aimed at optimising bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.

Specific goals are:

- consistent relaxation of the pelvic floor throughout voiding,
- normal flow pattern,
- no residual urine and
- resolution of both storage and voiding symptoms.

Strategies to achieve these goals include pelvic floor muscle awareness and timing training, re-peated sessions of biofeedback visualisation of uroflow curves and/or pelvic floor activity and re-laxation, clean intermittent self-catheterisation for large post-void residual volumes of urine, and antimuscarinic drug therapy if detrusor overactivity is present. If the bladder neck is implicated in in-creased resistance to voiding, alpha-blocker drugs may be introduced. Recurrent urinary infections and constipation should be treated and prevented during the treatment period.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms [88]. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dys-functional voiding is not well delineated and opti-mum duration of therapy is poorly described.

Level of evidence: 4

Grade of recommendation: C

4.3. Detrusor underactivity

Children with detrusor underactivity may demonstrate low voiding frequency and an inability to void to completion using detrusor pressure alone. Voiding is of long duration, low pressure, intermit-tent and often augmented with abdominal strain-ing.

Children with this condition usually present with urinary tract infections and incontinence. Urody-namically, the bladder has a larger than normal capacity, a normal compliance and reduced or no detrusor contraction during voiding. Abdominal pressure is the driving force for voiding. The pre-viously used term 'lazy bladder' is incorrect and is no longer used.

A correct diagnosis can only be made by urody-namic evaluation. Renal function studies, renal ultrasound and VCUG should be performed to as-sess the extent of renal damage and reflux. Long-standing overactivity of the pelvic floor may in some children be responsible for decompensation of the detrusor, leading to an acontractile detrusor. However, no data are available to support this theory.

Treatment:

Treatment is aimed at optimising bladder emptying after each void. Clean intermittent (self) catheterisation is the procedure of choice to promote complete bladder emptying, in combination with treatment of infections and constipation [which may be extreme in these patients]. Intravesical electrostimulation has been described, but now it is still not recommended as a routine procedure for children.

Level of evidence 4

Grade of recommendation C

4.4. Voiding postponement

Voiding postponement is a condition in which children habitually postpone imminent micturition until overwhelmed by urgency, resulting in urgency incontinence [88]. A study comparing children with typical OAB to those with voiding postponement revealed a significantly higher frequency of clinically relevant behavioural symptoms in postponers than in children with OAB, suggesting that voiding postponement is an acquired or behavioural disorder [88]. The rates of Oppositional Defiant Disorder (ODD) are especially high. Some children with voiding postponement have abnormal uroflow patterns (90).

Voiding postponement can develop out of previous OAB, but can represent a separate disorder. Also, voiding postponement can induce OAB. Therefore, different aetiologies need to be considered.

Only 20% exhibit a fluctuating voiding pattern. It remains to be determined whether voiding postponement can develop in the setting of a perfectly normal urinary tract or whether OAB is a necessary precursor.

Level of evidence 4

Grade of recommendation C

4.5. Giggle incontinence

In some children giggling can trigger partial to complete bladder emptying well into their teenage years, and intermittently into adulthood [91,92]. The condition occurs in girls and occasionally in boys and is generally self-limiting. The aetiology of giggle incontinence is not defined. Urodynamic studies fail to demonstrate any abnormalities, there is no anatomic dysfunction, the upper tracts appear normal on ultrasound, the urinalysis is normal and there are no neurological abnormalities [86,87]. It is postulated that laughter induces a generalised hypotonic state with urethral relaxation, thus predisposing an individual to incontinence, however the effect has not been demonstrated on either smooth or skeletal muscle. It has also been suggested that giggle incontinence is due to laughter triggering the micturition reflex and overriding central inhibitory mechanisms. One small study hinted at an association with cataplexy (associated involuntary truncal body movements) and narcolepsy (a state of excessive daytime sleepiness), suggesting involvement of central nervous structures, however with only 7 subjects further evidence is needed [94]. Since the aetiology of giggle incontinence is not known it is difficult to determine the appropriate form of treatment. Positive results have been reported with conditioning training, methylphenidate and imipramine [92- 98]. Others have tried antimuscarinic agents and alpha-sympathomimetics. There is no acceptable evidence that any form of treatment is superior to no intervention.

Level of evidence 3

Grade of recommendation D

4.6. Vesicovaginal entrapment

Urinary leakage that occurs in girls a short time after voiding to completion, that is not associated with any strong desire to void, may be the result of vesicovaginal reflux

[98]. Urine may become entrapped in the vagina during voiding due to labial adhesions, a funnel shaped hymen, or an inappropriate position on the toilet. The classic presentation is that of a girl who does not spread her legs apart during voiding and who is not sitting all the way back on the toilet seat, but who is rather sitting near the end of the toilet seat tilting forward. Obesity may be an associated risk factor. Changes in voiding position and treatment of labial adhesions will lead usually to resolution of the urine leakage.

Level of evidence 4

Grade of recommendation C

4.7. Bladder and bowel disorder

This is a term used to describe the association of any bowel and/or bladder disorder (11).

The genitourinary tract and the gastrointestinal system are interdependent, sharing the same embryologic origin, pelvic region and sacral innervation. Although children with voiding disturbances often present with bowel dysfunction, until recently this co-existence was considered coincidental. However, it is now accepted that dysfunction of both systems, in the absence of anatomical abnormality or neurological disease, is inter-related. The common neural pathways, or the mutual passage through the pelvic floor musculature, may provide a theoretical basis for this relationship, as may the acquisition of environmental and developmental learning. The latter can be influenced by episodes of urinary tract infection, constipation, anal pain or trauma, childhood stressors, reluctance to toilet and poor toilet facilities [69,78,100].

There is also evidence to suggest that in severe cases symptoms may have a neurological basis.

BBD is seen more frequently in girls than boys and is significantly associated with the presence of both VUR and UTI [101]. VUR is slower to resolve and breakthrough urinary tract infections are significantly more common in children with ES when compared to those without the diagnosis. Infections do not ameliorate with antibacterial prophylaxis. Age of first febrile UTI does not appear to be an aetiological factor [91], however, recurrence of UTI in children older than 5 years is associated with the presence of BBD [102-104].

Abnormal recruitment of the external anal sphincter during defecation or at call to stool is considered causative, in that it elicits concomitant urethral sphincter and pelvic floor co-contractions. Thus, in both systems a functional obstruction to emptying is generated. In the case of the urinary system, high pressures generated by the detrusor muscle to overcome a decrease in urethral diameter can stimulate detrusor hypertrophy, detrusor overactivity, and lead to incompetence of the vesicoureteric junctions. In the early stages of defaecation disorders, bowel emptying is incomplete, infrequent and poorly executed. As the dysfunction progresses stool quality becomes abnormal, the child develops distension of the rectum and descending colon, seems to lose normal sensation and develops faecal retentive incontinence. If constipation was not present as a predisposing factor, it rapidly develops [101].

Children with BBD commonly complain of daytime urinary incontinence, non-monosymptomatic nocturnal enuresis, recurrent urinary tract infections, imperative urgency to void (OAB) and exceptionally urinary frequency. On investigation, they are often noted to have poor voiding efficiency, vesicoureteric reflux, constipation, faecal incontinence, no regular bowel routine and infrequent toileting. The incidence of children with elimination syndrome and sub-clinical signs and symptoms is unknown.

It is important to differentiate between functional constipation and non-retentive faecal incontinence, as the treatment differs. The ICCS has provided documents for both disorders (105,106).

Assessment follows the same process as for other aspects of paediatric bladder dysfunction, with the addition of a 2-week bowel diary and relevant symptom score. The inclusion of an ultrasound rectal diameter measure when assessing the bladder, has been shown to be discriminative for children with elimination syndrome. Urinary flow curve, perineal EMG and post void residual urine estimate, when considered in isolation, are not conclusive for the diagnosis of elimination syndrome. There is no evidence to suggest that anorectal manometry is warranted as a first line investigation in these children. Recently a symptom scale for BBD has been developed providing objective assessment for diagnosis and quantification of severity [107].

Treatment:

Treatment aims at assisting a child to become clean and dry in the short term, by retraining appropriate bladder and bowel awareness and teaching optimal toileting skills. As bowel dysfunction is more socially isolating than urinary incontinence, and in the light of evidence that amelioration of underlying constipation can relieve bladder symptoms, most clinicians begin with treatment of the bowel. Strategies include disimpaction [if needed], prevention of stool reaccumulation, and post-prandial efforts to empty the bowel while maintaining optimal defaecation dynamics (106). Once stools are being passed regularly, treatment focuses on teaching awareness of age appropriate fullness in the bladder, and training unopposed emptying (without straining or pelvic floor muscle recruitment), at pre-scheduled times. Pelvic floor awareness training and biofeedback therapy are integral.

There are few studies of the efficacy of treatment in children with BBD. Several authors have evaluated the outcome of constipation management on bladder symptoms, however the baseline characteristics of subjects were not described adequately enough to allow clear diagnosis of BBD [72, 107]

A review on the effectiveness of biofeedback for dysfunctional BBD reports that 80% of children benefited from biofeedback but that the level of evidence was low due to poor study designs (106, 109).

Grade of recommendation C

5. PRINCIPLES OF NON-PHARMACOLOGICAL TREATMENT OF ALL DIFFERENT STATES

Treatment of the overactive bladder focuses on both the involuntary detrusor contractions and the child's awareness to these. The initial treatment of this and all other daytime urinary incontinence subtypes involves a behavioural and cognitive approach. Urotherapy is the umbrella term for all non-surgical and non-pharmacological interventions. The child and parent[s]/caregiver(s) are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and UTIs and any constipation are managed. Additional treatment involves pharmacotherapy, pelvic floor muscle relaxation techniques and biofeedback, either alone or in combination.

Although there are many studies reported in the literature assessing the effects of various forms of therapy on daytime incontinence and urinary symptoms, many of these are case series rather than being randomised or controlled trials. The paucity of studies evaluating basic standard therapy initiatives has precluded double-blinded trials of novel and multimodal interventions. Whilst clinically important benefits are commonly described, patient numbers, objective outcome measures and length of follow-up are sub-optimal.

The main objectives of treatment are to normalise the micturition pattern, normalise bladder and pelvic floor overactivity and cure the incontinence, infections and constipation. Traditional therapy for day-wetting children is cognitive and behavioural. Children learn to recognise the desire to void and to suppress this by normal central inhibition instead of resorting to holding manoeuvres [i.e. immediate voiding without postponement] to generate urethral compression. Children with dysfunctional voiding learn to initiate voiding with a completely relaxed pelvic floor and to pass urine in association with a detrusor contraction rather than via generation of abdominal pressure. Dietary changes and bowel regimens are used to treat the constipation [108]. Antibiotic prophylaxis may prevent recurrent UTIs, however, data to support this is limited.

Some authors contend that in less severely affected children a thorough explanation of the underlying causes and the expected progress of resolution is sufficient treatment [52]. More active conventional management involves a combination of cognitive, behavioural, physical and pharmacological therapy. Common modes of treatment include parent and child reassurance, bladder retraining (including timed toileting), pharmacotherapy, pelvic floor muscle relaxation and the use of biofeedback to inhibit rises in detrusor pressure associated with urinary incontinence [33, 110-112]. Further treatment options include suggestive or hypnotic therapy and acupuncture. A combination of bladder training programmes and pharmacological treatment, aimed specifically at reducing detrusor contractions, is often useful and sometimes necessary.

5.1. Bladder rehabilitation and urotherapy

Initial intervention for OAB, voiding postponement and dysfunctional voiding uses a non-pharmacological approach. Despite the use of urotherapy for many years there is no set format and many clinical studies utilise differing combinations of therapies, which makes it difficult to evaluate the results [111,112]. The aim of urotherapy is to normalise the micturition pattern and to prevent further functional disturbances. This is achieved through a combination of patient education, cognitive, behavioural and physical therapy methods.

A Danish report of the outcome of standard urotherapy in 240 children with daytime incontinence noted achievement of dryness in 126 children (55%). Alarm therapy has traditionally been used for the treatment of nocturnal enuresis but was recently used in management of daytime wetting. When a time watch was utilised as a reminder to void at regular intervals 70% of children became dry. An earlier study of a contingent alarm [which sounded when the child wets] versus a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) over 3 months in 45 children [113] was equally successful for the achievement of continence. Predictors for dryness included a low voiding frequency, larger volumes voided in relation to age-expected storage and fewer incontinent episodes per week [114].

There is evidence that for children who are therapy-resistant, timed voiding assisted by a timer watch added to urotherapy is effective (115).

Following a 3-month training programme, 42.8% of day wetting children were cured at 1 month, 61.9% by 6 months, and 71.4% by 1 year (116). Allen et al [117] reported that urotherapy patients with good compliance with timed voiding were significantly more likely to improve their continence than those with poor compliance. It has recently been highlighted however, that there is frequently conflict between school rules, routines and toilet facilities and the urotherapy programme components. Adaptive coping techniques added to urotherapy training may enhanced gains in dryness.

In children with OAB and dysfunctional voiding the pelvic floor muscles relaxation is impaired during voiding. Physiotherapy is concerned with re-training of specific muscle groups. Adjunctive physiotherapeutic input offers children different strategies to achieve pelvic floor relaxation during micturition.

Several centres offer intensive urotherapy called voiding schools or even inpatient rehabilitation. A prospective evaluation of 38 Belgian children who underwent this approach showed improvement in 90% of the children with 42% becoming dry, whilst no child

on the waiting list improved during the 6 months (118). Long-term follow-up of 75 incontinent children who underwent intensive urotherapy 16-22 years later showed a good result in 84%and the authors concluded that if the original outcomes of paediatric intensive inpatient urotherapy were good, they tend to remain so over time in most patients (119).

Level of evidence 3

Grade of recommendation C

5.2. Adjunctive biofeedback

Biofeedback is a technique in which physiological activity is monitored, amplified and conveyed to the patient as visual or acoustic signals, thereby providing the patient with information about unconscious physiological processes. Biofeedback is mainly utilized for the management of voiding phase (dysfunctional voiding due to pelvic floor muscle overactivity) abnormalities (120)

Biofeedback can help children to identify how to relax their pelvic floor muscles or recognize involuntary detrusor contractions.

Training with biofeedback can be used as a single treatment [121,122], or in conjunction with a comprehensive rehabilitation program [123,124]. It may be performed by a cystometrogram during which the child is taught to recognize and inhibit involuntary detrusor contractions by watching the pressure curve during cystometry. This is invasive and a time-consuming process with limited application as a routine treatment.

More commonly pelvic floor muscle relaxation is taught using EMG biofeedback and/or real-time uroflow. The child sits on a toilet with a flow transducer, watching both the flow curve and EMG on a computer display, and attempts to empty completely in one relaxed void. Ultrasound may be used to determine the post void residual and demonstrate complete emptying. Interactive computer games are commonly used to make biofeedback training more attractive to children [125,126], however care should be taken that posture and muscle recruitment approximates that of the voiding position. Home training can be performed with success using pure EMG-biofeedback.

The results of biofeedback are commonly reported as case series rather than RCTs. Results are generally positive but overall may not be superior to high quality standard urotherapy. The group receiving adjunctive biofeedback in the Vasconcelos study [116] did not achieve greater continence rates at the study end point, although a greater proportion of subjects achieved earlier dryness. Furthermore, the post void residual volumes were significantly reduced in the biofeedback group compared to the standard therapy only group.

Long duration follow-up, whilst desirable, confounds results of intervention in children who are continually growing and maturing. Hellstrom *et al* report results of a 6-week bladder rehabilitation programme inclusive of biofeedback [111] and note that at 3 years, 71% of the children with detrusor overactivity, 70% of those with dysfunctional voiding and 73% of those with a combined disturbance had a normal micturition pattern. The potential for bias from intercurrent events and interventions precludes statements about the efficacy of biofeedback alone.

Level of evidence: 3

Grade of recommendation C

5.3. Clean intermittent (self) catheterisation

In children with an underactive detrusor, bladder emptying can be achieved with timed and double voiding. If this does not adequately empty the bladder clean intermittent self-catheterisation (CISC) may be tried [127-129]. This requires careful guidance for both the child and the parents. Sometimes it is necessary to give the child a suprapubic catheter for a while and gradually prepare him/her to accept CISC. Once the infections have cleared and the child is continent it will become easier for both the parents and the child to accept. The frequency of CISC depends on the severity of the problem and may vary between four times a day and once a day before going to bed.

Level of evidence 4

Grade of recommendation C

5.4. Neurostimulation

Neurostimulation has been used in adults for a variety of lower urinary tract symptoms and has been applied in children. The main indication is OAB or urge incontinence with good success rates. The use of transcutaneous stimulation with surface electrodes stimulating the sacral root (S3) has shown promising results, especially when tested as part of a randomised controlled trial [130]. Transcutaneous and percutaneous neurostimulation delivered over either the sacral outflow or peroneal region of the ankle at a frequency between 10-25 Hz, has proven a useful adjunctive treatment in children with detrusor overactivity. Intravesical stimulation is rarely indicated and can affect the function of an underactive detrusor and potentially improve detrusor contractile function and enhance bladder emptying [131,132]).

Electrical current directly affects the central nervous system by activating CNS centres facilitating both neural plasticity and normative afferent and efferent activity of the lower urinary tract. For children with structural abnormalities, for example imperforate anus, electrostimulation is one method of facilitating strength gains in the skeletal muscle and its fascial attachments. Treatment is particularly useful in patients with very little pelvic floor awareness to stimulate muscle recruitment. Once neural efficiency has improved, training is augmented by active pelvic floor contractions.

In 2011 three papers were published reviewing the use of neurostimulation in children (133-135). This highlights the level of interest in this modality for treating LUTD and bowel dysfunction. A literature search revealed 27 reports of the use of neurostimulation in children with non-neurogenic bladder dysfunction. Only five of these studies were randomised controlled or randomised cross-over studies whilst the rest were case series. However, parasacral Tens has been shown to be more effective than sham in randomised trials in treating OAB. Use of neurostimulation in children with neurogenic LUT dysfunction has been reported in 12 studies, 5 of which were randomised controlled trials.

Previously most studies have looked at the use of electrical neurostimulation in children whose symptoms have been refractory to all other interventions, whereas it is becoming apparent that sacral neurostimulation, especially TENS as first-line treatment is beneficial.

A recent prospective study in 69 children where neurostimulation was used as first-line treatment, a complete resolution of symptoms was seen in more than half of them (55,1%), after 20 sessions (136).

Also, studies using intravesical, transcutaneous and implantable electrodes have noted improved bowel function. One randomised placebo-controlled trial using interferential current transcutaneously showed significant improvements in colonic transit times, decreased soiling and abdominal pain and increased quality of life in children with severe constipation (137). Following up on these children for an average of 3.5 years has shown that these improvements were maintained (145).

From Table 1 and 2 different modes of application have been trialled in mostly small series of children. There is minimal standardisation of populations, application parameters or outcome measures. Thus, evidence is largely drawn from low quality studies. Clearly neurostimulation in children warrants larger, controlled and randomised studies, including its use as first-line intervention and in children with combined bladder and bowel dysfunction. Despite the slow pace of research the reviewers of the articles mentioned above agree that there is a positive role for neurostimulation in children with LUTD, and that it is adjunctive to other interventions, with no known predictors of efficacy now, but also rare and minor adverse events. Neurostimulation of the bowel shows promise.

Reported changes on bladder function with neurostimulation include: significantly increased bladder capacity, decreased severity of urgency, improved continence, and decreased frequency of urinary tract infection. Significant improvement in urodynamic parameters of bladder compliance, number of involuntary contractions, and bladder volume at first detrusor contraction have also been noted.

Tables 1 and 2: Study parameters in paediatric neurostimulation trials

Author and year of publication	Population	Design	N	Mode of application	Outcome measure
Guys 2004	Neurogenic (Spina bifida)	RCT	42	Sacral implant	n/s difference from controls for continence

Boudaoud 2015 (147)	Non neurogenic	RCT	20	11 TCPNS vs 9 sham	Urodynamcs improves in PPTNS group, clinical results the same
Choi 2013	Neurogenic	Retrospec-tive study	88	Intravesical stimulation (IVES)	Bladder capacity increased DSD resolved in 55.6%

More recently the first reports on sacral nerve stimulation with implantable electrodes have been published. In a group of 20 patients between 8 and 17 years old followed prospectively, urinary incontinence, urgency and frequency, nocturnal enuresis and constipation were improved or resolved in 88% (14 of 16), 69% (9 of 13), 89% (8 of 9), 69% (11 of 16) and 71% (12 of 17) of subjects, respectively. Complications were seen in 20% of patients [138]. Different neuroanatomical pathways have been described as targets for invasive sacral neurostimulation. The third sacral (S3) nerve root remains the main access point used for neurostimulation treatment. A retrospective study of Luitzen-Albert Groen et al included 18 patients, of which 5 with neurogenic bladder showed a good short term (78%) and long term (73%) response (73%) (139). These results are similar to those of Hadad (140).

General limits of the evaluation of results for invasive SNS are the small number of patients in all series, the general absence of RCT, the different way to evaluate results and different clinical protocols, including implant techniques, furthermore in some countries as in the United States, SNS and PTNS have been approved by FDA for the treatment of urology diseases but SNS is not approved in children younger than 16 yrs. In Europe, the age limit is not so strictly defined as in the USA but the majority of experiences are mainly referred to postpuberal patients. Implantations of very young patient are generally avoided for a risk of electrode dislocation with statural growth during time, reduced collaboration and limitation for MRI studies. For all these reasons SNM in children still needs further studies (controlled and randomised). Evaluating SNM as first-line treatment in children with combined bladder and bowel dysfunction also depends on defining the criteria for optimal indications and predicting efficacy (149).

Due to the uncontrolled design the level of evidence is low. Experience from adults offered this treatment modality suggests future positive development in children to be likely.

Level of evidence: 3

Grade of recommendation C

5.5. Alarm therapy

Alarm therapy has traditionally been used for the treatment of nocturnal enuresis and has rarely been used for daytime wetting. Only one randomised clinical trial has been published to establish the efficacy of this form of treatment. Halliday *et al* compared a contingent alarm which sounded when the child wets with a noncontingent alarm system (which sounded at intermittent intervals to remind the child to void) [113]. Forty-four children participated in the study, 50% were assigned to each form of therapy for a 3-month period. Success was measured as 6 consecutive weeks without daytime wetting. Nine children in the non-contingent group and 6 children in the contingent group had persistent wetting. Although the risk of persistent wetting with the contingent alarm was 67% of the risk of persistent wetting with the noncontingent alarm, the difference in the reduction in wetting between the groups was not significant (RR 0.67, 95% CI 0.29 to 1.56). In a retrospective review by Van Laecke et al, a cure rate of 35% after the use of a daytime alarm was described [150]. Due to the retrospective design of the study the level of evidence is low.

Level of evidence: 3

Grade of recommendation C

5.6. Group training

Group training programmes have been developed for children with treatment-resistant incontinence. The program includes provision of information, coaching regarding drinking and voiding habits, relaxation and stress-reduction techniques, as well as cognitive-behavioural therapy (CBT). The training proved to be effective in pre-post analyses (151).

5.7. Conclusion

Many clinical studies describe combinations of therapies rather than single interventions, which makes it difficult to evaluate the results. Physiotherapy and biofeedback both focus on the pelvic floor. Relaxation of the pelvic floor during voiding is essential for normal voiding and most of these patients are unable to relax their pelvic floor muscles. Biofeedback is important for showing the children the effect of their relaxation efforts. Most studies only state the clinical responses, and do not provide information on urodynamic parameters before and after treatment. A 'normal' flow curve may not mean normal voiding if no information is provided on post-void residual urine. In most papers the inclusion and exclusion criteria are not clearly documented, and it may very well be that the more difficult patients with both storage and voiding dysfunction were included in the study population. Furthermore, different series may describe different groups of patients due to poor definitions and an inadequate classification system. In children with a suspected bladder outlet obstruction, endoscopic investigations should be performed. Most often the anatomic abnormality causing obstruction can be treated at the same time. In girls, a meatal web may cause a deflection of the stream upwards [causing stimulation of the clitoris and bulbocavernosus reflex]. A meatotomy may cure this problem, though no information on the long-term effects is available [79].

6. PHARMACOLOGICAL TREATMENT

6.1. Antimuscarinic therapy

Antimuscarinic therapy remains one of the common forms of therapy for overactive bladder / detrusor overactivity. Its use is predicated on the concept that parasympathetic mediated stimulation of muscarinic

receptors in the bladder causes detrusor overactivity, which is responsible for the symptoms of detrusor overactivity. Antimuscarinic agents have been demonstrated to increase bladder capacity, increase bladder compliance and decrease detrusor contractions in neurogenic detrusor overactivity. Detrusor overactivity is believed to play a role in many children with functional incontinence, vesicoureteral reflux and urinary tract infections [152]. More commonly, pharmacotherapy is instituted when behavioural therapy has failed to achieve a satisfactory outcome. Some clinicians use pharmacological therapy as first line in children with moderate to severe daytime incontinence [66].

Despite the frequent use of anticholinergic therapy, often in conjunction with a behavioural therapy regimen, the outcome of pharmacological therapy for daytime urinary incontinence is "unpredictable and inconsistent" and there are few randomised studies available to assess drug safety and efficacy.

The following antimuscarinics are briefly discussed:

Oxybutynin: approved for use in children FDA EMA

Propiverine: approved for use in children EMA

Tolterodine: tested phase 3 clinical trials, not approved for use in children

Solifenacin: tested phase 3 clinical trials, awaiting approval for use in children

Terodiline: investigated in a randomised placebo controlled trial, withdrawn because of serious cardiac side effects.

Trospium chloride: used in small series in children

Fesoterodine: used in small series in children

Oxybutynin

Currently the pharmacological therapy most widely used in children with detrusor overactivity is oxybutynin [153]. In 2002, a long-acting formulation, Oxbutynin- XL, has been approved by the FDA for use in children [154]. Historically, oxybutynin use has been limited by its adverse effect profile with such side effects as dry mouth, constipation, facial flushing and CNS effects. The incidence of side effects seems to be dose-related, both for oral and intravesical administration [155]. The CNS effects are related to the ability for oxybutynin to cross the blood brain barrier. Oxybutynin- XL utilises a novel delivery system, which results in absorption in the large intestine, thereby bypassing the first pass metabolism in the liver. This leads to a decrease in the amount of active metabolite [produced in the liver]: resulting in a more favourable tolerability profile. The delivery system requires an intact tablet and thus it cannot be cut or crushed to facilitate swallowing. Another method of delivery of oxybutynin is intravesical therapy. This method of delivery also avoids the first pass effect and leads to increased amounts of oxybutynin available compared to immediate release oxybutynin. Its use in the neurologically intact patient is limited by the need for catheterisation [155].

There are only a few studies and only one randomised and double blinded, assessing the efficacy of oxybutynin in detrusor overactivity in children. In the European Bladder Dysfunction study, 97 children with DO on cystometrogram, received oxybutynin or placebo: the placebo effect of 45% was equal to the effect of oxybutynin chloride (156).

Curran *et al*, in a retrospective review of 60 patients assessed the efficacy of several agents, primarily oxybutynin in children with non-neurogenic detrusor overactivity, confirmed by urodynamics, who were refractory to behavioural therapy. Some children were treated with combination therapy. Eighty percent had complete resolution or a significant improvement in their urinary symptoms. The authors noted an average time to resolution of symptoms of 2.7 years [range 0.2 to 6.6], however patients were not followed frequently [157]. In a study by Van Hoeck et al, holding exercises with and without oxybutynin showed no beneficial effect on bladder volume. [158].

Level of evidence: 3

Grade of recommendation C

Propiverine

Propiverine is the second antimuscarinic drug approved by the EMA for use in children. A randomised, double-blind, placebo-controlled phase 3 trial with propiverine in children aged 5-10 yr. was reported in 2008. Of 171 randomised children, 87 were treated with propiverine and 84 with placebo. The primary efficacy outcome, decrease in voiding frequency, was -2.0 episodes for propiverine versus -1.2 for placebo; p=0.0007. Superiority could also be demonstrated for increase in voided volume (31.4 vs. 5.1ml; p<0.0001) and reduction in incontinence episodes (-0.5 vs. -0.2 episodes per d; p=0.0005. This clinical trial showed superior efficacy of propiverine over placebo and good tolerability for the treatment of children suffering from DO and urinary incontinence. [159,160] This is the first study with level of evidence 1 that shows beneficial effect of anticholinergic therapy.

A retrospective study published in 2012 on 68 children with OAB, reports a response rate of 86.8% (161).

Level of evidence: 1

Grade of recommendation B/C (only single study)

The following antimuscarinics are not approved for use in children, and may only be used off-label.

Tolterodine

Tolterodine, a non-selective antimuscarinic used for the treatment of overactive bladder and detrusor overactivity in adults. It is the first antimuscarinic agent designed specifically for use in detrusor overactivity and is felt to be "bladder selective". It's affinity for the bladder compared to other organ systems

leads to an improved tolerability profile. The chemical nature of tolterodine makes it less likely to penetrate the blood brain barrier, which is supported by EEG studies [162]. The delivery system of the long acting preparation is such that the capsule may be cracked and "sprinkled" on food. Tolterodine has not been approved for use in children but there are several studies, which evaluate its safety and efficacy in children with detrusor overactivity. Hjålmas reported the results of an open label, dose escalation study using immediate release tolterodine in 33 children [163]. Doses ranged from 0.5 mg po BID to 2 mg po BID for 14 days. The results demonstrated a 21% (23% with 2 mg po BID) mean decrease from baseline in micturition frequency and a 44% mean decrease from baseline for the number of incontinence episodes in children treated with 1 mg and 2 mg po BID. Bolduc *et al* reported on a prospective crossover study of 34 children followed for > 1 year who were crossed over from oxybutynin to tolterodine because of adverse effects with oxybutynin [164]. Detrusor overactivity was confirmed in 19/20 who had urodynamic studies performed prior to therapy. Children received either 1 mg or 2 mg po BID and the median treatment period was 11.5 months. Efficacy was assessed by a questionnaire and was comparable for oxybutynin and tolterodine. Sixty-eight percent noted a > 90% reduction in wetting episodes at 1 year and an additional 15% noted a > 50% reduction in wetting episodes. Fifty nine percent reported no side effects with tolterodine and 18% reported the same side effect as with oxybutynin, but felt it was less severe. Eight patients [24%] discontinued tolterodine.

Munding *et al* reported on the use of tolterodine in children with "dysfunctional voiding" manifested as daytime wetting, frequency or urgency [165]. There was no documentation of uroflow studies to make the diagnosis of "dysfunctional voiding" and from the symptoms these children appeared to have detrusor overactivity. Children were started on behavioural modification for 4-6 weeks and pharmacological therapy was instituted if they failed or had only slight improvement with behavioural therapy. A minimum of 1 month's follow-up was needed for inclusion, but the mean follow-up was only 5.2 months. Doses ranged from 1 mg po BID to 4 mg po BID. Assessment of results was made by telephone survey. Thirty three percent had > 90% reduction in daytime and nighttime wetting episodes and 60% had > 50% reduction. Four patients [13.3%] had side effects, constipation in 2, dry mouth in 1 and diarrhoea in 1.

Reinberg *et al* performed an open label parallel group retrospective study of the efficacy and safety of immediate release and long acting tolterodine and extended release oxybutynin [166]. Children started out with the lowest possible dose, 2 mg tolterodine and 5 mg oxybutynin and titrated up according to response and side effects. Children were arbitrarily assigned to therapy based on the formulary restrictions of the health plan and there was an uneven distribution of patients in the treatment groups. Final dose and duration of treatment were not noted. Study nurses asked about side effects and a voiding diary was used to assess efficacy. The authors concluded that extended release tolterodine [$p<0.05$] and oxybutynin [$p<0.01$] were more effective than immediate release tolterodine in improving urinary incontinence symptoms and that extended release oxybutynin was more effective than extended release tolterodine in resolving diurnal incontinence ($p<0.05$) Long term tolerability of tolterodine extended release in a large paediatric population has been shown. [167]

Level of evidence: 3

Grade of recommendation C

Solifenacin

Solifenacin is an antimuscarinic agent used in children with OAB: Hoebeke *et al* published results on 139 children with therapy resistant OAB, with favourable results, and few side effects, in 2009 (168).

Bolduc *et al* conducted a prospective, open label study, and published their results in 2009: 72 children enrolled, 45 with non-neurogenic DO. Continence improved in all patients, including 24 who were dry, and 42 and 6 who were significantly and moderately improved, respectively (169).

Long term use showed that high subjective and objective success rates were maintained over a longer follow-up (170).

Phase 3 clinical studies in neurogenic children as well as in non- neurogenic children are being conducted.

Level of evidence: 2

Grade of recommendation 3

Terodiline

One of the drugs which has been investigated in a randomised placebo controlled trial was terodiline [171,172]. Because of serious cardiac side effects terodiline has been withdrawn from the market and is of only historical interest.

Trospium chloride

Trospium chloride has been used in small series in children. It is currently available in a twice a day dosing formulation. In the adult population, there is a 16% intra-individual variability in bioavailability and 36% inter-individual variability. Absorption is affected by food intake. Trospium's chemical structure make it unlikely to penetrate the blood brain barrier as supported by EEG studies. Lopez Periera *et al* evaluated the use of trospium in 62 children with documented detrusor overactivity and absence of 'detrusor sphincter dyssynergia' [173]. Children were randomly assigned to 10, 15, 20 or 25 mg of trospium administered in 2 divided doses or placebo. Fifty-eight children were evaluated. Response rates were assessed by incontinence episodes and urodynamic parameters. Overall, 32% had an excellent response, 42% a good response and 8% a fair response. Detrusor

overactivity completely resolved in 35%. Four children had medication related adverse effects including headache, dizziness, abdominal cramps and dry mouth.

Level of evidence: 3

Grade of recommendation C

Fesoterodine

Fesoterodine is approved for adults, and is reportedly safe and effective. A post marketing surveillance study with 2978 adults with OAB scored on efficacy in Korea showed amelioration in 91% (174)

Comparison with solifenacin showed no difference in efficacy, but more side effects with fesoterodine (175).

Expert opinion is that fesoterodine has a similar tolerability and side effect profile to other antimuscarinics and is, therefore, unlikely to revolutionise the treatment of the overactive bladder (176).

In children, the only study done is a Dose-escalating study of the pharmacokinetics and tolerability, showing steady-state plasma 5-hydroxy-methyltolterodine exposures similar to those in adults. The doses given were well tolerated. Only 10 children with non-neurogenic bladder and OAB were included (177).

Darifenacin

Darifenacin is approved for use in adults too. Although already mentioned in 2004 to be promising, in children, up to date no studies have published (178).

Some authors try combinations of anticholinergics for refractory OAB: Bolduc *et al* treated 33 children with a combination of oxybutynin and solifenacin or tolterodine with good success (179, 180).

Fahmy *et al* enrolled 72 children in a prospective study where trospium chloride was added to oxybutynin in refractory OAB: 68% showed improvement, 22,2% was completely dry (181).

6.2. Beta3-adrenoceptor agonists

Mirabegron is the first of a new class of drugs for the treatment of OAB. Stimulation of β3-adrenoreceptors results in relaxation of the detrusor smooth muscle and improves bladder compliance and bladder capacity. Randomised controlled trials in adults show that mirabegron decreased the number of micturitions and incontinence episodes in a 24-hour period compared with placebo. Mirabegron is approved for use in adults (182,183).

There is only one study published in children. A prospective off-label study in 58 children with refractory OAB or with significant side effects with at least two different antimuscarinic agents were recruited. Continence improved in 52 of 58, with 13 being completely dry. Eight patients reported mild or moderate side effects. Absence of a placebo group is a limitation of the study (184).

Phase 3 studies with mirabegron are currently running in children with neurogenic bladder, but not yet in neurologically normal children.

6.3. Botulinum Toxin

Botulinum toxin is used in children, mainly with neurogenic detrusor overactivity. Initial results are promising, but more studies need to be done. In children 100-200 Units on average, are injected in 30-40 spots [185]. The trigone should not be injected, as there is an increased risk of vesico-ureteric reflux. The results last about 6-9 months. Botulinum toxin is not registered for injection in the detrusor or the sphincter in children. It is used off-label and further prospective studies are needed before a general recommendation can be made (186).

One prospective uncontrolled study by Hoebeke *et al* in 21 children shows beneficial effects of botulinum toxin in 70% of children with therapy resistant detrusor overactivity [187].

Urodynamic assessment proves amelioration after botulinum toxin A in detrusor contractions and bladder capacity in a prospective study with 13 children included (188). Leon *et al* published an even smaller prospective uncontrolled series in 2014 on 8 children with favourable results (189). Other published studies are all retrospective: A retrospective study in 30 patients by Blackburn et al published in 2013 and a retrospective study in 57 patients by Mc Dowell published in 2012 demonstrates good response (190, 191). Injection of botulinum toxin into the external sphincter is also possible, but the results are more variable and last only 3-4 months [192]. Radojici *et al* describe excellent results in the treatment of dysfunctional voiding. In 20 children, good results are described for 17 patients [193]. In a retrospective study by Franco et al, similar results are described in 16 children, however using a higher dosage [194].

These results are confirmed by 't Hoen *et al*, and by Vricella *et al*, but the effect in their series is longer: they report safe and persistent satisfactory results during an average of 13-months in 18 of 20 patients and 15 months in 8 of 12 patients respectively with therapy-refractory dysfunctional voiding (195,196).

Less invasively, botulinum toxin can be administered electromotively: a small study in 15 children shows the administration is feasible, safe, and results in considerable improvement on urinary incontinence (197).

Level of evidence: 3

Grade of recommendation C

6.4. Alpha-adrenergic blockers

Treatment of the overactive pelvic floor and sphincter is much more difficult. Treatment with alpha-adrenergic blockade seems promising, but from the presented studies it is difficult to draw firm conclusions:

as most series are small, not randomised and describe a mixed patient population [198-200].

In a more recent uncontrolled study by Donohoe *et al* a total of 26 patients with Primary Bladder Neck Dysfunction (20 males, 6 females, mean age 12.8 years) were treated with alpha-blockers. Mean average and maximum uroflow rates improved from 5.5 to 12.6 cc per second and from 10.3 to 19.7 cc per second, respectively, while mean EMG lag time decreased from 24.4 to 5.7 seconds and post-void residual urine volume from 98.9 to 8.9 cc (all p <0.001). Mean follow-up was 31 months and no major adverse side effects were observed [201]. Further randomised controlled studies are needed to define the place of alpha-blockers.

Level of evidence: 3

Grade of recommendation C

Because there is much variability in presenting symptoms as well as the underlying pathology an individual approach is advisable: a step by step algorithm has been developed by Marschall-Kehrel, which seems to deal with many of these variables [202].

Level of evidence 3.

Grade of recommendation B/C

The limited number of identified randomised controlled trials does not allow a reliable assessment of the benefits and harms of different methods of management in children. Further work is required in this difficult clinical area. The establishment of outcome measures is needed, to facilitate randomised controlled trials of routine therapy. Interventions that would benefit from further investigations include: bladder and voiding education, bladder retention training, bowel management, hypnotherapy and alternative therapies, psychology, prophylactic antibiotic medication, neuromodulation, biofeedback therapy and pelvic floor muscle awareness and specific relaxation. Only then can the efficacy of new interventions be measured in children with detrusor overactivity or dysfunctional voiding.

6.5. Conclusion

A wide therapeutic choice available to clinicians, many of the commonly used treatments are of dubious value and have not been rigorously evaluated in careful clinical trials with an appropriate study design. Children who suffer this distressing condition, and their families, and those who care for them clinically, need clear guidance as to which treatments are of proven value. They need access to treatments which work, and they need protection from treatments which do not work.

Children who present with urinary symptoms may have been victims of sexual abuse. In these cases, the use of invasive diagnostic procedures (VCUG and urodynamic studies) must be regarded as contraindicated, as must the use of invasive intra-anal treatment devices. Development of less invasive methods of diagnosis and treatment should therefore be encouraged.

V. NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION

1. INTRODUCTION

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop because of a lesion at any level in the nervous system. This condition contributes to various forms of lower urinary tract dysfunction which may lead to incontinence, urinary tract infections (UTIs), vesicoureteral reflux (VUR), and renal scarring. Surgery may be required to establish adequate bladder drainage, and potentially, if not managed properly, NDSD can cause renal failure, requiring dialysis or transplantation.

Management of neurogenic detrusor sphincter dysfunction in children has undergone major changes over the years. While the use of diapers, permanent catheters, external appliances and various forms of urinary diversion were acceptable treatment modalities; these are now reserved for only a small number of resistant patients (1). Initially, long-term renal preservation was the only aim of therapy and early diversion had the best long term results for preserving renal function. Despite some of the complications of ileal conduits and cutaneous urostomies requiring secondary surgery, this form of treatment offered the best outcome for renal preservation with socially acceptable continence (2).

Introduction of clean (self) intermittent catheterisation revolutionised the management of children with NDSD. It, not only made conservative management a very successful treatment option, but also made surgical creation of continent reservoirs a very effective alternative with a good quality of life (3).

The causes and presentation of a neurogenic bladder in a child is different from adult forms. In most cases, the paediatric neurologic bladder is caused by congenital problems, and many investigators differentiate between a neurologic and a neuropathic bladder. A neurogenic bladder is one from a true neurologic deficit like spina bifida (SB), and a neuropathic bladder is one that acts like a neurogenic bladder but is not caused by an innervation problem like valve bladder syndrome. Acquired forms caused by trauma, infection, or behavioural issues are more comparable with adult clinical pictures (4).

The most common cause of NDSD in children is neurospinal dysraphism and this condition presents with various patterns of detrusor-sphincter dysfunction within a wide range of severity. About 15 % of neonates with myelodysplasia have no signs of lower urinary tract dysfunction (LUTD) when initially studied (5). However, there is a high risk of progressive changes in the dynamics of the neurological lesion in

time and even babies with normal LUT function at birth have a 1 in 3 risk of developing either detrusor sphincter dyssynergia or acontractile detrusors by the time they reach puberty (6). Nearly 60 % of the neonates with neurospinal dysraphism may develop upper tract deterioration due to increased detrusor filling pressures and infections, with or without reflux (7,8).

As our understanding of urodynamic studies has evolved it allowed us to understand the nature and severity of the problems and administer management in a more rational manner differing according to the functional characteristics of each detrusor sphincter unit. Although the last quarter century has witnessed a remarkable progress in understanding pathophysiology, pathogenesis and the management of these children, the main goals of treatment remained the same i.e. the prevention of urinary tract deterioration and the achievement of continence at an appropriate age.

2. PRESENTATION OF NEUROGENIC DETRUSOR-SPHINCTER DYSFUNCTION IN CHILDREN

Neurogenic detrusor sphincter dysfunction can develop because of a lesion at any level in the nervous system, including the cerebral cortex, spinal cord or the peripheral nervous system. The level of the defect on the spine is strongly associated with survival and the development of cognitive and motor skills, with cervico-thoracic levels performing significantly lower in comparison with lumbosacral defects.

The type and degree of detrusor sphincter dysfunction is poorly correlated with the type and spinal level of the neurologic lesion.

The closure of spinal canal in utero takes place in caudad direction from cephalic end and is completed at around 35 days of gestation. The failure of mesodermal in-growth over the developing spinal canal results in an open lesion most commonly seen in the lumbosacral area. The degree of this closure deficiency contributes to a variable presentation of neural injury with varying degrees of LUTD and lower extremity problems.

Myelodysplasia, also commonly known as **spina bifida** (SB), is a general term that describes incomplete closure of the vertebral column and malformation of the embryonic neural tube. This term includes a group of lesions like spina bifida occulta, meningocele, lipomyelomeningocele, or myelomeningocele. Myelomeningocele is by far the most common defect seen and the most detrimental. Traumatic and neoplastic spinal lesions of the cord are less frequent in children (9).

In **meningocele,** the meninges protrude through a vertebral canal defect but the neural elements of the cord remain confined within the canal.

In **myelomeningocele,** the neural roots or segments of the spinal cord herniate through the incompletely closed vertebrae.

The neurological lesions produced by myelodysplasia are variable and contingent on the neural elements that protrude within the meningocele sac. The bony vertebral level correlates poorly with the neurologic lesions produced. Additionally, different growth rates between the vertebral bodies and the elongating spinal cord can introduce a dynamic factor to the lesion, and scar tissue surrounding the cord at the site of meningocele closure can tether the cord during growth (11).

In **occult myelodysplasia**, the lesions are not overt and often with no obvious signs of neurological lesion. The diagnosis of this condition has increased since the advent of spinal ultrasonography and magnetic resonance imaging. Yet, in nearly 90% of patients, a cutaneous abnormality overlies the lower spine and this condition can easily be suspected by simple inspection of the lower back. These cutaneous lesions can vary from a dimple or a skin tag to a tuft of hair, a dermal vascular malformation, or an obvious subdermal lipoma. (9) Alterations may be found in the arrangement or configuration of the toes, along with discrepancies in lower extremity muscle size and strength with weakness or abnormal gait. Back pain and an absence of perineal sensation are common symptoms in older children. Incidence of abnormal lower urinary tract function in patients with spina bifida occulta is as high as 40%. Occult lesions may also become manifest with tethering of the cord later in life. This can lead to changes in bowel, bladder, sexual and lower extremity function.

Sacral agenesis is a rare congenital anomaly that involves absence of part or all of one or more sacral vertebrae. Perineal sensation is usually intact and lower extremity function is usually normal and the diagnosis is made when a flattened buttock and a short gluteal cleft is seen on physical examination. This lesion may produce variable degrees and patterns of LUTD.

Cerebral palsy patients may also present with varying degrees of LUTD usually in the form of overactive detrusor and wetting.

Imperforate anus is a rare anomaly and presents with a closed rectum that does not open onto anal skin verge. These children may present with accompanying spinal cord pathology. This is more common when the rectum ends above the pelvic floor muscles and they should undergo a MR imaging for detection. Early detection of this problem in imperforate anus patients is important to improve the child's chance of maintaining healthy kidneys and becoming continent.

3. CLASSIFICATION: PATTERN RECOGNITION

The purpose of any classification system is to facilitate the understanding and management of the underlying pathology. There are various systems of classification of the neurogenic bladder.

Most systems of classification were formulated primarily to describe those types of dysfunction secondary to neurologic disease or injury. Such systems are based on the localisation of the neurological lesion and findings of the neuro-urologic examination. These classifications have been of more value in adults as neurogenic lesions are usually due to trauma and more readily identified.

In children, the spinal level and extent of congenital lesion is poorly correlated with the clinical outcome. Indeed, severe detrusor sphincter dysfunction has been associated with minimal bony defects. Various possible neuropathological lesions of the spinal cord including syringomyelia, hydromyelia, tethering of the cord and dysplasia of the spinal cord are the causes of these disparities and they may extend several segments above and below the actual site of the myelomeningocele. Therefore, urodynamic and functional classifications have been more practical for defining the extent of the pathology and planning treatment in children.

The detrusor and sphincter are two units working in harmony to make a single functional unit. The initial approach should be to evaluate the state of each unit and define the pattern of bladder and sphincter dysfunction. Determined by the nature of the neurologic deficit, they may be either in an overactive or in an inactive state. The detrusor may be overactive with increased contractions during filling, with a diminished bladder capacity and compliance or be underactive with no effective contractions during voiding; the bladder outlet (urethra and sphincter) may be independently overactive causing functional obstruction or paralysed with no resistance to urinary flow leading stress incontinence.

These conditions may exist in any combination (10-15).

Urodynamic evaluation (preferably in combination with fluoroscopy) makes pattern recognition possible. Four major types are usually used to describe the detrusor-sphincter dysfunction:

1. Detrusor overactivity with overactivity of the sphincter (mostly dyssynergia),
2. Detrusor overactivity with normal or underactivity of the sphincter,
3. Detrusor underactivity with sphincter overactivity and
4. Detrusor underactivity with sphincter underactivity.

Besides these 4 patterns, one can use the ICS classification: overactive detrusor, underactive detrusor, overactive sphincter and underactive sphincter. Sometimes this is more helpful, as the detrusor may be overactive during filling, but underactive during 'voiding'.

The urodynamic investigation is considered normal when there is suitable age appropriate capacity, good compliant bladder with no overactivity and normal innervation of the sphincter with normal sacral reflexes and an increase in pelvic floor activity during filling and no activity during voiding. Presence of detrusor overactivity during filling with or without decreased capacity and compliance, is usually seen when there is upper motor neuron lesion and this is usually accompanied by overactivity of the sphincter and failure to relax during voiding. A lower motor neuron lesion is considered when the voiding detrusor contractions are weak or lost and the sphincter is underactive. Urodynamic investigations make it possible to establish a management plan for each individual patient.

Level of evidence: 3

Grade of recommendation B

For the very young child the combination of an overactive detrusor and sphincter is potentially dangerous because of the high intravesical filling pressures, which will put the upper tract at risk (vesicoureteral reflux and hydronephrosis), whereas an underactive detrusor and a paralysed sphincter is relatively safe, providing a low-pressure reservoir (16-19).

Level of evidence: 2

4. PRENATAL DIAGNOSIS AND FETAL SURGERY

In utero intervention holds the promise of reversing some of the sequelae and improving outcome in SB patients. To prospectively evaluate the value of intrauterine surgery, a randomised controlled trial was established in 3 centres. The endpoints of this Management of Myelomeningocele Study (MOMS) included fetal and infant mortality, the need for a ventriculoperitoneal shunt at 1 year of age, and the evaluation of mental and motor development at 30 months of age. There were no maternal deaths and the rates of adverse neonatal outcomes were generally similar between the two groups (20). Long-term (5-year) follow-up has occurred in this cohort of patients. Previous reports have documented decreased incidence of ventriculoperitoneal shunting and neuromotor functioning, showing improved outcomes (less trabeculation and open bladder neck) compared with historical controls (21). The evidence to suggest prenatal surgery is still low and it should only be done in designated centres.

5. MANAGEMENT

The main aim in management of NDSD in children is to ensure and maintain a reservoir with normal age-matched capacity and good compliance that can be emptied completely at low pressures and at regular intervals. Urological care is initiated soon after a child with SB is born and is maintained throughout childhood. In the first years of life, the kidneys are highly susceptible to backpressure and infection. Bladder drainage is essential during and after the closure of the spinal defect in early in life. Following the closure within a few weeks emphasis will be on documenting the pattern of neurogenic detrusor- sphincter dysfunction and assessing the potential for functional obstruction and whether there is vesicoureteral reflux (19,22). Ultrasound studies and a VCUG or video-urodynamics to exclude reflux must be performed soon after birth. Measurement of residual urine during both ultrasound and cystography should also be done. These studies provide a baseline for the appearance of the upper and lower urinary tracts, can facilitate the diagnosis of hydronephrosis or vesicoureteral reflux and can help identify children at risk for upper urinary tract deterioration and impairment of renal function.

Concerning the bladder function, 2 general scenarios are common. One group of patients will have an overactive sphincter and develop high detrusor leak point pressures greater than 40 cm H_2O and are, therefore, at risk for upper tract damage. The other group will have underactive sphincter resulting in free urine flow at low pressures into the diaper with little risk to the upper tract. A urodynamic evaluation can be done after some weeks and needs to be repeated at regular intervals, in combination with evaluation of the upper tracts (22).

Level of evidence 3

Grade of recommendation: B

Overwhelming experience gained over the years with early management of neurogenic bladder in infants has led to a consensus that children do not develop upper tract deterioration when managed early with CIC and antimuscarinic medication (22-25). Therefore, initial treatment should consist of oral or intravesical antimuscarinic drugs in combination with clean intermittent catheterisation, to start soon after birth in all babies and especially in those with signs of possible outlet obstruction (26-30). The volume of urine collected with CIC and severity of urine leakage in between CIC will provide more information about the characteristics of bladder storage and drainage.

Level of evidence 2

Grade of recommendation: B

The early initiation of intermittent catheterisation in the new-born period, makes it easier for parents to master it and for children to accept it as they grow older (31,32). With early management, not only are upper tract changes fewer, but also bladders are better protected and incontinence rates are much lower.

It has been suggested that increased bladder pressures due to detrusor-sphincter dyssynergia cause secondary changes to the bladder wall. These fibroproliferative changes may cause loss of elasticity resulting in a small non-compliant bladder with progressively elevated pressures. It is believed that early institution of intermittent catheterisation and anticholinergic drugs may prevent this in some patients (33-35).

Level of evidence 3

Retrospective evaluation of patients has also shown that significantly fewer bladder augmentations were required in patients with early start of CIC (30,31).

Level of evidence 4

The main disadvantage of CIC is bacteriuria which is found in 60% of the patients, but symptomatic UTI are less common (20%) with CIC when compared to the group without CIC (40%). Since the risk of reflux is similarly low with CIC, the renal scar rates are lower. CIC alone, when begun in infancy can achieve continence at a rate of 60 %. When combined with newer and more potent antimuscarinic drugs continence rates approach 75-80%. (36-39)

Due to high risk of latex sensitivity in the NDSD population, non-latex catheters are recomended. Hydrophilic-coated catheters have become more popular as they are more practical to use and are associated with less pain in use. In a randomised trial comparing hydrophilic-coated catheters to uncoated catheters, there was a reduction in microscopic haematuria and better overall satisfaction with the hydrophilic-coated catheters (40).

A Cochrane review examined sterile versus clean catheterisation technique, coated (pre-lubricated) versus uncoated (separate lubricant) catheters, single (sterile) or multiple use (clean) catheters, self-catheterisation versus catheterisation by others, and any other strategies designed to reduce UTIs with respect to incidence of symptomatic UTI, haematuria, other infections, and user preference, in adults and children using CIC (41). This review found a lack of evidence to state that the incidence of UTI is affected by any parameter. Another recent review failed to show that single use hydrophilic-coated catheters decrease the incidence of symptomatic urinary tract infection, when compared to clean multiple use polyvinylchloride catheters (42). The evidence to suggest one specific catheter type, technique, or strategy is weak and choice of catheters and regimens should be made on an individual basis.

Level of evidence 3

At present oxybutynin, tolterodine, trospium, propiverine and solifenacin are the most frequently used anticholinergic drugs to treat detrusor overactivity in children.

The clinical efficacy and side effects from anticholinergics is related to the receptor subtype present in the target organ. There are several muscarinic receptor subtypes throughout the body named as M1, M2, M3, M4, and M5. The predominant muscarinic subtype in the bladder is the M2 receptor (66%); however, it is the M3 receptor subtype (33%) that is more important for detrusor activity (43).

Some clinical studies are available, but not many randomised placebo controlled studies have been performed (35,44-46).

Oxybutynin is the first anticholinergic agent which has undergone a broad investigation in children with NDSD. It is the only FDA approved anticholinergic for paediatric use in NDSD. The dosing of oral and intravesical oxybutynin is 0.2 mg/kg/dose every 8 hr. Despite its high efficacy, oxybutynin has major side effects, which include: dry mouth, constipation, blurred vision, headache, somnolence, learning disability, flushing, constipation and dry itchy skin.

If children are unable to tolerate oral oxybutynin, other modes of delivery can help reduce side effects. The intravesical route does not rely on gastrointestinal absorption and therefore largely avoids hepatic metabolite, N-desethyloxybutynin, that is generated. It is an active metabolite with similar pharmacological properties to oxybutynin, increasing the potential for adverse effects. A meta-analysis involving intravesical oxybutynin in children with NBD supports its efficacy in lowering the mean maximum detrusor pressure while increasing bladder capacity, but side effects are nevertheless present, although fewer than with oral oxybutynin. Incontinence has been shown to be improved significantly in most studies, with "dry and improved" rates ranging from 61% to 83% (47,48). The transdermal route is an alternative route with similar benefits as intravesical treatment as it circumvents the production of N-desethyloxybutynin (49). The main limitations with transdermal delivery are local skin site irritation and the necessity for continual skin adherence.

A prospective controlled trial evaluating trospium in children reports that trospium is effective and safe in correcting detrusor overactivity in children but this study did not include patients with a neurogenic bladder (50). Tolterodine has undergone a trial in children with NDSD by the FDA. Study design limitations, however, prevent therapeutic labelling for tolterodine in the treatment of children with NDSD. In small case studies two different forms of tolterodine have been investigated in children. Tolterodine has similar efficacy and tolerability to oxybutynin in children with NDSD and the extended release formulation of tolterodine was as efficient as the instant release form with the advantages of being a single dose and less expensive (51,52).

In a randomised, controlled trial once-daily solifenacin oral suspension in children with overactive bladder was superior to placebo for mean voided volume (primary efficacy endpoint) and was well tolerated (53).

Mirabegron added to solifenacin was also shown to be a safe alternative for children with refractory overactive bladder. Dual therapy is well tolerated and adjusted dose regimen appears safe in this first paediatric study (54).

Based on the data available in children with neurogenic bladder over activity use of anticholinergic drugs is the mainstay of medical treatment. There is high level of evidence to suggest use of anticholinergic drugs in children with NDSD to reduce storage pressures and increase voided volume.

Level of evidence 2

Grade of recommendation: B (side effects)

Use of medication in children with neurogenic bladder to facilitate emptying has not been studied well in the literature. Few studies investigating the use of alpha-adrenergic blockade in children with neurogenic bladder report good response rates but they are non-controlled studies and long-term follow-up is lacking (55-57). A recent study with selective α1-blockers (doxazosin) in children with NDSD and increased leak point pressure (LPP) did not show any evident efficacy (58).

Level of evidence 4

In neurogenic bladders that are refractory to antimuscarinics and remain in a low capacity and high-pressure state, injection of onabotulinumtoxinA (BTX) into the detrusor has been introduced as a new treatment alternative (59-60). Initial promising results in adults have initiated its use in children. So far paediatric studies have been open-label and prospective controlled trials are lacking (61-63). In a recent systematic review examining 12 series (all non-randomised and only 2 with control group) injection of BTX A in therapy resistant bladders causes a significant improvement in terms of continence, maximum detrusor pressure, maximum cystometric capacity, and bladder compliance. This treatment seems to be more effective in bladders with evidence of detrusor overactivity, while non-compliant bladders without obvious detrusor contractions are unlikely to respond to this treatment (64).

Level of evidence 2

Grade of recommendation B

Dosage in children should be determined by body weight, with caution regarding total dose if also being used for treatment of spasticity, and minimum age (65- 68). In most published studies, the dose of BTX-A is 10 U/kg up to a maximal dose of 300 U involving 30 trigone sparing injections of 10 U/kg/ml in the detrusor. BTX-A seems to reach efficacy levels at 2 weeks and maximum effects within a month. Duration of the BTX-A effect ranges from 3 to 8 months depending on short-term versus long-term repeated in-

jections (69-70). Few adverse events have been reported in children, but the need for CIC after injection is an important consideration and is higher when high doses are used (71).

BTX-A injection into the urethral sphincter has been shown to be effective in decreasing urethral resistance and to improve voiding (72). A meta-analysis of BTX-A injection (in mainly adults with spinal cord injury) to the sphincter has shown its effectiveness in reducing postvoid residual urine and demonstrating a statistically significant reduction in detrusor pressure and urethral pressure 1 month postinjection (73). Current evidence is insufficient to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases (74, 75).

Level of evidence 3

Grade of recommendation B

Intravesical electrical stimulation of the bladder was introduced more than four decades ago and it has been tested in some open clinical trials in children since 1984 (76). Its practice is limited to a few centres who have reported varying results.

The only randomised controlled trial looking at this mode of therapy has failed to show efficacy (77).

The nature of this type of treatment (time consuming and very dedicated personnel) renders it unattractive for most treatment centres.

Level of evidence 2

Grade of recommendation C

Nerve stimulation via the sacral or transcutaneous route has been also studied in the treatment of patients with a non-neuropathic bladder.

Although transcutaneous nerve stimulation has been found to be effective in treating overactive bladder disorders in chronic pelvic pain/painful bladder syndrome and in children with non-neurogenic lower urinary tract disorders; its effectiveness has not been established for children with NDSD (78).

In a report of a prospective study, sacral nerve modulation conducted in children with NDSD, comparison of urodynamic variables revealed no statistically significant difference except that functional bladder capacity was better in the oxybutynin group and leak point pressure was better in the sacral neuromodulation group (79).

Although nerve stimulation has good evidence for its efficacy in non-neurogenic bladder overactivity, both in children and adults, there is no evidence for its effectiveness in neurogenic overactivity. Its use remains investigational (80).

Children with neurogenic bladder also have disturbances of bowel function. Faecal incontinence in these children is frequently unpredictable; it is related to the loss of lower bowel sensation and function, altered reflex activity of the external sphincter and the consequent failure to fully empty the rectum (81).

Most children with a neurogenic bladder also have constipation and this is managed most commonly with laxatives, such as mineral oil, combined with enemata to facilitate removal of bowel contents. A regular and efficient bowel emptying regimen is often necessary to maintain faecal continence and this may have to be started even at a very young age. With antegrade or retrograde enemata, most of these children's constipation can be managed and they may attain some degree of faecal continence (82-86).

With availability of retrograde enemata devices with a balloon on the rectal catheter to prevent leakage of solution, retrograde enemas have become more efficient and more popular in comparison to antegrade enemata (87).

Level of evidence 3.

Grade of recommendation C

Biofeedback training programmes to strengthen the external anal sphincter have not been shown to be more effective than a conventional bowel management programme in achieving faecal continence (88). Electrostimulation of the bowel may also offer a variable improvement in some patients (89).

Level of evidence 3

Grade of recommendation D

Urinary tract infections are common in children with neurogenic bladders. In the absence of reflux, patients with urinary tract infections should be treated if symptomatic. There is strong evidence not to prescribe antibiotics to patients with asymptomatic bacteriuria (90-93). Bacteriuria is seen in more than half of the children using clean intermittent catheterisation (CIC), but this is not an indication for treatment.

Level of evidence 3

Grade of recommendation B

Patients with vesicoureteral reflux and frequent urinary tract infection require prophylactic antibiotics to reduce the incidence of pyelonephritis, which can potentially lead to renal damage (94).

Sexuality, while not an issue in early childhood, becomes progressively more important as the patient ages. This issue has historically been overlooked. Patients with myelodysplasia have sexual encounters, and studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. Therefore, counselling patients regarding sexual development is important in early adolescence.

Children with a good response to antimuscarinic treatment and an overactive sphincter may be continent between catheterisations. Bladder pressure and (normal) development of the upper tracts will determine whether additional treatment is necessary.

Children with therapy resistant overactivity of the detrusor, or small bladder capacity and poor compliance will usually need additional surgical treatment such as bladder augmentation.

Children with detrusor overactivity but with underactive sphincters will be in a better shape in terms of protecting their upper tracts, but they may be severely handicapped because of their incontinence. Initial treatment will be intermittent catheterisation (as it may reduce the degree of incontinence and offers a much better control over urinary infections) in combination with antimuscarinic drugs. At a later age the outlet resistance must be increased to render them continent (95). There is no medical treatment of proven efficacy that increases bladder outlet resistance. Alpha-receptor stimulation of the bladder neck has not been very effective. Surgical procedures need to be considered for maintaining continence (96-98).

It is important to establish adequate bowel emptying before attempting to correct bladder dysfunction surgically or medically.

Patients with a neurogenic bladder require lifelong supervision; monitoring of renal function is extremely important. Periodic investigation for upper tract changes, renal function and bladder status is mandatory. Therefore, repeat urodynamic studies are needed more frequently at younger ages and less frequentlyas time progresses. A repeat urodynamic study is warranted when the patient has a change in symptoms or undergoes any neurosurgical procedure. In case of any apparent changes both in the upper and lower urinary tract or any changes of neurological symptoms, a more detailed examination including urodynamics and MRI of the spine is indicated. Renal failure usually progresses slowly but may occur with startling rapidity.

VI. SURGICAL MANAGEMENT OF URINARY INCONTINENCE IN CHILDREN

1. INTRODUCTION

The core of current NDSD management is non-surgical. Intermittent catheterisation and drug therapy are usually sufficient in most cases for maintaining continence and preserving upper tracts. Surgical procedures should be considered if conservative measures fail to achieve continence between catheterisations or preserve upper tracts.

There is no particular surgical procedure which is suitable for everyone. Surgical management must be tailored to each individual case, based on careful consideration of urodynamic findings, medical history, age and presence of other disability.

Surgical intervention is required for congenital and acquired diseases interfering with the function of the storage function of the bladder, the sphincter mechanisms or which bypass normal sphincter mechanisms. A plethora of different surgical procedures has been proposed to maintain continence by using different mechanisms. Various procedures using different mechanisms for maintaining continence may be used in the same patient.

In many cases measures such as intermittent catheterisation and drug therapy are needed in addition to surgery since most of the surgical procedures can achieve ‘dryness’, but rarely restore normal voiding.

Patients with bladder neck incompetence pose a real challenge and require a different approach. All surgical procedures to “reconstruct” the bladder neck have one thing in common; an obstruction is created to enhance bladder outlet resistance. Even if successful, normal spontaneous voiding with low pressures without external help is not possible in most patients. Considering the long-term outcome, it may be better not to void spontaneously when bladder outlet resistance is increased because longstanding outlet resistance may cause secondary changes of the bladder wall.

The rarity and complexity of the conditions associated with congenital incontinence in children precludes the establishment of higher levels of evidence because of the rarity and spectrum of the pathology. Choice of surgical treatment depends on the need of each patient and there is never one surgical protocol that is good for everyone. The results are highly dependent on the skills and experience of the individual surgeon. Therefore, graded recommendations for specific procedures cannot be provided. There are no randomised controlled trials (level 1 and 2 evidence). Based on the available literature most studies have a level of evidence 3-4 and grade of recommendation C or D.

1.1. Abnormalities of storage

Bladder Exstrophy: The incidence of bladder exstrophy is 1 per 30,000 live births. (male to female ratio 2:3.1-6.1). Closure of the bladder is generally performed within the first days of life; pelvic osteotomies facilitate reconstruction of the abdominal wall and may improve ultimate continence (1,2,3). Some children will develop more or less normal capacities. Even after successful closure there will be some children who end up with poorly compliant small bladders, requiring later bladder enlargement or urinary diversion (ureterosigmoidostomy) (4,5,6,7). Patients with a good bladder template who develop sufficient bladder capacity after successful primary closure and epispadias repair can achieve acceptable continence without bladder augmentation and intermittent catheterisation (8,9,10).

Reconstruction of the bladder neck can either be done at the time of bladder closure or at a later stage. Early reconstruction may facilitate normal bladder

function, but should be attempted only at centres experienced with such surgery (11,12). Continence rates vary from centre to centre and may range between 43 to 87% (13,14).

Cloacal Exstrophy: The incidence of cloacal exstrophy is 1 per 200,000 live births. This is a much more complex deformity that requires an individual approach. Most of these children have anomalies of the nervous system, upper urinary tract and gastrointestinal tract that can adversely affect urinary tract reconstruction. Before reconstructive procedures are considered, an extensive evaluation must be carried out.

Agenesis and duplication of the bladder are both extremely rare. Agenesis is rarely compatible with life. In bladder duplication, other associated congenital anomalies are often observed such as duplication of external genitalia or lower gastrointestinal tract.

Abnormal storage function in combination with other anomalies is usually caused by a neurological deficit or is secondary to bladder outlet obstruction. Sacral anomalies are frequently seen with cloacal malformations and imperforate anus (15, 16, 17,18).

Posterior urethral valves may cause severe hypertrophy of the detrusor with a small poorly compliant bladder (19,20). Unfortunately, following valve ablation, these bladders may not return to normal function (21,22).

1.2. Abnormalities of sphincteric function

Epispadias (without exstrophy): incidence 1 in 60,000 live births, male to female ratio: 3-5:1. All patients with bladder exstrophy also have complete epispadias.

In male patients with complete epispadias and in all females, the sphincteric mechanism is deficient and the child has complete incontinence. Reconstruction of the bladder neck is either performed at the time of epispadias repair or at a later stage. The bladder function may or may not be normal in these patients (23,24).

Malformation of the Urogenital Sinus occurs exclusively in phenotypic females. The incidence is 1 in 50,000 live births. In patients with classical urogenital sinus or cloaca, the sphincteric mechanism is insufficient and due to associated neurological abnormalities the bladder function may be abnormal.

Ectopic ureteroceles protruding into the urethra may be responsible for a partial defect of the bladder neck. In these rare cases, sphincteric incontinence may be the result.

Sphincter abnormalities secondary to spina bifida and other neurological disorders are of importance. The sphincter may be overactive (like in detrusor-sphincter dyssynergia) or underactive. Overactivity of the sphincter causes secondary changes of the bladder wall (increased collagen type III with decreased elasticity and compliance). Continence is usually achieved with antimuscarinic drug treatment or bladder augmentation (using the overactivity of the sphincter for continence). In cases of incompetence of the sphincter, different types of surgical intervention are possible to enhance the sphincteric mechanism. In general, all patients with a neurogenic bladder need Clean Intermittent Catheterisation (CIC). In patients reliant upon wheelchair mobiity a suprapubic channel can be created (Mitrofanoff) to facilitate CIC.

Bypass of sphincteric mechanism

Ectopic Ureter is an abnormally located terminal portion of the ureter. Instead of the ureter opening in the bladder, it opens in the urethra, vagina, or uterus. Ectopic ureters occur more frequently in girls and are commonly part of a duplex system: in girls, the ectopic orifice of the upper pole moiety drains into the urethra below sphincteric level or vaginal vestibule, thus causing incontinence (25).

When the ectopic ureter represents a single system, the trigone is usually asymmetrical and not well developed. These children may suffer from continuous incontinence as well as a deficient sphincteric mechanism: this is particularly true in bilateral ectopia of single systems. In these patients, the trigone and bladder neck are functionally abnormal and treatment includes surgical reconstruction of the bladder neck. When the upper pole ureter opens in the mid or distal female urethra or outside the urinary tract (i.e. vulva or vagina) incontinence results. Upper pole nephrectomy or ipsilateral uretero-ureterostomy solves the problem.

A rare and a challenging condition is when there are bilateral ectopic ureters. Since the bladder is hypoplastic, in these children achieving normal bladder capacity and function may require additional procedures to ureteric reimplantation (26,27,28).

Urethral duplication. Most patients with urethral duplication will leak urine from the abnormal meatus during voiding. In rare cases, when the urethra bypasses the sphincteric mechanisms, continuous leakage may be present (29).

Vesicovaginal fistulae. Acquired fistulae may be traumatic or iatrogenic, following procedures on the bladder neck.

1.3. Evaluation and diagnosis

A detailed history and physical examination in combination with imaging studies and urodynamic evaluation are the corner stones for successful management. Imaging studies are essential to define the anatomical abnormalities responsible for and associated with incontinence. Ultrasonography of bladder and kidneys as well as a voiding cystourethrogram are the basic studies. In infants and small children sacral ultrasonography can demonstrate normal position and mobility of the spinal cord. The scout film of the contrast voiding cystourethrogram (VCUG) assesses the lower spine and sacrum, intersymphyseal distance, and faecal retention. The contrast films will show bladder configuration, presence of

vesicoureteral reflux, incomplete voiding, bladder neck competence, urethral anatomy, and vaginal reflux. Occasionally, an intravenous urogram will provide the clearest assessment of the urinary tract. MRI and CT scanning can be helpful in defining spinal abnormalities as well as congenital abnormalities in the urinary tract.

In addition to imaging studies, urodynamic studies (cystometrography, and when needed, electromyography of the sphincters and urinary flow studies) are useful for all patients with neurogenic incontinence, and after surgery in some cases of bladder exstrophy and after posterior urethral valves resection to help define the mechanism of any continued incontinence. However, in many patients much useful information on the function of the lower urinary tract can be obtained with very basic studies including ultrasound and cystometry.

2. INDICATIONS FOR SURGICAL PROCEDURES TO CORRECT URINARY INCONTINENCE

2.1. Storage function

Reduced bladder capacity is the main indication for simple bladder augmentation. Reduced capacity can be congenital (bilateral single ectopic ureters, bladder exstrophy) or caused by previous surgery e.g. bladder neck reconstruction in exstrophy patients, where a part of the bladder is used to create an outlet resistance. Other indications are low functional bladder capacity as it may be present in neurogenic detrusor overactivity, or poor bladder compliance (meningomyelocele), or bladder scarring from previous surgery or obstruction. Bladder scarring from bilharzia remains common in areas where this is endemic and is increasingly common with immigration to the developed world. In all such cases surgery is indicated when conservative treatment has failed.

Several studies suggest that aggressive early intervention with CIC and anticholinergic therapy improves bladder compliance and may protect children from augmentation surgery (30,31).

A survey has reported that there has been no change in augmentation rates during the last 5 years: rates demonstrate significant inter-institutional variability (32).

2.2. Sphincter function during storage

Most of the diseases in childhood requiring surgical repair for incontinence not only have an influence on bladder capacity but also on sphincter function. Conservative measures to improve sphincter function have limited value and surgery is required in many cases. There are different surgical options; either to increase outlet resistance or to create or implant a new sphincter mechanism. In neurologically normal patients such as classic exstrophy patients, early anatomic reconstruction may allow 'normal' bladder and sphincter function. Sling procedures are indicated when the residual sphincter function is not sufficient to avoid incontinence. This may be the case in patients with neurogenic bladder disturbances and urethral incontinence. If there is no residual sphincter function or outlet resistance, an autologous tape or colposuspension in girls, and an artificial sphincter in boys, may be required. Primary urinary diversion (rectal reservoirs / continent stoma) offers an alternative solution to this problem.

2.3. Procedures to bypass the sphincter

If bladder outlet surgery fails or urethral catheterisation is not possible, a continent stoma may be constructed. Some patients prefer catheterising through a continent stoma rather than through the sensate urethra. The continent stoma (Mitrofanoff principle) may be combined with bladder augmentation and/or bladder neck reconstruction or closure. An alternative to such procedures would be the use of the anal sphincter for urinary continence with the use of colon as the storage reservoir

3. BLADDER RESERVOIR CONSTRUCTION

3.1. Ureterosigmoidostomy

This type of continent urinary reconstruction may be utilised in reconstruction for bladder exstrophy, an incontinent urogenital sinus or the traumatic loss of the urethral sphincter. As this reconstruction is totally dependent on the normal function of the anal sphincter, contraindications include incompetence of the anal sphincter, anal prolapse, previous anal surgery, and irradiation. Because of the potential for electrolyte resorption, renal insufficiency is also a contraindication.

Low pressure rectal reservoirs are superior to simple ureterosigmoidostomy because the augmented or reconfigured rectal bladder achieves lower pressure storage and accordingly, enhances continence.

There are two techniques which have been utilised:

a) The augmented rectal bladder in which the rectosigmoid is opened on its antimesenteric border and augmented by an ileal segment. The sigmoid may be invaginated to form a nipple valve to avoid reflux of urine into the descending colon and thus to minimise metabolic complications.

b) The sigma-rectum pouch (Mainz pouch II) in which there is an antimesenteric opening of the recto-sigmoid and a side to side detubularisation anastomosis. Ureteral reimplantation of normal sized ureters is by a standard submucosal tunnel (Goodwin, Leadbetter). If the ureter is dilated the technique utilizing a serosa lined extramural tunnel may be more appropriate (33,34).

As reported by D'elia et al, the results of these low-pressure rectal reservoirs are excellent with day and night continence better than 95% and complications related to the surgical procedure range from 0 -10% with the sigma-rectum pouch to 34% for the augmented rectal bladder (35). Late complications for the sigma-rectum pouch range from 6-12.5% and the late complications for the augmented rectal bladder are 17%. Early complications include pouch leakage while late complications are mainly related to the ureteral implantation into the bowel and pyelonephritis. Metabolic acidosis also occurs (69% of the patients had a capillary base excess of –2.5 mmol/L and used oral alkalinizing drugs to prevent hyperchloraemic acidosis).

Periodic follow-up is important to check the upper urinary tract and prevent metabolic acidosis. Due to the risk of malignancy at the ureterointestinal anastomosis, colonoscopy should be performed annually beginning at postoperative year 10 (30,36,37,38,39).

Level of evidence: 3

Grade of recommendation: B

3.2. Bladder augmentation, bladder replacement and continent urinary diversion, using intestine

The indication for bladder augmentation, replacement of the bladder, or the creation of a continent urinary diversion, is either the morphological or functional loss of normal bladder function. The main goal of this surgery is to relieve high pressure and low capacity of the urinary bladder and create a new reservoir with low storage pressures that can be emptied periodically. It is particularly important that the patients understand that spontaneous voiding will not be possible after such surgery and lifelong intermittent catheterisation will be required.

Before deciding on what type of procedure can be performed some significant factors must be addressed. These are

3. Physical and mental capacity of the patient to do intermittent catheterisation.
4. Previous surgery (on urinary tract and bowel)
5. Renal function status (including acid base state)
6. Absence or presence of reflux
7. Outlet resistance
8. The need for a catheterisable channel

The different technical approaches to bladder augmentation or replacement are dependent on the clinical presentation of the patient:

- a simple bladder augmentation using intestine may be carried out if there is any bladder tissue, a competent sphincter and/or bladder neck, and a catheterisable urethra,
- an augmentation with additional bladder outlet procedures such as bladder neck reconstruction or other forms of urethral reconstruction are required when both the bladder and outlet are deficient. This occurs most commonly in spina bifida or bladder exstrophy. It must be appreciated that bladder outlet procedures may complicate transurethral catheterisation.
- augmentation with surgical closure of the bladder neck may be required primarily, or as a secondary procedure in certain rare clinical situations. In this situation, a continent stoma will be required. However, most urologists prefer to leave the bladder neck and urethra patent as a safety precaution: when the bladder is very full leakage will occur and it allows transurethral manipulations such as catheterisation if the continent reservoir cannot be emptied through the suprapubic catheterisable channel.
- an augmentation with formation of an additional continent stoma is utilised primarily following failure of previous bladder outlet surgery. It is advisable also when an inability to catheterise transurethrally can be anticipated. An abdominal wall continent stoma may be particularly beneficial to the wheelchair bound spina bifida patient who often can have difficulty with urethral catheterisation or who is dependent on others to catheterise the bladder. For continence with augmentation and an abdominal wall stoma, it is essential that there be an adequate bladder outlet mechanism to maintain continence.
- total bladder replacement in anticipation of normal voiding in children is very rare, as there are infrequent indications for a total cystectomy, with preservation of the bladder outlet and a competent urethral sphincter. This type of bladder replacement is much more common in adult urological reconstruction.

The main contraindications are the inability of the patient to be catheterised, or perform CIC him or herself and the anticipation of poor patient compliance. When there is reduced renal function generally with a creatinine above 2 mg/dl or a creatinine clearance below 40 ml./min/1.73 m^2, there is a relative contraindication to the use of ileum or colon because of metabolic acidosis secondary to resorption. The stomach with its excretion of acid may be used with a low creatinine clearance possibly in preparation for transplantation. It is, however, not wise to use stomach in any voiding patient or one with any questions of an incompetent bladder outlet because of the severe skin irritation that the acid urine may produce (haematuria-dysuria syndrome).

3.3. Which intestinal segment should be utilized?

a) Stomach

Stomach has limited indications primarily because of the complications that have been seen. It is the only intestinal segment suitable in patients with significantly reduced renal function (40,41,42).

Additionally, when no other bowel may be available, such as after irradiation or in the presence of a short bowel syndrome, as in cloacal exstrophy, this may be the only remaining alternative.

b) Ileum / Colon

Clinically these two intestinal segments appear to be equally useful. In children, sigmoid colon is widely used except in those who have been treated for imperforate anus. Use of the ileocaecal region can be associated with transient and sometimes prolonged diarrhoea. Use of this segment should be avoided in patients with a neurogenic bowel such as in myelomeningocele or who have been subject to previous pelvic irradiation. If the ileocaecal valve must be used, it can easily be reconstructed at the time of performing the ileo-colonic anastomosis. The ileum can be satisfactorily used for bladder augmentation: however, because of its smaller diameter a longer segment of ileum is required to create a comparable reservoir to that created from colon. Colon has greater flexibility for ureteral implantation and construction of a continent catheterisable channel.

c) General principles

There are several important principles for bladder augmentation and replacement that should be respected:

- use the minimal amount of bowel and, if available, use hindgut segments or conduits from previous surgical procedures,
- a low-pressure large capacity reservoir is essential. This requires detubularisation of any intestinal segment used.
- for colonic reservoirs, a sigmoid segment of 20-30 cm is generally satisfactory. A slightly longer segment of ileum is generally used. The length of the segments can be scaled down in smaller children. Care should be taken not to use more than 50 to 60 cm of ileum in adolescents and comparable lengths in younger children because of reduction of the intestinal resorptive surface.
- the jejunum is contraindicated in intestinal reconstruction of the urinary tract because of its metabolic consequences (hyponatraemia, hypercalcaemia, and acidosis).
- it is wise to strive to achieve an anti-reflux ureteral anastomosis into the reservoir to avoid the potential for reflux and consequently ascending infection: in high pressure bladders with reflux the reflux usually disappears spontaneously following augmentation (43,44).
- a reliable continence mechanism (continent urinary outlet) must be assured.
- because of the risk of stone formation only resorbable sutures and staples should be used in bladder augmentation and reservoir construction.

d) Bladder augmentation techniques

1. In gastric augmentation, a 10-15 cm wedge-shaped segment of stomach is resected. Most commonly this is based on the right gastroepiploic artery but can be based on the left artery as an alternative. The segment is brought down to the bladder easily in the retroperitoneal space along the great vessels.
2. When using large or small bowel the segment to be utilised is opened on the antimesenteric border and detubularised prior to anastomosis to the bladder remnant. The anastomosis of the intestinal segment to the bladder remnant and to itself is usually carried out in one running layer of inverting absorbable sutures.
3. The techniques for urinary diversion with continent stoma (Mainz pouch, Indiana pouch, Kock pouch) are covered in the chapter on urinary diversion in adults (45,46,47).

Currently, augmentation cystoplasty is the standard treatment for low capacity and/or low compliance bladders secondary to neurogenic, congenital and inflammatory disorders. Due to the relatively high morbidity of conventional augmentation there is renewed interest in alternative methods (48, 49,50,51,52,53). These alternative techniques try to avoid the contact between urine and intestinal mucosa and include gastrocystoplasty, bladder auto-augmentation, seromuscular augmentation, alloplastic or biodegradable scaffolds grafted with autologous urothelium developed in cell culture, and ureterocystoplasty.

e) *Auto-augmentation*

The principle of auto-augmentation of the bladder is the excision of a great portion of the detrusor while leaving the urothelium intact, creating a large diverticulum for the storage of urine at lower pressures. This urine stored at a low pressure can be drained by intermittent catheterisation. The theoretical advantages of this procedure are the low complication rates of the surgery, reduced operative morbidity with shorter stay in the hospital, absence of urine salt resorption, less mucus production in the urine and possibly absence of potential carcinogenesis. Although some series showed good results with this procedure (54,55,56,57), most authors have been unable to achieve the early reported rates of success (58). Long-term results have been rather disappointing: MacNeily et al concluded that of 17 patients with neurogenic bladder following auto-augmentation, 71% were clinical failures and 14 out of 15 were urodynamic failures (59). Similar findings have been reported by others (60,61). The inability of this procedure to achieve long-term good results may be due to the regeneration of nerve fibres divided during the

surgery as well as the ischaemic atrophy of the mucosa.

Although there are many potential advantages to this approach to a small poorly compliant bladder the inconsistency of success make it a less favourable option. It is generally felt that pressures can be lowered but that capacity remains unchanged.

More recently, some authors have proposed the laparoscopic auto-augmentation as a minimally invasive procedure for the treatment of a low capacity/low compliance bladder. (62,63). Despite the indifferent results, some still suggest its consideration before a standard augmentation because of the reasons listed above (64,65,66).

Level of evidence 4

Grade of recommendation C

f) Seromuscular patch

To overcome one of the major disadvantages of a conventional augmentation, that is mucus formation, several techniques have been developed to use intestinal segments free of mucosa. The first attempts resulted in viable seromuscular segments covered with urothelial mucosa (67,68). The intense inflammatory response and shrinkage observed in the intestinal segment discouraged its use in humans (69). Further attempts consisted of using the association between demucosalised intestinal segments and auto-augmentation. In the initial model using sheep, the animals tolerated the procedure poorly, reflected by inflamed, haemorrhagic colonic segments in the animals sacrificed within one month. In addition, colonic mucosa regrowth occurred in one third of the animals (70). Follow-up studies in a dog model with previously reduced bladder capacity suggested that the contraction of the intestinal patch in seromuscular enterocystoplasty can be avoided by the preservation of both the bladder urothelium and lamina propria, together with the submucosa and muscularis mucosa of the intestinal patch (71,72). This form of bladder augmentation was shown to prevent absorption of toxic substances like ammonium chloride (73). Other authors using the same technique to line de-epithelialised gastric patches in the mini-pig model found it useless due to the fibrotic changes and decreased surface of the patch (74).

The initial experience in treating humans with colocystoplasty lined with urothelium were reported by Gonzales and Lima who independently developed a slightly different technique (75,76). Bladder capacity increased significantly while bladder pressures decreased. Biopsies demonstrated urothelium covering the augmented portion of the bladder in the majority of cases. Longer term follow-up is now available and although the results are very encouraging, they seem to be highly operator dependent and the way in which the mucosa is removed seems to be crucial. Lima *et al* no longer preserve the bladder urothelium and use a silicone balloon to prevent the augmented segment from contracting (they remove the balloon after 2 weeks: urine is diverted using ureteral stents): in 123 patients, no ruptures were found and only 10% were regarded as failures (77).

Gonzalez *et al* found seromuscular colocystoplasty in combination with an artificial urinary sphincter successful in 89% of their patients and that it effectively achieved continence with no upper tract deterioration, they concluded that this is their preferred method of augmentation when adverse bladder changes occur after implanting the AUS (78).

Although more authors have now reported their results this procedure remains a more complex form of augmenting the bladder and has not received general acceptance among the paediatric urological community. It is is being done in some designated centres (79,80,81,82). A recent comparison of the long-term outcome of this technique with standard intestinocystoplasty has indicated that most of the risks and benefits of augmentation cystoplasty performed using intestine and seromuscular patch appear similar.

Grade of recommendation C

g) Ureteral bladder augmentation

Another alternative to avoid the morbidity of intestinal bladder augmentation is the use of ureteral segments to improve bladder capacity and/or compliance. Megaureters associated with poorly or non-functioning kidneys provide an excellent augmentation material with urothelium and muscular backing, free of potential electrolyte and acid base disturbance, and mucus production (83,84).

An alternative in patients with ureteral dilation and good ipsilateral renal function, is to combine transureteroureterostomy with ureterocystoplasty (85). An additional option in patients with bilateral dilated ureters with preserved renal function is bilateral reimplantation and the use of the distal ends for detubularised bladder augmentation (86,87).

Bladder augmentation with ureter may be effective in a small sub group of patients with ureteral dilatation and poor bladder capacity. Overall long-term results are good and remain so over a longer period (88,89,90,91,92,93).

In a recent evaluation of the long term functional outcome of this technique, ureterocystoplasty provided durable functional urodynamic improvement, yet some patients (4 out of 17 in this series) eventually needed a standard intestinal cystoplasty (94).

Level of evidence 3

Grade of recommendation B

This type of augmentation can also be employed in children who require a kidney transplantation (95,96,97).

h) Experimental Methods

The artificial bladder has been the topic of speculation and experiment that remains outside the bounds of clinical application. Somewhat nearer to clinical application may be engineered autologous urothelium and bladder muscle cells. These cells may be grown on biodegradable scaffolds—both naturally derived and synthetic—for the temporary support of growing tissues which can then be used for augmenting the bladder. Several synthetic materials and natural matrices have been used in experimental and clinical settings and major improvement has been made in techniques of cell harvest, culture, and expansion as well as polymer design.

A range of applications of engineered bladder tissues are at different stages of development. There have been a few in preclinical trials, recent progress suggests that engineered bladder tissues may have an expanded clinical applicability in the future. Clinical trials with these methods are not far away (98-110). Although this field of research may represent the future of bladder reconstructive surgery, currently only experimental studies are available and it may be some time before clinical use becomes a practical reality. We strongly encourage further research in this field.

4. BLADDER OUTLET SURGERY

4.1. Urethral enhancement

In those children where sphincteric incompetence is the only cause of incontinence or plays a major role in association with decreased bladder capacity or compliance, surgical procedures to enhance outlet resistance should be considered. In many cases bladder outlet surgery needs to be combined with other procedures aimed at creating a large low pressure storage reservoir.

4.2. Bulking agents

The injection of bulking substances in the tissues around the urethra and bladder neck to increase outlet resistance in children dates to at least 1985. However, concern about distant migration of the injected substance and risk of granuloma formation prevented this technique from gaining widespread acceptance (111,112).

The search for safer, biocompatible substances to create periurethral compression has first led to the use of cross-linked bovine collagen, with initially reported success in about 20-50% of children (113,114,115). Collagen injection appeared to effectively improve urethral resistance, but this did not always translate into satisfactory dryness, besides, the effect of the injection is of short duration and repeated injections were often necessary (116,117). Because of this collagen is no longer recommended for this indication.

Currently, the following substances are available and have been tested in children with incontinence: dextranomer / hyaluronic acid copolymer (a nontoxic, nonimmunogenic, non-migrant synthetic substance) and polydimethylsiloxane.

Usually the substance is injected endoscopically in the bladder neck area (finding the best spot is often the most difficult part of the procedure): more than one procedure may be necessary. On average 2.8 – 3.9 ml is injected. More than 50% of patients need more than one injection. Initial results of 75% success have been reported, but after 7 years there is a gradual decrease and only 40% remained dry (118,119,120). Others have reported success rates of 0 - 70% (121-128). Despite limited success bulking agents remain an option for all patients who are poor surgical candidates and those who want to avoid extensive bladder neck reconstruction. An alternative route may be the injection around the urethra using laparoscopy (129).

Level of evidence: 3

Grade of recommendation C

4.3. Artificial urinary sphincter (AUS)

Since its introduction in 1973, the AUS has undergone major transformations over the years. Different devices are currently in use: one of the most frequently used devices is the AS800-T that has been in use for almost 20 years (130). It consists of an inflatable cuff, a pressure regulating balloon and a unit containing a pump and control mechanisms. The inflatable cuff can only be implanted around the bladder neck in females and pre-pubertal males. In post-pubertal males, bulbar urethral placement is possible but not recommended for patients either requiring a wheelchair or those who perform intermittent catheterisation (131). In patients who have had extensive urethral surgery (exstrophy and epispadias) placement may not be technically feasible.

Implantation of an AUS requires special training and difficulties may be encountered in the dissection of the space around the bladder neck in obese, post-pubertal males or in patients with a history of previous bladder neck procedures. A 61-70 cm H_2O pressure balloon is used exclusively when the cuff is around the bladder neck and a lower pressure balloon when it is around the bulbous urethra. Although high in cost, the artificial sphincter remains the most effective means or increasing urethral resistance and preserving the potential for voiding. The ideal candidate for AUS implantation is a patient with pure sphincteric incompetence who voids spontaneously and has good bladder capacity and compliance. Unfortunately, only a small proportion of children with sphincteric incontinence meet these criteria. The AUS may also be used in those dependent on clean intermittent catheterisation. The compatibility of the AUS with intermittent catheterisation and enterocystoplasty is well documented (132,133,134).

The ability to empty the bladder spontaneously or by Valsalva manoeuvre may be preserved after AUS implantation. In series reporting children with AUS, the majority having neurogenic incontinence, 25% void spontaneously (135). When the AUS is implanted before puberty, the ability to void spontaneously may be lost after puberty. Overall, 40 to 50% of neurogenic patients require a bladder augmentation concomitantly or subsequently to the AUS implantation (133,136,137,138). The continence rate ranges from 63 to 97% (139-146). Herndon et al reported a success rate of 86% (of 134 patients): 22% voided, 11% had to perform CIC after voiding, 48% only performed CIC through the urethra, 16% performed CIC through a continent channel and 3% used diversion (147). Mechanical problems occurred in 30% of patients who had an 800-model implanted (versus 64% in the old model). Revisions (in 16%) were significantly less in the 800 model. Erosion occurred in both groups (16%). A major complication was perforation of the augmented bladder in this group (occurring in 10 patients). In 28% a secondary bladder augmentation was necessary.

Another interesting aspect of the AUS is that in some children the device is either deactivated or no longer functions but they remain dry: others have reported that placing a cuff only without activation is all that is required to make them dry (148).

The complications most commonly encountered in patients with AUS are mechanical failures. The longevity of the present devices is expected to exceed 10 years, although Spiess et al reported a mean lifetime of only 4.7 years (149). The second most common problem is the development of reduced bladder compliance with time. This may result from an error in the preoperative evaluation or the reaction of the detrusor to obstruction (a reaction noted in some patients with spina bifida). These changes can be seen after many years of follow-up. The results of decreased capacity and compliance may be incontinence, upper tract deterioration, or the development of vesicoureteral reflux. Therefore, long term follow-up with ultrasound, renal scintigraphy and if indicated urodynamics is mandatory in all patients with an AUS.

Infection of the prosthesis should occur in no more than 15% of all cases. Erosions of the tissues in contact with the prosthesis are rather infrequent. Bladder neck erosions are practically non-existent when the sphincter is implanted around a “virgin” bladder neck. When the AUS is used as a salvage procedure following bladder neck reconstruction, the erosion rate may be as high as 30% (137). Despite the high complication and revision rate, AUS results show that acceptable continence rates can be achieved in the long-term. For this reason, AUS implantation may be better considered as the initial treatment in selected cases (150).

4.4. Fascial slings.

Fascial slings constructed with the fascia of the anterior rectus muscle have been used to increase outlet resistance in incontinent children, particularly those with neurogenic dysfunction since 1982 (151). The sling is used to elevate and compress the bladder neck and proximal urethra. The dissection around the urethra may be facilitated by a combined vaginal and abdominal approach, however, this option is limited to post-pubertal females (152). Several technical variations of the sling have been reported. The fascial strip may be a graft or a flap based on the rectus sheath on one side. The fascial strip can be crossed anteriorly or wrapped around the bladder neck to enhance urethral compression. Although the short-term success rate reported by most authors is encouraging, there are no series reporting detailed results at 5 years (153-154). Most authors report a greater success when fascial slings are used in conjunction with bladder augmentation and success seems more likely in females than in males (155-158). In patients with neurogenic incontinence postoperative CIC is recommended.

The pubovaginal sling in girls may also be placed through the vagina: in 24 girls with spina bifida this procedure was successful in 19, while another 3 became dry following additional injections with bulking agent around the bladder neck via a suprapubic needle introduction. CIC was possible in all patients. One patient developed a vesicovaginal fistula (159). Complications of sling procedures include difficulties with intermittent transurethral catheterisation, erosion of the urethra and persistent incontinence. Overall, the increase in outlet resistance provided by slings seems less than that provided by the artificial sphincter. Experience with these procedures suggests an overall success between 50 and 80% in females. Numerous alternatives are now being used; small intestinal submucosa has been used in 20 children and showed equivalent rates of continence. The advantage being that it is available off-the-shelf. Results were better in girls than in boys (85 vs 43% being dry) (160,161,162).

When combining bladder augmentation with a Gore-Tex sling in 19 children the results were poor: because of erosion the sling had to be removed in 14 patients, all except in one who also had a bladder stone. In this respect, this type of sling should not be used (163).

From the data published it presently seems that the AUS provides more consistent results in boys and for girls capable of spontaneous voiding who have not had previous bladder neck surgery. Bladder neck slings may be used for the enhancement of bladder outlet resistance in most patients with neurogenic bladder who need augmentation cystoplasty and whom we do not expect will be capable of voiding spontaneously. Sling procedures are probably equally effective for girls, dependant on intermittent catheterisation and in conjunction with bladder augmentation. At present, given the cost and lack of effectiveness of injection procedures, their use does not appear justified in incontinent children. The cost of the AUS may restrict its use.

Level of evidence 2.

Grade of recommendation B

It is important that one should know these patients who undergo bladder outlet surgery need long-term follow-up not only because of the complications but also, because their bladder behaviour may undergo unexpected clinically asymptomatic changes that could impair their upper tracts if augmentation is not performed at the same time (164).

4.5. Bladder neck closure

In 'desperate' cases the bladder neck may be closed, the indication for this being persistent leakage despite several attempts to enhance outlet resistance by bulking agents or other surgical procedures. Although initial results are acceptable, long-term results are usually disappointing: persistent urinary leakage, stomal stenosis and leakage or stone formation (in up to 40%) (165,166). One of the most important factors seems to be compliance with intermittent catheterisation and bladder irrigation.

4.6. Bladder outlet reconstruction

Surgical procedures to achieve urinary continence are dictated by functional and anatomical deficiencies and by the goal of either continence (with normal voiding) or dryness (dependent on intermittent catheterisation).

Construction of a functional urethra for continence usually implies an anatomical defect without a neurogenic component (epispadias / exstrophy) and includes urethral and bladder neck narrowing and urethral lengthening (167-172).

Such procedures may initially require intermittent catheterisation or occasional post voiding catheterisation, but bladder emptying by voiding is anticipated.

Urethral reconstruction for dryness, however, mandates intermittent catheterisation. The goal in surgery to achieve dryness is to create a urethra suited to catheterisation, which has closure such that intraluminal pressures always exceed intravesical pressure. The most dependable procedures for dryness utilise a flap valve or tunnel to achieve urethral closure, although urethral slings, wraps and injections have also been used (173).

Level of evidence 3

Grade of recommendation C

Reconstruction to achieve continence is based on the principle that proximal reduction of the calibre of the urethra supports the inherent proximal sphincteric mechanism of the bladder neck and proximal urethra. The narrowing must be dynamic to permit closure for continence and yet permit opening with funnelling during voiding. Several techniques have been described to achieve this goal (3, 166-176). Young (1922) performed a "double sphincter technique" that involved the excision of a wedge of tissue at the anterior bladder neck, as well as removal of a wedge of tissue just proximal to the epispadiac meatus (external sphincter). Dees (1949) added the concept of lengthening the urethral tube to that of narrowing. In his procedure, parallel incisions were made through the existing bladder neck area which created a posterior urethral plate from what had previously been the trigone of the bladder. This is tubularised to give added length to the proximal urethra. The added length provides increased potential for urethral closure and moves the bladder neck and proximal urethra into the abdominal cavity. Leadbetter (1964) modified the Young-Dees procedure by creating muscular flaps from the area of the bladder neck and proximal urethra which were used to wrap the newly created proximal tube. This procedure was popularized by Jeffs (1983) who applied it to a staged repair of exstrophy. He supported a lengthened urethra by a suspension. They report their long-term continence rate with this procedure as greater than 80%, without the need for CIC or augmentation (177).

Presently, this represents the gold standard for reconstruction for continence, however, modifications of the technique have reported similar or improved results. Most urethral lengthening procedures utilising the posterior urethra and bladder neck require ureteral reimplantation and preservation of the posterior urethral plate. Because part of the bladder is used to create the functional lengthening of the urethra, bladder capacity decreases following the procedure. It also remains to be seen whether the created urethra is actually a functioning urethra: in many patients fibrosis around the urethra prevent it from being really 'functional': in these patients, it may act as an anatomical obstruction and long-term follow-up is necessary to follow not only the bladder but also the upper tracts.

In a study examining the long-term outcome of urethral lengthening procedures (Kropp and Salle procedures) nearly 80% dryness was achieved at 4 hourly intervals and 90% at 3-hourly intervals, but the need for additional procedures were high (catheterisable channel: 54%, delayed augmentation: 47%) (178).

Surgery for dryness is dependent on the effectiveness of intermittent catheterisation and is usually reserved for patients with neurogenic dysfunction or multiple previous surgeries. Procedures to achieve dryness usually create a urethral closure pressure that exceeds bladder pressure.

A flap valve can be constructed by using an anterior or posterior bladder flap (full thickness) to construct a tube that is placed in a submucosal tunnel (171,175,176).

The major disadvantage of these procedures (flap valves) is that the valve will not allow leakage with high intravesical pressures, potentiating renal damage. Therefore, these procedures can be dangerous to the patient who is not totally committed to follow catheterisation recommendations.

Bladder outlet procedures without augmentation cystoplasty remain controversial. It is generally advised to combine it with augmentation cystoplasty to avoid upper tract changes and continued incontinence. In a review of 109 patients who underwent bladder outlet procedures without augmentation cystoplasty the need of augmentation cystoplasty was 30% and additional continence procedures was 70%. There were upper tract changes in more than 50% and chronic kidney disease 20% in a cumulative 10-year follow-up (179-181).

Unfortunately, the ideal procedure for surgical reconstruction of the bladder neck does not exist. The surgical approach to urinary incontinence in the child must be multifaceted because of the inherent complex and varied nature of the problem.

Recent data support the concept that very early reconstruction in the exstrophy / epispadias group may result in physiological bladder cycling which facilitates normal bladder and urethral development. This results in higher potential for continence without the need for bladder augmentation and bladder neck reconstruction (Level 3). More work and clinical experience in this area is strongly recommended.

Grade of recommendation A

4.7. Alternative continence channels

In the surgical treatment of incontinence in children every effort must be made to preserve the natural upper and lower urinary tract. The bladder is the best urinary reservoir, the urethra the best outlet and the urethral sphincters the best control mechanism. If the bladder is partly or wholly unusable it may be augmented or replaced by a variety of techniques.

Urethral failure may occur either because the sphincters are incompetent or because it is overactive and does not allow spontaneous voiding. It would be preferable for the former to be treated by one of the techniques described above and the latter by intermittent catheterisation (CIC). If these fail, continent supra pubic diversion is indicated.

a) The Mitrofanoff principle.

Mitrofanoff's name is given to the technique of burying a narrow tube within the wall of the bladder or urinary reservoir whose distal end is brought to the abdominal wall to form a catheterisable stoma suitable for intermittent catheterisation (182). The technique is simple and familiar to all urologists who are accustomed to re-implanting ureters. Several narrow tubes are available for the Mitrofanoff conduit (183,184). In the original description, the appendix was used. However, even if the appendix is still present, it may be unusable in 31% of patients (184).

If no suitable tube is found, a good tube can be formed by tailoring ileum transversely so that only 2-3cm of ileum can be made into a 7-8 cm conduit. This modification was originally described by Yang in humans and by Monti in experimental animals (185,186). It is increasingly used though great care must be taken in its construction to avoid an internal fistula (187). The ureter may be used but there may be some difficulty in achieving sufficient calibre with a previously normal ureter. Earlier reports that the Fallopian tube could be used have not stood the test of time.

The Mitrofanoff system achieves reliable continence, which is maintained in long-term follow-up, for a high proportion of patients. Long-term follow-up data show that in the original series of Paul Mitrofanoff of 23 patients after a mean follow-up of 20 years, 1 patient had died, but in the other 22 patients no metabolic changes were noted. The bladder neck was closed in 21 patients. Secondary bladder augmentation had to be performed in 8, while in 4 children a non-continent diversion was created. With time the need for additional surgery decreased and after 20 years 16 patients had a good and stable continent diversion (189). The pressure generated within the lumen of the conduit is 2 to 3 times higher than that within the reservoir so that continence is preserved even when the intra-abdominal pressure is raised by straining. Conversely, the pressure in the lumen of a Kock nipple is only slightly higher than that in the reservoir so that continence is less reliable (189,190). The conduit may be buried either between the mucosal and muscle layers of the reservoir, or may be completely embrocated in the full thickness of the reservoir wall. Any well supported tunnel of about 2- 4 cm will suffice. The choice depends both on the nature of the reservoir and on the conduit (192). Continence rates of 90-100% with the Mitrofanoff Principle are reported, regardless of diagnosis, reservoir or conduit type (192,193). Follow-up for at least ten years has shown that the system is resilient (194-196). Retrospective review of short and long-term outcomes of patients with the Mitrofanoff procedure reveal that stoma stenosis and leakage are the most frequent complications (within wide ranges of 10 – 60 % each) and occur early during the first two years after creation. After the initial peak of complications, there is a relatively complication-free period. Yet late complications occur in long-term evaluations, probably because of wear and tear of the channels and to anatomical modifications at adolescence with commonly associated obesity (197-201).

A modified technique of vesicostomy is described using a gastrostomy button, which could be used as a continent urinary stoma in children with incomplete voiding. Button vesicostomy is a useful addition to the options available for a catheterisable continent urinary stoma in children in the short or medium term (202). Although perfect continence seems attractive, it may not be in the child's best interests. A 'pop-off' valve may be in the interest of the child if catheterisation is impossible or forgotten.

b) The Ileo-caecal valve.

The ileo-caecal valve is an obvious sphincter to combine with cecum and ascending colon as the reservoir

and the terminal ileum as the conduit. The early continence rate of 94% was not sustained because of high pressures in the tubular reservoir and weakness of the valve (203-205). The Indiana system is based on the competence of the ileo-caecal valve but with a detubularised reservoir (206). The valve itself is reinforced with non-absorbable plicating sutures and the terminal ileum which forms the conduit is tailored. The best reported continence rate is 96% with a 2% rate of catheterisation difficulties.

In the complete Mainz I pouch a length of terminal ileum is intussuscepted through the ileo-caecal valve as a Kock nipple (207). It is impossible to say whether the nipple or the ileocecal valve (or both) produce the continence which is reported in 96% of patients. Both of these systems work well as complete reconstructions and are widely used as bladder replacements in children. The sacrifice of the ileo-caecal valve may cause gastro-intestinal complications.

c) Kock pouch

The first workable continent diversion was the Kock pouch (42). The reservoir is made from 40cm ileum reconfigured to reduce the intrinsic pressure. The continence mechanism is formed by intussusception of 12cm of ileum. In a complete form it requires 72cm of ileum which may be more than can be spared from the gastro-intestinal tract. Although first described as a mechanism for a continent ileostomy in children the Kock pouch is not commonly used in children because of the problem with large amount of bowel needed, stone formation and mediocre success with dryness of the catheterisable stoma (208,209).

d) Artificial Sphincter

As a last resort, the AUS may be considered to give continence to a reconstructed outlet. Experimental evidence suggests that AUS cuffs can be placed safely around intestine providing the cuff pressure is low (210). The AUS has been used successfully around large bowel, in three of four children with follow-up to 11 years (211).

e) Where to place the cutaneous stoma

In patients with spina bifida, particularlythose unable to walk, the site must be chosen with care. The natural tendency is for the spine to collapse with time so that the lower half of the abdomen becomes more pendulous and beyond the range of vision. A low site may seem appropriate in the child, but will become unusable in the adult. It is best to use a high, midline site, preferably hidden in the umbilicus. The site should be determined in a sitting position and marked before surgery because in the supine position the position will change dramatically. In some patients, the best position may not be in the midline at all: special care must be taken that the patient can manage bladder emptying and irrigation him/herself.

For most other patients, the site of the stoma should be chosen by cosmetic criteria. The umbilicus can be made into a very discrete stoma; the risk of stenosis is low and it is a readily identifiable landmark. Otherwise, the stoma should be as low on the abdominal wall as possible and certainly below the top of the underpants. However, many surgeons find the best results by placing the catheterisable stoma in the umbilicus.

The problem of stomal stenosis remains ever present. It can occur at any time so that only follow up of many years could determine whether any system of anastomosis to the skin is better than any other. The published rate of stomal stenosis is between 10 and 20%. The multi-flap V.Q.Z. stoma is claimed to have the lowest rate but follow up is short and it may well not pass the test of time (212).

5. COMPLICATIONS OF CONTINENCE SURGERY IN CHILDREN

5.1. Storage and emptying complications

In the short term, continent diversions can store urine and can be emptied by clean intermittent catheterisation (CIC). It is apparent that there is a constant need for review and surgical revision. This observation mirrors the late complications of augmentation cystoplasty for neuropathic bladder where the median time to revision surgery is as long as ten years (213,214).

In general, once continent, they remain continent, although there are occasional reports of late development of incontinence. The problem lies more in difficulties with catheterisation, particularly stenosis and false passages which may occur in up to 34% of patients (192). In a recent retrospective evaluation of 500 augmentations over 25 years with a median follow-up of 13.3 years, the cumulative risk of further surgery at the bladder level was 0.04 operations per patient per year of augmentation and 34% of the patients needed further surgery for complications. Bladder perforation occurred in 43 patients (8.6%) with a total of 53 events and 125 surgeries done for bladder stones in 75 cases (215). The principal complications arise because the reservoir is usually made from intestine. Ideally, urothelium should be used and preservation of the bladder epithelium gives fewer complications than enterocystoplasty (216). Combinations of detrusor myomectomy and augmentation with de-mucosalised colon have given promising results in the short term. The surgery is difficult as the bladder epithelium must not be damaged and the intestinal mucosa must be removed completely. When achieved there are no metabolic problems and many patients can void (216).

When augmentation can be done with a dilated ureter, the results are good and the complication rate low even in children with compromised renal function or transplantation (217). All intestinal reservoirs produce mucus. The amount is difficult to measure and most

estimates are subjective. No regime has been shown to dependably reduce mucus production (218).

5.2. Reservoir rupture

The most morbid and disastrous complication following bladder augmentation is perforation, which may lead to peritonitis, sepsis, and even death. Reported rates of bladder perforation following augmentation range between 6 and 13 % (219-222).

There may be delay in diagnosis although the history of sudden abdominal pain and diminished or absent urine drainage should make it obvious. The patient rapidly becomes very ill with symptoms of generalized peritonitis (223,224). A 'pouchogram' may not be sensitive enough to demonstrate a leak. Diagnosis is best made by history, physical examination, ultrasonography and a CT cystogram. If diagnosed early, catheterisation and broad spectrum antibiotics may sometimes lead to recovery. If the patient fails to respond within 12 hours on this regime or if the patient is ill, laparotomy should be performed at once. If there is any instability of the patient laparotomy should be considered as an immediate necessity as bladder rupture in this clinical situation can be lethal.

Level of evidence 2.

Grade of recommendation A

Figures are not available on the incidence of this complication in reservoirs made only of bowel but come from patients with intestinal segments in the urinary tract. Most papers report small numbers. In a multicentre review from Scandinavia an incidence of 1.5% was noted. There were eight patients with neurogenic bladder which was said to be disproportionately high (223). In a series of 264 children with any sort of bowel reservoir or enterocystoplasty, 23 perforations occurred in 18 patients with one death (224). Therefore, as this complication is more common in children it becomes a very important consideration (222). A review of 500 bladder augmentation procedures performed during the preceding 25 years, spontaneous perforations occurred in 43 patients (8.6%), for a total of 54 events. The calculated risk was 0.0066 perforations per augmentation-year (225).

Patients and their families should be warned of this possible complication and advised to return to hospital at once for any symptoms of acute abdomen, especially if the reservoir stops draining its usual volume of urine. All young patients with urinary reconstructions including intestinocystoplasty should carry suitable information to warn attending physicians of their urinary diversion in case of emergency.

5.3. Metabolic complications

Because enteric tissue, although incorporated into the bladder, retains its absorptive and secretory properties, there are potential serious consequences, especially for children with an expected longer life span than adults (226.227). Metabolic changes are common when urine is stored in intestinal reservoirs and must be carefully monitored. It is uncertain whether they are commoner in children or whether they just live longer and are more closely monitored. Nurse *et al* found that all patients absorbed sodium and potassium from the reservoirs but the extent was variable (228). A third of patients (but 50% of those with an ileocecal reservoir) had hyperchloraemia. All patients had abnormal blood gases, the majority having metabolic acidosis with respiratory compensation. The findings were unrelated to renal function or the time since the reservoir was constructed. In 183 patients of all ages at St Peter's Hospitals who had any form of enterocystoplasty, hyperchloraemic acidosis was found in 25 (14%) and borderline hyperchloraemic acidosis in an additional 40 (22%) patients. The incidence was lower in reservoirs with ileum as the only bowel segment compared to those containing some colon (9% v 16%). When arterial blood gases were measured in 29 of these children a consistent pattern was not found (229). In a series of 23 patients, Ditonno et al found that 52% of patients with a reservoir of right colon had hyperchloraemic acidosis (230). In ileal reservoirs, Poulsen et al found mild acidosis but no patients with bicarbonate results outside the reference range (231). Many authors do not distinguish between patients with normal and abnormal renal function. All of 12 patients in one series with a preoperative serum creatinine above 2.0mg% developed hyperchloraemic acidosis within 6 months of enterocystoplasty (232). It is prudent to monitor patients for metabolic abnormalities, especially hyperchloraemic acidosis, and to treat them when found (233).

With increasing experience, it has become clear that there is a risk of developing vitamin B12 deficiency, sometimes after many years of follow up. It is likely that resection of ileum in children leads to an incomplete absorption defect. Stores of B12 may last for several years before the serum level becomes abnormal. At a mean follow up of six years, low levels of B12 have been found in 14% of children. There was a corresponding rise in the serum methyl malonic acid which accumulates in B12 deficiency, suggesting that the finding was clinically significant. Similarly, in adults, 18.7% have B12 deficiency at five years. In the adults, the mean B12 level was significantly lower when the ileo-caecal segment as opposed to ileum alone had been used (413 ng/ml compared to 257 ng/ml) (234,235). To avoid the serious neurological complications, regular monitoring of B12 levels is essential. In a review of 500 augmentations starting at 7 years postoperatively, 6 of 29 patients (21%) had low B12 values, while 12 of 29 (41%) had low-normal values (236). Paediatric patients who have undergone ileal enterocystoplasty are at risk for development of vitamin B12 deficiency. These patients are at the highest risk beginning at 7 years postoperatively, and the risk increases with time. An annual serum B12 value in children beginning at 5 years following bladder augmentation is recommended.

Level of evidence 2

Grade of recommendation B

The stomach has had a chequered career as a urinary reservoir. Its non-absorptive role in the gastro intestinal tract has made it particularly useful in reconstruction of children with inadequate intestine, such as those with cloacal exstrophy. There is little effect on gastrointestinal function. Metabolically, the acid production leading to hyperchloraemic alkalosis may be positively beneficial in children with renal failure. It produces no mucus and the acidic urine is less easily infected and seldom grows stones. However, about a third of children have had serious long term complications, often multiple. The quite severe dysuria / haematuria and the skin complications from the acid urine, particularly, have limited its use (237,238).

5.4. Effects on the gastrointestinal tract

Little attention has been paid to the effects on gastro intestinal motility of removing segments of ileum or cecum for urinary reconstruction in children. In adults, disturbance of intestinal function has been found to be more frequent and more debilitating than might be expected. Disturbance of bowel habit does not mean diarrhoea alone. It also includes urgency, leakage and nocturnal bowel actions. Quality of life may be seriously undermined by changes in bowel habit (239). It is known that the bowel has a considerable ability to adapt, especially in young animals, when parts are removed. Nonetheless, reconstruction should be undertaken with the smallest length of bowel possible. Care should be taken in children with neurological abnormality in whom rectal control is already poor. Poorly controlled faecal incontinence may occur in a third of patients (240,241).

5.5. Renal function

Obstruction and high pressures in the bladder during storage have devastating effects on the upper urinary tract. Bladder augmentation eliminates these high pressures. Urinary diversion with recurrent urinary tract infections and stone formation also may have deleterious effects on renal function. It is therefore of utmost importance to evaluate renal function in young children who have undergone undiversion or continent diversion. In the follow-up so far available, these procedures do not seem to affect renal function. When function has improved after such surgery it is likely to be the result of eliminating obstruction or high bladder storage pressure. In rats with near complete nephrectomy the rate of progression of renal failure is no worse in those with ileocystoplasty compared to those with normal bladder (242). This suggests, experimentally, that storage of urine in small intestine is not, on its own, harmful to renal function.

Clinically, in the longer term, renal deterioration has been related to obstruction, reflux and stone formation. In one long-term study of Kock pouch patients, these complications occurred at the same rate as that found in patients with ileal conduits: 29% at five to 11 years (243). Similarly, in a prospective follow-up to a minimum of 10 years, it was found that the deterioration in glomerular filtration rate (GFR), that was found in 10 of 53 patients, was due to a 'surgical' cause in all but one (244).

Although a more complicated procedure, a renal transplant can be anastomosed to an intestinal reservoir with similar long term results as those using an ileal conduit (245,246).

5.6. Infections and stones

The incidence of bladder reservoir stones varies between 12 and 25%. This is higher in children compared to adults. Palmer *et al* reported an incidence of 52.5% during a follow-up of four years (247). Renal stones are uncommon, occurring in about 1.6% of patients, an incidence which would be expected in a group with congenital urinary tract anomalies.

In a series comparing the Kock pouch with the Indiana pouch (which does not have staples), 43.1% of 72 Kock reservoirs formed stones compared to 12.9% of 54 Indiana reservoirs (248). Furthermore, no patient with an Indiana pouch formed a stone after 4 years, but patients with Kock pouches continued to do so at a steady rate up to eight years.

Apart from the presence of a foreign body, several factors have been blamed for the high stone risk. Almost all reservoir stones are triple phosphate on analysis, though Terai *et al* found carbonate apatite, urate and calcium oxalate in up to 50% of stones from patients with an Indiana pouch (249). This suggests that infection rendering the urine alkaline is a key factor. Micro-organisms that produce urease and split urea to form ammonia are the main culprits. The incidence of infection in reservoirs is high, 95% in one series, and yet the majority of patients do not form stones, suggesting that there are predisposing factors other than infection and the anatomical abnormality of the urine reservoirs (250). It has been suggested that the immobility associated with spina bifida may be responsible, but this seems to have been in series with a predominance of such patients and was not confirmed in other studies (251). In intestinal augmentation, mucus formation is especially troublesome as it tends to block catheters and requires regular irrigation, and may predispose to stone formation. The finding of a spectrum of stone formation from mucus, through calcification to frank stone lends some support to this aetiology. However, it could be a secondary event, with mucus becoming adherent to a stone that has already formed. Many surgeons encourage patients to wash out their reservoirs vigorously with water two or three times a week. There seem to be fewer stones in those that claim to practice regular washing. In a prospective study a regime of weekly washouts did not improve the incidence of stones in 30 children compared to historical controls (252). Mathoera *et al* found an incidence of 16% during a follow-up of 4.9 years in 90 patients: girls were more frequently affected than boys and concomitant bladder neck reconstruction, recurrent infections and difficulties with CIC were other risk factors identified, while the frequency of irrigation did not appear to be a risk factor (253).

Mucins are an important component of the epithelial barrier and protect the epithelium from mechanical and chemical erosion. Mucins are known to act as important adhesion molecules for bacteria. Mucins may also enhance the formation of crystals (254). Mucin expression changes after incorporating the intestinal segment in the bladder. Upregulation of MUC1 and MUC4 expression occurs in transposed ileal segments resembling normal epithelium, whereas ileal segments in enterocystoplasty showed an upregulation of MUC2,3,4 and 5AC expression towards the site of anastomosis with the ileal segment. These changes which may be due to exposure to urine coincide with a change from ileal sialomucins to colonic sulfomucins by a change in glycosylation. The mucins bind calcium and may form a template resembling the crystal structure on which crystals are formed and grow. From these studies, it is concluded that inhibition of bacterial adhesion (by using different irrigation fluids based on sugars) could be of eminent importance in the prevention of certain types of infection stones. An interesting comparison has been made between children with a native bladder alone and those with an augmentation, all of whom were emptying by self-catheterisation. There was no significant difference in the incidence of stones with or without an augmentation (255).

Stones are associated with inadequate drainage in the sense that CIC through the urethra, the most dependent possible drainage, has the lowest stone rate. Patients with the most 'uphill' drainage, that is with a Mitrofanoff channel entering the upper part of an orthotopic reservoir have a higher incidence of stones (254). Kronner *et al* made the observation, that the incidence of stones was statistically associated with abdominal wall stomas and a bladder outlet tightening procedure (21.1% compared to 6% in patients with augmentation alone) (250). Once a bladder stone has been diagnosed it has to be removed: several methods are available, but ESWL should be avoided as it is difficult to remove all fragments (and small particles may get trapped in mucus and the pouch wall), which may form the focus of a new calculus. Because of the recurrent nature of these stones the least invasive method should be recommended (256,257). Because of the high incidence of stones following enterocystoplasty several measures should be recommended to the patients and their parents. Regular CIC under hygienic circumstances with adequate fluid intake and irrigation seem to be the most important (258). It is unclear whether prophylactic antibiotics are useful, but a clinical infection should be treated adequately. Maybe in the future different types of irrigation fluid may prove helpful.

5.7. Growth

The suggestion that enterocystoplasty delayed growth in height seems to have been ill founded. In a group of 60 children reported in 1992 it was stated that 20% had delayed growth (259). Current follow up of the same group has shown that all have caught up and achieved their final predicted height. Furthermore, measurements in a group of 123 children from the same unit have shown no significant delay in linear growth (260). Enterocystoplasty may have an effect on bone metabolism even if growth is not impaired. At least in rats with enterocystoplasty there is significant loss of bone mineral density especially in the cortical compartment where there is endosteal resorption. These changes are not associated with HCA and are lessened by continuous antibiotic administration (261,262). More recent follow-up data shows either no effect on growth or a decreased linear growth (263-266).

5.8. Pregnancy

When reconstructing girls it is essential to have a future pregnancy in mind. The reservoir and pedicles should be fixed on one side to allow enlargement of the uterus on the other. Pregnancy may be complicated and requires the joint care of obstetrician and urologist (267). Problems include upper tract obstruction and changes in continence as the uterus enlarges. Pregnancy with an orthotopic reconstruction appears to have a good outcome but chronic urinary infection is almost inevitable and occasionally an indwelling catheter is needed in the third trimester (268). With a suprapubic diversion, catheter drainage for incontinence or retention may be needed in the third trimester (269). Except in patients with an artificial urethral sphincter and extensive bladder outlet reconstruction, vaginal delivery is usual and caesarean section should generally be reserved for purely obstetric indications (distorted pelvis in spina bifida patients). During the delivery, the bladder reservoir should be empty and an artificial sphincter deactivated. The urologist should be present during Caesarean section to ensure protection for the reservoir, the continent channel and its pedicles.

5.9. Malignancy

The risk of malignancy in enteric augmentations has been reported to be higher than expected, and the risk increases with length of follow-up. Malignancy occurs in 0.6-2.8% of patients during median follow-up of 13-21 years. In a study including 153 patients with a median follow-up time of 28 years, malignancy was found in 4.5% (270). Animal data suggest that faecal and urinary streams must be mixed in bowel for neoplasia to occur. However, if it is chronic mixed bacterial infection, rather than the faeces *per se*, then all bowel urinary reservoirs are at risk. The malignancy seemed to be associated with coexisting carcinogenic stimuli or with the inherent risk present with bladder exstrophy. In patients with colonic and ileal cystoplasties high levels of nitrosamines have been found in the urine of most of the patients examined (271). Clinically significant levels probably only occur in chronically infected reservoirs (272). Biopsies of the ileal and colonic segments showed changes like those that have been found in ileal and colonic conduits and in ureterosigmoidostomies. More severe

histological changes and higher levels of nitrosamines correlated with heavy mixed bacterial growth on urine culture (273). In a review by Filmer *et al*, 14 cases of pouch neoplasm were identified (274). Special features could be found in nearly all the cases. Ten patients had been reconstructed for tuberculosis; four tumours were not adenocarcinomas; one patient had a pre-existing carcinoma; six patients were over 50 years old. Cancer was found in bowel reservoirs at a mean of 18 years from formation. This is a few years earlier than the mean time at which malignant neoplasms are seen in ureterosigmoidostomies. In a review of 260 patients with a follow-up of more than 10 years, Soergel *et al* found 3 malignancies (all transitional cell carcinoma): 2 following ileocecal and 1 after caecal augmentation. The age at augmentation was 8, 20 and 24 years respectively: the tumours were found when they were 29, 37 and 44 years old. All had metastatic disease and died. The incidence of malignancy in this group was 1.2%: considering that the development of tumours usually takes 20-25 years the probable incidence of malignancy following enterocystoplasty may be as high as 3.8 % (275). Hussmann *et al* studied a group of 153 patients with a mean follow-up of 27 years (10-52 yrs.) after augmentation cystoplasty. In those with a neurogenic bladder (n=97) they found 2 patients with transitional cell carcinoma (both smokers), in 38 patients with bladder exstrophy 3 multifocal adenocarcinomas in the augmented segment were found and in 2 of 18 patients with urethral valves an adenocarcinoma was discovered. The overall risk of cancer was 4.5% after a median period of 32 years. Of the 7 patients 5 died suggesting that these tumours are very aggressive and metastasised early (270). This level of carcinogenesis was also confirmed by Sung (276).

Patients who undergo bladder augmentation with a gastric remnant are at increased risk for malignancy, probably similar to that in patients with enterocystoplasty. In a review of 119 patients underwent augmentation cystoplasty with stomach in 2 institutions, three patients had gastric adenocarcinoma, while the other had poorly differentiated transitional cell carcinoma. Each case progressed to malignancy more than 10 years after augmentation (277-279). It has also been shown that patients with neurogenic bladder managed solely with clean intermittent catheterisation have an increased risk of bladder cancer, and this risk may be increased following bladder augmentation (280). If cancer is going to be a common problem, there will be some difficulty in monitoring the patients at risk (281). Endoscopy with a small instrument through a stoma may not be sufficient. Ultrasound may not be able to distinguish between tumours and folds of mucosa. Three-dimensional reconstruction of computerised tomography may be helpful, though the equipment is expensive and not widely available at present (282). Although many advise to perform an annual endoscopic evaluation in all patients following enterocystoplasty starting 10 years after surgery, some argue that yearly endoscopy is not cost-effective and the potential morbidity makes it an ineffective screening procedure (283).

5.10. Psychological consequences and quality of life

The main justification for performing a bladder reconstruction or continent diversion is to improve the individual's Quality of Life (QoL). It would seem logical that continent urinary diversion would be better than a bag. This is not always the case. In adults, the only sure advantage is cosmetic. Validated QoL surveys in children have not been reported, primarily because of the lack of suitable instruments (284). Our prejudice is that reconstruction does, indeed, improve the lives of children although supporting evidence is very thin and based on experience in adults.

The ileal conduit has been a standard part of urological surgery for over 50 years. It has well known complications but few would seriously suggest that they were more troublesome than those of the complex operations for bladder replacement. In an early investigation into quality of life issues, Boyd *et al* investigated 200 patients, half with an ileal conduit and half with a Kock pouch: there was little difference between the groups except that those with a Kock pouch engaged in more physical and sexual contact. The only patients that were consistently 'happier' were those who had had a conduit and subsequently were converted to a Kock pouch (285).

In a recent QoL survey in adults, a wide range of complications were considered to be acceptable, although an ordinary urological clinic would be full of patients trying to get rid of such symptoms: mild incontinence (50%), nocturia (37%), bladder stones (12%), urinary infections (9%), hydronephrosis (5%). Nonetheless, their QOL was judged to be good, primarily because 70% had experienced no adverse effect on their normal daily lives (286).

Quality of life does not mean absence of disease or a level of complications acceptable to the reviewing clinician. It is a difficult concept to measure because lack of validated instruments, difficulties in translating from one culture or language to another, and the difficulties in selecting control groups and variations in clinical situations. Gerharz *et al* have constructed their own 102 item instrument and compared 61 patients with a continent diversion and 131 with an ileal conduit. Patients with a continent diversion did better in all stoma related items indicating that containment of urine within the body and voluntary emptying is of major importance. In addition, they had better physical strength, mental capacity, social competence and used their leisure time more actively. There was little difference in satisfaction with professional life, financial circumstances and in all interactions within the family including sexual activity (287).

Consensus statement on surgical treatment of urinary incontinence in children

Forms of urinary incontinence in children are diverse, however, a detailed history, physical examination and voiding diary obviate the need for further studies for the majority. This should identify that limited group that may require surgery. Many patients in this group will have obvious severe congenital abnormalities.

Because of the spectrum of problems, specific treatment is usually dictated by the expertise and training of the treating physician. The rarity of many of these problems precludes the likelihood of any surgeon having expertise in all areas. Furthermore, nuances in surgical procedures develop gradually and are often never systematically evaluated.

Nevertheless, it may be that newer forms of very early aggressive surgical approaches to severe complex anomalies such as exstrophy, myelodysplasia and urethral valves may provide a successful model for significant impact on the ultimate continence in such patients. Ultimately these may provide a basis for randomised studies to determine the most specific and effective mode of therapy.

The committee would encourage vigorous research on the molecular basis of bladder development and support the development of surgical and treatment strategies which would utilise the natural ability of the bladder to transform in the early months of development and immediately after birth.

Furthermore, efforts to promote bladder healing, and to protect and achieve normal bladder function should be supported. Such studies and research may lead to earlier and more aggressive treatment of many of the complex anomalies now treated by the surgical procedures outlined in this report.

VII. PSYCHOLOGICAL ASPECTS OF URINARY INCONTINENCE, ENURESIS AND FAECAL INCONTINENCE

List of abbreviations used in this section

ADHD Attention-Deficit/Hyperactivity Disorder

CBCL Child Behaviour Checklist

DSM-5 Diagnostic and Statistical Manual of Mental Disorders – 5

DUI Daytime urinary incontinence

HKD Hyperkinetic Disorder

FI Faecal incontinence

ID Intellectual Disability

ICD-10 International Classification of Diseases – 10

LUTS Lower urinary tract symptoms

NE Nocturnal enuresis

ODD Oppositional Defiant Disorder

Since the publication of the 4th ICI report in 2009 (1) an increasing body of reviews has been published on psychological factors of incontinence in children (2-5). A new focus of research and clinical practice is on children with special needs, who have higher rates of incontinence and behavioural problems (6). This chapter includes an update based on the recent literature and especially the ICCS standardisation document on psychological aspects in urinary and faecal incontinence (7), as well as other ICCS documents.

1. INTRODUCTION

Children with urinary incontinence, enuresis and faecal incontinence carry a higher risk for manifest behavioural disorders, as well as for subclinical emotional and behavioural symptoms. It is important to assess and integrate psychological factors in treatment for two reasons:

1. As can be seen in table 1, the rate of comorbid behavioural and emotional disorders is much higher than possible organic causes (7). The same care used to exclude organic causes should be applied to the assessment of behavioural aspects. Therefore, paediatricians and urologists should have a basic understanding of psychological principles to treat their young patients adequately.

2. In functional or non-organic incontinence, provision of information, cognitive therapy and behavioural modification are the most effective, first-line approaches to treatment. Medication can be helpful in many cases, but are usually not the mainstay of treatment. Surgery is rarely indicated. As most of the techniques used in “urotherapy” are based on cognitive-behavioural psychotherapy, it is essential to be acquainted with the basic psychological principles.

Table 1: Organic causes and comorbidity of clinically relevant psychological disorders or symptom scores*

Nocturnal enuresis	
Organic causes	< 1%
Behavioural comorbidity*	20-30%
Urinary incontinence	
Organic causes	<10%
Behavioural comorbidity*	20-40%
Faecal incontinence with constipation	
Organic causes	< 5%
Behavioural comorbidity*	30-50%
Faecal incontinence without constipation	

Nocturnal enuresis	
Organic causes	< 1%
Behavioural comorbidity*	30-50%

**** Comparable population norms: 10%***

This chapter provides information on comorbid manifest clinical disorders, as well as symptoms which might be emotionally distressing for children and parents, but do fulfil the criteria for a disorder. Often, these will resolve upon attaining continence, while manifest disorders usually do not. In addition, children with psychological disorders are less compliant, and this explains why the failure rate of children's incontinence treatment is much higher. It is recommended that both incontinence and any comorbid psychological disorder are treated separately to ensure effective therapy.

The relevance of psychological factors for the different subtypes of incontinence will be considered. The terminology of the ICCS for enuresis and urinary incontinence as well as of the Rome-IV classification for faecal incontinence will be used (8,9).

2. CLINICAL BEHAVIOURAL DISORDERS

Worldwide, approximately 10 to 20% of children are affected by clinically relevant mental health disorder according to ICD-10 (10) or DSM-5 (11) criteria (12). Even under most conservative estimates, 15% of children and adolescents have psychological disturbances with daily incapacitation. But are these disorders increasing? Bor *et al*. tackled this question in their very carefully conducted review and found that for toddlers and children, there was no major increase of psychological disorders (13). However, adolescents show an increasing risk for internalising disorders such as anxiety and depression, especially girls. The rate of comorbid behavioural disorders is increased in children with all types of incontinence. Comorbidity denotes the co-occurrence of two or more disorders at the same time (concurrent comorbidity) or in sequence (sequential comorbidity). The focus on comorbidity allows a descriptive approach without referring to possible causal associations. Basically, four combinations are possible:

- A behavioural disorder can be a consequence of the wetting problem,
- A behavioural disorder can precede and induce a relapse when a genetic disposition for enuresis is present, for example in secondary nocturnal enuresis,
- Wetting and a behavioural disorder can both be due to a common neurobiological dysfunction (such as in nocturnal enuresis and ADHD),
- With such common disorders, no causal relationship can be present and the two may co-exist by chance.

A psychological disorder (synonyms: psychiatric, psychic, mental disorder) "is a syndrome characterised by clinically significant disturbance in an individual's cognition, emotion regulation, or behaviour that reflects a dysfunction in the psychological, biological, or developmental processes underlying mental functioning. Mental disorders are usually associated with significant distress or disability in social, occupational, or other important activities" (DSM-5) (11).

Clinically relevant disorders can be assessed by two basic methods: the categorical and the dimensional approach. The categorical method is based on a detailed diagnostic process (including history, observation, exploration, mental state examination, questionnaires, testing, physical examination and other procedures) and are professional diagnoses according to standardised classification schemes: ICD-10 (10) or DSM-5 (11). Dimensional assessment is based on symptom scores by questionnaires, but do not represent diagnoses. Cut-offs are defined to delineate a clinical (and sub-clinical) range.

One can differentiate three broad categories:

1. Externalising or behavioural disorders with outwardly-directed, visible behaviour (examples: conduct disorders and ADHD),
2. Internalising, i.e. inwardly-directed, intrapsychic disorders such as emotional disorders (examples: separation anxiety, social anxiety, phobias, sibling rivalry and depressive disorders),
3. Other disorders that do not fit into the two categories, such as anorexia nervosa, tic disorders and autism spectrum disorders.

Five of the most important disorders occurring in children and adolescents with NE, DUI and FI are summarised below:

Major depression has a prevalence of 2-5%. The aetiology is multifactorial with a 40-50% contribution of genetic factors. Symptoms include sadness, unhappiness, loss of enjoyment, lack of energy and interest, negative thinking, sleep and appetite problems. Treatment includes counselling, cognitive-behavioural, interpersonal and psychodynamic psychotherapy which can be combined with antidepressant medication. A population-based study of 2079 6-year old children has shown that depressive and anxious symptoms are more common in children with NE and DUI, and especially high in FI (14).

Anxiety disorders affect 5% of children. Again, aetiology is multifactorial, including family, temperament and to 40% genetic factors. Four subtypes predominate: separation anxiety disorder, characterised by fears associated with separation; generalised anxiety disorder with the main symptom of worrying; in social phobia avoidance of social situations is typical and in

phobia a fear of objects. Treatment consists of counselling, cognitive-behavioural therapy, relaxation, exposure and skills-based techniques, psychodynamic psychotherapy and medication in severe cases (antidepressants). Studies on anxiety in children with incontinence are still rare; exceptions are the study by Equit *et al.* (14).

Attention-deficit/hyperactivity disorder (ADHD) has a prevalence of 6% and a predominantly genetic aetiology (70-80%). The main symptoms are inattention, hyperactivity and impulsivity. Treatment includes counselling, parent training and cognitive-behavioural therapy. Medication plays a major role (mainly stimulants). In one population-based study of 1391 6-year old children, children with DUI had the highest rates of ADHD (15). Many studies have been conducted on the associations of ADHD and incontinence, which have been summarised in the systematic review of von Gontard and Equit (5).

Oppositional Defiant Disorder (ODD) is characterised by persistent hostile, provocative and noncompliant behaviour and affects 2-5% of children. The aetiology is best explained by a gene-environment interaction, including a genetic disposition and dysfunctional parenting practices. Treatment consists of counselling, parent training, cognitive-behavioural therapy, school-based interventions, but usually not medication. One population-based study on 718 6-year-old children showed a high rate of ODD, especially in children with DUI (16); and another study of 1676 6-year old children, especially those with FI were affected by ODD, ADHD or both (17).

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder, defined by persistent deficits in social communication and social interaction and restricted, repetitive patterns of behaviour, interests and activities (DSM-5) (11). These disorders are present from the early developmental period, cause clinically significant impairment and are associated with intellectual and language impairment, other disorders. The prevalence of ASD is 0.6-1%. The aetiology is mainly genetic, with up to 90% of the variance being due to genetic factors. 15% of ASD are syndromal forms, with the Fragile-X Syndrome, Tuberous Sclerosis being the most important syndromes. The diagnosis is based on a full child psychiatric, paediatric and genetic assessment. Treatment consists of parent training and counselling, autism-specific training programmes and behavioural therapy. Medication includes neuroleptics, stimulants, antidepressants (SSRI), which are not given routinely, but only when indicated. In a recent systematic review, the associations of ASD and incontinence were summarised, as well as the many open research questions (18).

3. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH NOCTURNAL ENURESIS AND DAYTIME URINARY INCONTINENCE

Children with urinary incontinence show a higher rate of comorbid behavioural and emotional problems (16.5% to 51.9%) than non-wetting children (7.8% to 10.2%), in both epidemiological and in clinical studies. The overall relative risk is 1.4 – 4.5 times higher, based on early population-based studies (7). Epidemiological studies have the advantage of revealing representative associations. They often cannot differentiate well between subgroups. To date, the largest and best population-based studies are those of Joinson et al., based on the British ALSPAC birth cohort (19, 20, 21) (see table 2).

Table 2: Epidemiological, population-based studies: Percentage of children with clinically relevant behavioural problems in comparison to controls and their relative risk*

Study	Age (yrs)	N	Type of wetting	Incontinent children	Controls	Odd's ratio
Joinson 2007 (19)	7 ½ years	8242	NW	Separation anxiety: 8.0%	6.4%	1.3
				Social anxiety: 7.0%	4.6%	1.5
				Specific phobia: 14.1%	11.5%	1.2
				Generalised anxiety: 10.5%	7.7%	1.4
				Depression: 14.2%	10.9%	1.3
				ODD: 8.8%	4.7%	1.9
				Conduct disorders: 8.5%	5.7%	1.5
				ADHD: 17.6%	11.9%	1.5
Joinson 2006 (20)	7-9	8213	DW	Separation anxiety: 11.4%	6.8%	1.8
				Attention/activity: 24.8%	13.8%	2.1

				Oppositional behaviour:10.9%	5.8%	2.0
				Conduct problems: 11.8%	6.2%	2.0
Joinson 2006 (21)	7-8	8242	FI	Separation anxiety: 4.3%	0.8%	5.4
				Specific phobia: 4.3%	1.0%	4.3
				Generalised anxiety: 3.4%	0.4%	8.5
				ADHD: 9.2%	1.9%	4.8
				ODD: 11.9%	1.9%	6.3

DUI = Daytime urinary incontinence

FI = Faecal incontinence

NE = Nocturnal enuresis

3.1. Nocturnal enuresis

The ICCS differentiates between primary (never dry) and secondary NE (relapse after a dry period of 6 months); and monosymptomatic (no lower urinary tract symptoms - LUTS) and non-monosymptomatic NE (with LUTS). Therefore, four subgroups of nocturnal enuresis can be differentiated:

- Primary monosymptomatic nocturnal enuresis
- Primary non-monosymptomatic nocturnal enuresis
- Secondary monosymptomatic nocturnal enuresis
- Secondary non-monosymptomatic nocturnal enuresis

Epidemiological studies show clearly that, depending on definitions and instruments used, 20-30% of all nocturnal enuretic children show clinically relevant behavioural problems, 2 to 4 times higher than non-wetting children (7).

In the British population-based ALSPAC-study of 8242 children at the age of 7 ½ years, children with NE were affected by: separation anxiety (8.0%), social anxiety (70%), specific phobia (14.1%), generalised anxiety (10.5%), depression (14.2%), ODD (8.8%), conduct disorders (8.5%) and ADHD (17.6%) (table 2) (19).

Children with primary nocturnal enuresis were not different from controls in epidemiological studies (22). Secondary nocturnal enuresis was preceded by a higher rate of weighted life-events (23) and was significantly associated with a higher rate of psychiatric disorders, which can persist into adolescence (22). By adolescence, the attainment of dryness after the age of 10 years increased the risk for behavioural problems, independently of the primary or secondary status (24).

The only epidemiological study addressing monosymptomatic nocturnal enuresis included 8242 children aged 7 ½ years (25). Though not adhering to the ICCS criteria, children with monosymptomatic nocturnal enuresis showed fewer behavioural symptoms than those with daytime problems (i.e. the non-monosymptomatic forms), although the differences did not reach significance.

Regarding the types of behavioural and emotional disorders, externalising disorders such as ADHD and ODD predominate (5, 15,16,17, 26).

In a retrospective study of patients with ADHD, 20.9% wetted at night and 6.5% during the day. The odds-ratios were 2.7 and 4.5 times higher, respectively, which means that there is a nonspecific association of ADHD and both night and daytime wetting (27). 25% of 140 children with ADHD were affected by nocturnal enuresis compared to 10.8% of 120 controls (28). The highest comorbidity rates of 40% for ADHD and nocturnal enuresis were reported by Baeyens *et al.* (29), possibly due to selection bias: 15% had a combined, 22.5% an inattentive and only 2.5% a hyperactive type of ADHD. In a community based sample, the prevalence rate was much lower. ADHD continued to be present in 72.5% of children in a two-year follow-up indicating a high stability (37). Children with ADHD continued to wet at follow-up much more often (65%) than controls (37%) (Odds-ratio 3.17). At a 4-year follow-up, 64% still had ADHD: of these, 42% continued to wet at night (compared to 37% of the controls) (30).

In clinical practice, children with ADHD are more difficult to treat. In a retrospective study, 113 children with ADHD and nocturnal enuresis had a worse outcome on alarm treatment than controls (with nocturnal enuresis only): 43% (vs. 69%) were dry at 6 months and 19% (vs. 66%) at 12 months. There was no difference if they were treated with medication, which does not require active cooperation. Non-compliance was reported in 38% of children with ADHD, but only in 22% of the controls (31). This means that

children with both enuresis and ADHD require special attention – and both need to be treated separately.

3.2. Daytime urinary incontinence

Daytime wetting has been neglected in epidemiological research. The most important study is based on a cohort of 8213 children aged 7 ½ to 9 years (20). Children with daytime wetting had significantly increased rates of psychological problems, especially separation anxiety (11.4%), attention deficit (24.8%), oppositional behaviour (10.9%) and conduct problems (11.8%). Externalising disorders predominate in daytime wetting children, which, in turn, will interfere with treatment. In the same cohort, 10,000 children aged 4 to 9 years were analysed. Delayed development, difficult temperament and maternal depression / anxiety were associated with daytime wetting and soiling (32). In another population-based study, 36.7% of children with urinary incontinence had ADHD symptoms, in comparison to 3.4% of dry children (15).

ADHD is a common problem among day wetting children, as well. Compared to controls, children with ADHD had more symptoms of incontinence, constipation, infrequent voiding and dysuria (33). With ADHD, treatment outcome is worse. In a retrospective analysis, 68% of day wetting children with ADHD became dry compared to 91% of controls. Non-compliance was much higher for timed voiding (31).

Daytime wetting is a heterogeneous group of disorders. According to the ICCS terminology, following subgroups can be differentiated (8):

- Over-active bladder including urgency incontinence
- Voiding postponement
- Underactive detrusor
- Dysfunctional voiding
- Obstructive voiding
- Stress urinary incontinence
- Vaginal reflux
- Giggle incontinence
- Extraordinary daytime urinary frequency

Only some of these subgroups have been studied regarding comorbid psychological disorders.

Children with urgency incontinence have fewer behavioural problems than those with other types of DUI. 29 % of children with urgency incontinence had an ICD-10 diagnosis and 14% had an internalising disorder. 13.5 % had a clinical total problem score in the CBCL, again mainly internalising problems (34, 35). The children are distressed by their wetting and family functioning is intact. In another study, 35% of children with urgency incontinence fulfilled the criteria for an ICD-10 diagnosis (36). Children with urgency incontinence have lower rates of comorbid disorders than those with voiding postponement (36% vs. 59%), but higher than controls (9%). Children with urgency incontinence predominantly have emotional, introversive disorders. In summary, children with urgency incontinence have only a slightly increased rate of comorbid psychiatric disorders. If they are affected, emotional, introversive symptoms predominate.

Children with voiding postponement, on the other hand, fall into two groups: in some it represents an acquired habit, in others, it is associated with externalising psychological disorders, especially oppositional defiant disorder (ODD). In a systematic study of children with voiding postponement in a paediatric and child psychiatric setting, 53.8 % fulfilled the criteria for at least one ICD-10 diagnosis (34). These were mainly externalising disorders in a third children such as Oppositional Defiant Disorder (ODD). Also, 37.3 % of children had a CBCL total score in the clinical range, again, with externalising symptoms predominating. In addition, family functioning was impaired (34,35). In another sample, 53% of children with voiding postponement had at least one ICD-10 diagnosis (37). In summary, children with voiding postponement have highly increased psychiatric risks. Voiding postponement as one of the most important subgroups of DUI was the topic of a recent review (38).

Studies on comorbid behavioural problems in children with underactive bladder have not been performed. Systematic investigations of psychological aspects of dysfunctional voiding are rare. In some children, it represents an acquired habit, in others severe psychological disturbances are present (39). Dysfunctional voiding following severe sexual abuse and deprivation as well as other familial stressors such as migration has been described in case reports (40). There have been no systematic investigations of children with giggle incontinence. From clinical experience, they are highly distressed by the symptom and try to avoid situations in which they might be forced to laugh. Social withdrawal, not going to parties and meeting with friends has been observed. It is not known if the rate of behavioural disorders is increased. Regarding the other subtypes of urinary incontinence, not even anecdotal data are available.

4. CLINICAL BEHAVIOURAL DISORDERS IN CHILDREN WITH FAECAL INCONTINENCE

According to the Rome-IV classification, two subtypes of faecal incontinence can be differentiated (9):

- Functional constipation (with or without incontinence)
- Non-retentive faecal incontinence.

4.1. Epidemiological Studies

In the large ALSPAC study of 8242 children aged 7-8 years, children with faecal incontinence had significantly increased rates of separation anxiety, specific phobias, generalised anxiety, ADHD and ODD (see table 2) (21). In other words, soiling children show a completely heterogeneous pattern of both internalising and externalising disorders. Again, these will require assessment in the individual child, as they will interfere with treatment of the incontinence.

In clinical studies, 35% to 50% of all children with faecal incontinence had a total behavioural score in the clinical range in this parental questionnaire. Compared to the normative population (10%), 3.5 to 5 times more children with faecal incontinence have total behaviour scores in the clinical range (7). Children with behavioural maladjustment are less compliant than children without psychological disorders (71% vs. 38% non-compliant) – so if these behavioural problems are not addressed treatment will be less successful (41).

Children with faecal incontinence and constipation have the same rate of behavioural scores in the clinical range as children without constipation (39% vs. 44%, (42) and 37% vs. 39%, (43)). This means that the two major types of faecal incontinence cannot be differentiated according to the behavioural comorbidity. More importantly, regarding the aetiology, there is no evidence that one type (i.e. with constipation) has more somatic aetiology, while the other type (i.e. without constipation) has a more psychogenic aetiology. There is no specific psychopathology typical for faecal incontinence: all types of behavioural and emotional disorders can co-exist.

4.2. Subclinical signs and symptoms

Subclinical behavioural signs and symptoms are common, understandable, adequate reactions towards the wetting problem and not disorders. Many studies have addressed the impact of wetting on children.

a) Impact on children

Most children are distressed by enuresis. For example, 35% said that they felt unhappy, 25% even very unhappy about wetting at night in one study (40 children aged 5-15 years) (44). In a Finnish population-based study, 156 day and night wetting children (from 3375 7-year olds) showed significant differences compared to 170 controls regarding following personality traits (45): they were more fitful (vs. peaceful), more fearful (vs. courageous), more impatient (vs. calm), more anxious (vs. does not worry) and had more inferiority feelings (vs. feels equal). In a large population-based British study of 8209 children aged 9 years, 36.7% of children consider bed-wetting to be "really difficult" – ranking 8th behind other stressful life-events (46).

One construct of special importance is that of self-esteem. In one study, lower self-esteem in children with enuresis disappeared upon attaining dryness (47). In another, global self-esteem was significantly lower in children with nocturnal enuresis than in controls (48) and in yet another, the self-esteem total score was higher among enuretics than norms (49). Therefore, it was concluded that there is no clear evidence that bedwetting leads to lower self-esteem (50) – but there can be no doubt that self-esteem can improve upon attaining dryness (49). Self-esteem increases even if treatment of enuresis is not successful (51), showing that care and "good doctoring" for children and parents is of great help – regardless of outcome. Recently, a focus has been on quality of life, which is reduced in children with urinary incontinence (52). Questionnaires to assess quality of life will be presented later.

Children with faecal incontinence tend to feel less in control of positive life events and had a lower sense of self-esteem than children with other chronic conditions (53). However, in a more recent study, self-esteem did not differ between children with faecal incontinence and controls (54).

b) Impact on parents

Enuresis and urinary incontinence may be just as distressing for parents as for children. Generally, parents are very concerned about the welfare of their child. In a population based study, 17% worried a great deal and 46% some or a little (55). In one study, the greatest maternal concerns were: emotional impact, social relationships, smell, extra washing and financial aspects (56). Mothers of children with nocturnal enuresis had a reduced quality of life scores (bodily pain and emotional role) and more depressive symptoms (57).

Parents also believe that their child should be dry at a very early age, which can induce anxiety and stress: the mean anticipated age of dryness was 3.18 years in one study (58) and 2.75 years in another (59). Also, many parents think that emotional factors are the cause of nocturnal enuresis and forget that they might be the effect of the wetting problem instead (58,59).

A minority of parents show an attitude that was described as "maternal intolerance" by Butler et al (60). Convinced that their child is wetting on purpose, the risk for punishment is increased. In some cultures, punishment is very more common: 42% of Turkish children were spanked and 13% beaten (61). Chinese parents show a high level of parenting stress associated with externalising behavioural problems or their child (62). These parental attributions and experiences must be considered in all treatment plans for enuresis, as they can decisively influence the outcome.

Parents of children with faecal incontinence are also stressed and worried about the problem (63). In one study, children with faecal incontinence had family environments with less expressiveness and poorer organisation than controls (54). In another study of 104 families, nearly half (51%) had no unusual family

problems; 23 had severe and widespread difficulties including sexual abuse; 11 families described moderate difficulties and 18 a single traumatic event (64). In other words, the atmosphere was warm and supportive without major difficulties in at least half of the families.

5. CHILDREN WITH SPECIAL NEEDS

Special needs is an umbrella term referring to individuals who require additional medical, psychiatric, psychological and educational assistance (6). Those with special needs comprise heterogeneous groups of physical and intellectual disability, as well as a wide variety of neurodevelopmental disorders. These disorders and disabilities continue to affect adults, i.e. they are life-long conditions. Incontinence is major, but often neglected disorder in people with special needs.

Studies have shown repeatedly that all types of incontinence are more common in children with special needs than in normally developing children, i.e. nocturnal enuresis (NE), daytime urinary incontinence (DUI) and faecal incontinence (FI). Also, incontinence has a higher likelihood of persisting into adolescence and adulthood, i.e. becoming a chronic condition. Incontinence can have an additive negative effect on the emotional state, self-esteem and quality of life of the child with special needs – and can affect his/her own daily school and family functioning.

Many children with intellectual disability have special needs. Intellectual disability (ID) is defined by an IQ < 70. Mild ID (IQ 50-69) and severe ID (IQ < 50) are the two broad categories. Many different syndromes and disorders are associated with ID, most with prenatal, genetic causes. Overall, incontinence is more common in children, adolescent and young adults with ID (65). Also, there is an inverse relationship between IQ and incontinence, i.e. the lower the IQ is, the more often incontinence occurs.

Incontinence has been studied only in some of the specific syndromes of ID, such as Fragile-X, Williams, Down and Angelman syndromes (66-69). In addition to the IQ-level, syndrome-specific risk factors for incontinence have been identified, such as . epilepsy in Angelman syndrome and behavioural factors in other syndromes.

As many children with special needs do not receive standard assessment and adequate treatment. Professionals working with children with special needs should realise that incontinence is a major and common problem in their patients and should actively offer effective treatment based of incontinence, the underlying condition and associated, comorbid disorders. Daily distress will be reduced for patients, as well as parents and caregivers.

6. GENERAL PRINCIPLES: ASSESSMENT

6.1. Screening Questionnaires

Due to the high rate of comorbid behavioural disorders, the ICCS recommends screening with a broad-band, validated questionnaire (7,8). Broad-band means that a wide range of psychological symptoms are assessed. Narrow-band questionnaires are less useful as screening instruments, but are valuable in the diagnosis of specific disorders. Narrow-band questionnaires include those for depression, anxiety, ADHD, obsessive-compulsive behaviour, tics and autism spectrum disorders. If a manifest psychological disorder is suspected by history, clinical observation, exploration and broad-band questionnaires, a child psychological or psychiatric assessment is recommended. Short, medium and long screening questionnaires are available.

a) Short broad-band screening questionnaires

The 'Parental Questionnaire – Enuresis/Urinary Incontinence (PQ-EnU)', a parental questionnaire which has been used widely in clinical care and research, has recently been validated (3, 70). It contains yes/no questions regarding nocturnal enuresis (NE) (12 items), daytime urinary incontinence (DUI) (10 items), voiding and stool habits (19 items), as well as behavioural problems (10 items). In the validation sample of 496 patients, a high correlation of .723 to .778 with diagnoses of incontinence (NE, DUI and faecal incontinence -FI) could be demonstrated. A factor analysis of the Behavioural Problem Scale (BP) revealed three factors: "attention and school deficits" (Cronbach's α =.665), "impulsive-aggressive behaviour" (Cronbach's α =.731) and "internalising problems" (Cronbach's α =.409). These factors showed significant correlations with Child Behaviour Checklist (CBCL – see below) total, internalising and externalising scales (.351 to .608). In summary, the PQ-EnU is a valid questionnaire to examine children with incontinence and can be used as a screening for psychological symptoms. It can be downloaded without charge (3).

The 'Short Screening Instrument for Psychological Problems in Enuresis (SSIPPE)' is a comparable instrument available in appendix of Van Hoecke et al. (71). It is a validated parental questionnaire, based on the Child Behaviour Checklist (CBCL) (72). It has three scales including 7 Items for emotional problems, 3 Items for attention symptoms and 3 Items for hyperactivity/impulsivity symptoms. The authors recommend that if more than two yes answers are given for any of the 3 problem areas (emotional, attention, hyperactivity/impulsivity), this should be followed by a more detailed questionnaire such as the CBCL. If the CBCL T-scores are in clinical range (or many problem items are answered with a "2"), then a detailed child psychiatric assessment should follow.

b) Medium-length broad-band screening questionnaire

The Strengths and Difficulties Questionnaire (SDQ) is a medium-length behavioural screening questionnaire about 3-17 year olds (73). Parent and teacher versions are available, as well as self-reports for 11-17-year-old children and adolescents. It exists in several versions to meet the needs of researchers, clinicians and educationalists. In addition to the standard version, one version additionally assesses impact and incapacitation, while another version is useful for follow-up. Official translations are available in 77 languages.

All versions of the SDQ ask about 25 attributes, some positive and others negative. The items are scored on a three-point scale: not, somewhat and certainly true. The 25 items are divided between 5 scales: emotional symptoms (5 items), conduct problems (5 items), hyperactivity/inattention (5 items) and peer relationship problems (5 items) – these 4 scales form the total difficulties score. A fifth scale measures prosocial behaviour (5 items).

The Strengths and Difficulties Questionnaires, whether in English or in translation, are copyrighted documents that may not be modified in any way. Paper versions may be downloaded and subsequently photocopied without charge by individuals or non-profit organizations provided they are not making any charge to families. The questionnaires, scoring instructions, norms and related articles can be downloaded free of charge at following website: www.sdqinfo.org

c) Long broad-band screening questionnaires

The family of Achenbach questionnaires covers the age groups from 1 1/2 years to 30 years – with self-informant-, parent- and teacher versions (72). The parental Child Behaviour Checklist (CBCL/6-18) is one of the most widely used questionnaires worldwide with translations in many different languages (over 90) and with national norms.

As the name implies, the CBCL/6-18 is a parental questionnaire for the age groups of 6 to 18 years. It consists of a 113 problem items, which are scored on a three-point scale: 0= not true; 1= somewhat or sometimes true; 2= very true or often true. Three composite scales can be calculated (total score, internalizing, externalising behaviour). For these composite scales, the clinical cut-off is at the 90th percentile and the borderline cut-off at the 85th percentile. In addition, 8 other syndrome scales can offer valuable information.

The CBCL is one of many questionnaires within the Achenbach family of instruments: these aim at the pre-schoolers (1 ½ - 5 years), school age children (6-18 years), young adults (18-30 years), adults (18-59 years) and older adults (60-90 years). Self-report, parent and teacher versions exist, so that behaviour can be assessed in different contexts. All Achenbach questionnaires (such as the CBCL), manuals and related materials can be ordered under: www.aseba.org

In the ICCS documents, a general screening for emotional and behavioural problems in all settings (paediatric, urologic, child psychiatric, etc.) with a validated and standardised parental behavioural questionnaire is recommended because of the high rate of comorbid disorders in 30-50% of children (8). This can be done in two steps: using a short screening questionnaire first, flowed by a long questionnaire; or in one step: using a validated, medium of long questionnaires. If many problem items are checked, a child psychological or psychiatric assessment should follow. If comorbid disorders are present, counselling or treatment, if necessary, is recommended (see figure 1).

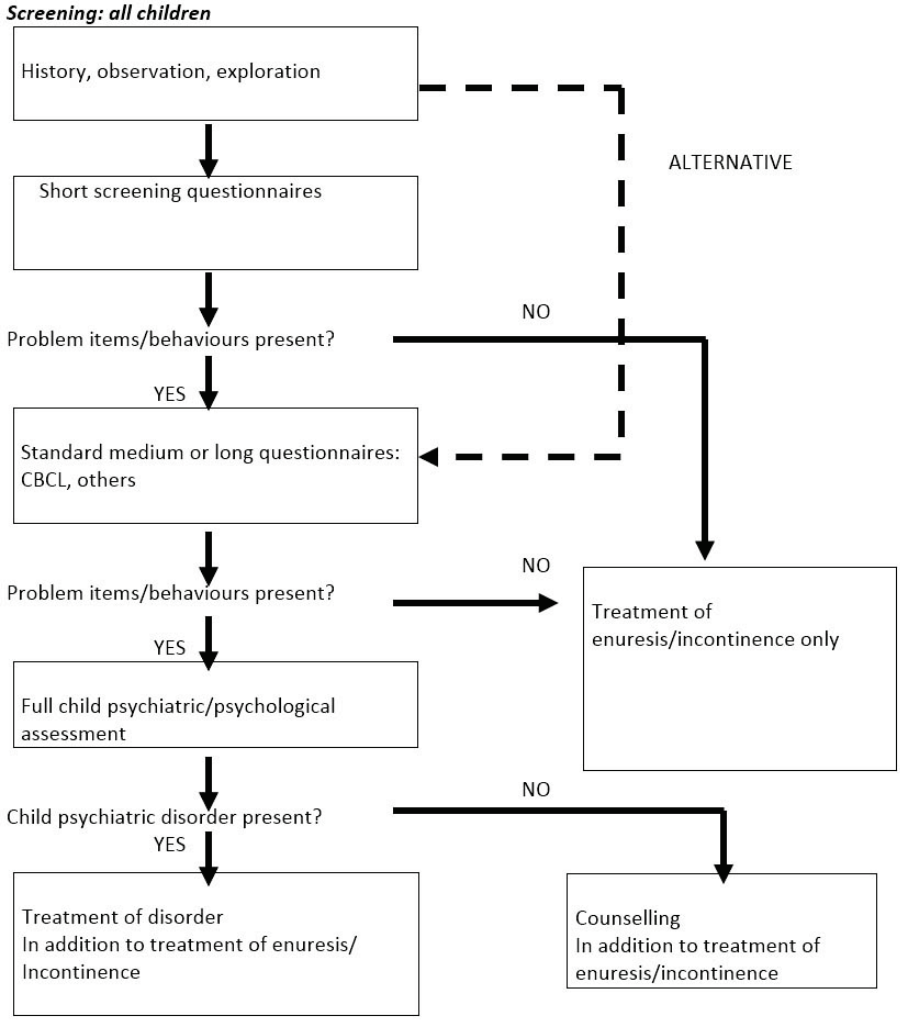

Figure 1: Flow chart for assessment of psychological symptoms (subclinical) or disorders (clinical). The specific treatment for enuresis / incontinence is the same for all children including those with symptoms requiring counselling, and those with disorders needing treatment (7)

One construct of special interest in children with incontinence is that of health-related quality of life (HQOL). In their standardisation document, the ICCS recommends to screen for changes of health-related quality of life (HrQoL) and specifically recommends using the PinQ-questionnaire, which is by far the best condition-specific HrQoL for children with incontinence (8, 74).

Generic HrQoL questionnaires can be useful in research in comparison with healthy controls and with children affected by other chronic medical conditions (75-77). Self-report versions for different age-groups, as well as proxy-report versions exist. The youngest age for self-report is 4 to 6 years, with reliable results available from 8 years onwards. The most commonly used proxy report is by parents, but caregivers, nurses and doctors can fill out these questionnaires, as well. Parental and child appraisal of HrQoL can differ. In research, comparison of child and own parental QoL can be interesting (77,78), but is usually not feasible in clinical practice.

In general, as HrQoL is a multidimensional construct, different aspects are assessed such as physical functioning, psychological well-being, social relationships, everyday life activities, satisfaction, discomfort, etc. These questionnaires can also be useful in monitoring the effects of therapy – in research, as well as in clinical practice. HrQoL-questionnaires are not useful in screening for psychological disorders, i.e. the information is not sufficient to decide if a disorder could be present or not.

6.2. Child psychiatric assessment

A child psychiatric assessment is a professional procedure with the goal of coming to a categorical decision: to see if a diagnosis, according to the standardised classification schemes (ICD-10 or DSM-I5) is present in the child or not (10,11).

The first step is a detailed developmental, behavioural and family history in much greater detail than provided in the outline in the appendix. The next step is to observe the child as well as the parent-child-interaction, followed by an active exploration of the child. The information gained from history, observation and exploration forms the basis of the mental state examination. This is a descriptive, phenomenological assessment of mental and behavioural signs and symptoms (for example: CASCAP-D) (79).

Questionnaires are always an essential part of child psychiatric assessment. They are a time-efficient way to gather information from different informants. They can contribute towards but do not provide a diagnosis. Behavioural questionnaires can again be divided into general and specific questionnaires. The best known, most widely used general parental questionnaire is the Child Behaviour Check List, which has been translated into many languages (CBCL/6-18)(72). In the meantime, Achenbach and co-workers have produced a whole “family” of questionnaires for different age groups (infants, children – adolescents, young adults) and different informants (parents, teachers and for children themselves starting from age 11). In addition, other specific questionnaires address circumscribed areas such as depressive symptoms or ADHD problems.

An intelligence test is not routinely indicated in the assessment of children with elimination disorders, as the IQ is in the normal range for most children with wetting, as well as soiling problems. However, the rate of elimination disorders is clearly increased in children with general developmental disorders, including those with mental and physical handicap (6). If a lower intelligence is suspected, one-dimensional tests (such as the CFT or CPM/SPM tests) or multidimensional tests such as the Kaufman or the Wechsler tests can be performed. If specific developmental disorders such as dyslexia or dyscalculia are suspected, specific tests for these circumscribed disorders are indicated. Disorders of speech or language (such as articulation, expressive and receptive speech disorders) require a detailed assessment by an audiologist and speech therapist. Motor disorders can be assessed clinically by including soft neurological signs in the physical examination of children.

After the diagnostic process has been completed, the child’s disorder is diagnosed according to standardized classification schemes. The two standard classification systems are the ICD-10 (10), which is widely used in Europe and in other parts of the world and the DSM-5 (11) employed in the United States.

In child psychiatry, a multi-axial classification is used. Six different axes denoting different domains are used, including:

1. Axis: clinical psychiatric diagnosis (such as anorexia nervosa, depressive episodes, etc.)
2. Axis: specific developmental disorders (such as dyslexia)
3. Axis: intelligence (such as dyslexia, speech and motor disorders)
4. Axis: somatic diagnosis (such as epilepsy and other paediatric diagnoses)
5. Axis: psychosocial risks occurring within the last six months (such as distorted intra-familial interaction, isolated family and other stressful life events)
6. Axis: the global severity of a disorder (ranging from mild incapacitation to disorders requiring constant supervision and guidance)

Only after the diagnostic process has been completed and discussed with parents and children, should therapeutic interventions be planned.

6.3. General principles: treatment of psychological disorder

For most children with elimination disorders, a symptom-orientated approach is sufficient. If, however, another, co-occurring child psychiatric disorder is present, additional types of treatment will be necessary. In these cases, a differential indication for therapy is mandatory. The question is: which treatment is most effective for this child in this family at this moment?

For some disorders (such as ADHD), medication plays a major role. For most others, psycho-therapeutic interventions are the first-line treatment. There can be no doubt that psychotherapy in children is effective. In one of the best and largest meta-analysis of 150 studies, Weisz et al. (80) conclude that “psychotherapy with young people produces positive effects of respectable magnitude “(i.e. effect sizes in the medium to large range - 0.5 to 0.8). It has been estimated that over 500 different types of psychotherapies exist in the USA for children and adolescents alone (81). Of those which have been evaluated, four basic schools of psychotherapy can be differentiated:

1. Depth psychology (or psycho-analysis), which addresses and works with unconscious aspects of the psyche;
2. Client- (or child-) centred-psychotherapy, which focuses on the current conscious experience of the child and the healing aspects of their therapeutic relationship;
3. Family therapy, which focuses on the interaction between family members but not the individual person;

4. Cognitive-behavioural therapy, focusing on cognitions and observable behaviour.

Before initiating any psychotherapy, a differential indication for therapy as to be made. The first basic question should be: is treatment needed at all? In many cases counselling of parents and child is all that is required. In other cases, changes in the child's environment (such as changing school) or help from social services can be more useful than psychological treatment in the narrower sense.

The modality should be considered. Although parents are nearly always included, the focus can be on an individual, group or family therapy. The intensity and duration should be addressed: is a short focal therapy focused on one specific problem needed, or a longer more general treatment? The age of the patient plays an important role: while older children and adolescents can be reached verbally, younger children require play or other non-verbal media in their therapy.

Psychotherapies can be combined with other methods, such as pharmacotherapy, but also by using speech, occupational, physiotherapy, music and other types of therapies – if indicated. The decision should no longer be based on personal inclinations. Instead, empirically based "practice parameters" or "guidelines" have been developed in many countries. These interventions are usually performed on an outpatient basis. Day clinic treatment can be indicated in more severe disorders, which require a more intense approach and management. Finally, in-patient child psychiatric treatment is indicated in severe disorders, in which a more intense type of treatment is possible.

6.4. General principles

a) Urotherapy

A major part of therapy of incontinence in children is non-pharmacological and non-surgical. The term urotherapy is used in some countries. It is an umbrella term which has been defined as a "type of training which makes use of cortical control of the bladder, teaching children to recognise and employ conscious command over their lower urinary tract. Its main ingredients are information about normal lower urinary tract function and the specific dysfunction in the child, instruction about what to do about it and support and encouragement to go through with the training programme (82).

Although not a psychotherapy in a narrow sense, it employs many psycho-therapeutic techniques borrowed especially from counselling and cognitive-behavioural therapies. As these approaches have been shown to be most effective, basic principles and findings shall be outlined.

b) Non-specific approaches

The first step in any diagnostic and therapeutic process is to create a good relationship with both the child and the parent. One should enquire and talk about all relevant facts, signs and symptoms openly. It is also important to ask about the subjective meanings and connotations. Next, the provision of information is essential, because many facts are not known. It is often forgotten that not only parents but each child needs information, as well. This should be provided in words and concepts that a child understands and in a format that is attractive. Increasing motivation and alleviation of stress and guilt feelings are also part of all patient contacts.

c) Counselling

Counselling is already part of the treatment process, which has been defined as the provision of assistance and guidance in resolving personal, social, or psychological difficulties. For many children, even with psychological disorders, counselling is, in fact, sufficient. Sometimes, it can be helpful to enhance the verbal counselling by other techniques. One simple technique is that of "demonstration", e.g. actively showing how an alarm works. In "coaching", parents and children take an even more active role, e.g. they set and activate an alarm themselves. They can be observed and corrected. Other techniques might include "modelling" and "role-playing". The learning effect is much greater in these active forms of teaching than in solely verbal counselling.

d) Cognitive –behavioural therapy

Cognitive-behavioural therapy (CBT) is a subtype of psychotherapy that has shown to be effective for many disorders. Cognitive therapy focuses on irrational, dysfunctional conditions, thoughts and beliefs. Cognitive therapy encompasses a whole variety of techniques such as "self-monitoring" (observation and registration), "activity scheduling" (organisation of activities) and "labelling" (using positive suggestive statements). Behavioural therapy concentrates on observable behaviour, which it aims to modify with a variety of techniques. These include "classical conditioning" and "operant conditioning", which basically means learning by success, which can be achieved by different strategies using positive or negative reinforcement.

e) Baseline and observation

Baseline and observation are effective techniques used in cognitive-behavioural therapy. Children (and parents) are advised to observe a defined symptom. Different parameters such as frequency (how often it occurs), severity (how marked it is), symptomatology (in what form it occurs) and in which situation (associated factors) can be registered, e.g. in an observation chart. The mere observation and registration has a therapeutic effect and many symptoms diminish if they are simply observed.

In nocturnal enuresis, children are asked to fill out a calendar or chart depicting the wet and the dry nights symbolically for two to four weeks (3). These non-specific measures have been shown to be successful and are associated with fewer wet nights (3). In one clinical trial, for example, 18% became dry after an 8-week baseline (83).

In urgency incontinence, the cognitive aspects are stressed in treatment: children are asked to register feelings of urgency, refrain from using holding manoeuvres, to void and register the voiding (or any wetting) in a chart (3). For children with voiding postponement, timed voiding 7 times a day and registration in a chart is recommended (3,38).

For all children with faecal incontinence, stool regulation is an essential part of treatment. Children are asked to sit on the toilet three times a day after mealtimes in a relaxed mode for five to ten minutes (4). This is documented in a chart and can be reinforced positively. If constipation is present and a large amount of faecal mass has accumulated, disimpaction has to be performed at the beginning of treatment. Oral disimpaction is the preferred method. To avoid re-accumulation of faecal masses, maintenance therapy with oral laxatives, such as polyethylenglycol (PEG) is recommended for at least six, and up to twenty-four months (84). The preferred oral laxatives are osmotic laxatives such as PEG.

f) Biofeedback

Biofeedback has been shown to be effective in some elimination disorders such as dysfunctional voiding (85). It is defined as a variety of techniques, by which physiological activity is registered, enhanced and presented to the patient in real time by visual and acoustical signals). In faecal incontinence, biofeedback is no more effective than standard behavioural techniques in faecal incontinence both with (86) and without constipation (87).

g) Alarm treatment

Alarm treatment for nocturnal enuresis is also a type of cognitive behavioural therapy. It works by positive reinforcement, as well as aversive, negative experiences and has been shown to be highly effective and was introduced by Mowrer and Mowrer (88).

It is the most effective form of treatment of nocturnal enuresis with the best long-term results (grade I level of evidence according to reviews and meta-analyses). Houts et al. (89) compiled a systematic review and meta-analysis on 78 randomised studies on nocturnal enuresis. 62% were dry at the end of treatment and 47% at follow-up. The authors conclude that “urine alarm treatments should not only be considered the treatment of choice, but the evidence from this review suggests that cure rather than management is a realistic goal for the majority of children suffering from nocturnal enuresis”. Therefore, when indicated, alarm has been endorsed as a first line curative treatment by various guidelines and by the ICCS (90).

The effect of alarm treatment can be enhanced by adding additional behavioural components to the treatment. Programmes that include alarm in addition to other behavioural components showed following general effects: 72% of children became dry at the end of treatment, and 56% remained so at follow-up (meta-analysis) (89).

These specific programmes including alarm are all essentially cognitive-behavioural techniques. Arousal training is a simply and easily performed (91,92). Children are instructed to turn off the alarm within three minutes, go to the toilet and reset the alarm. This goal is reinforced positively with two tokens. If the goal is not reached, one token has to be returned. The initial success rate (89 %) and the rate of dryness after 2 ½ years (92 %) were higher than with alarm treatment alone (73 % and 72 % respectively).

Finally, alarm treatment can be combined with pharmacotherapy, although the evidence for combination treatment is conflicting. The combination of desmopressin and alarm treatment has been reported in several studies (92,93). The combination with anticholinergics plays an important part in clinical practice, but has not been investigated systematically. However, when alarm treatment fails, the ICCS recommends switching to desmopressin alone (90).

6.5. Conclusion and summary

This review summarised the most important psychological aspects in children with enuresis, urinary incontinence and faecal incontinence.

The rate of comorbid clinical behavioural disorders is increased. Children with DUI are more affected than those with NE. Children with secondary and non-monosymptomatic NE have especially high rates of comorbid psychological disorders. The most common single diagnosis is ADHD, but other disorders such as depression, anxiety disorders and autism spectrum disorders can exist and must be considered.

Children with DUI have mainly externalising behavioural disorders. Children with urgency incontinence have a low comorbidity, those with voiding postponement are characterised by oppositional behaviour. Children with FI have the highest rate of associated disorders – both internalising and externalising.

These disorders will not disappear upon attaining dryness. They must be addressed, as they will interfere with the incontinence therapy due to low compliance. Even if comorbid disorders are not present, children and parents are highly stressed by the incontinence. These subclinical symptoms will often recede upon successful treatment. Children with special needs, especially those with ID, have very high rates of incontinence. Assessment and treatment of incontinence should be offered to all affected children.

Questionnaires are useful as screening instruments in the assessment process. It is recommended that questionnaires are used as a general screening procedure for emotional and behavioural problems routinely in all settings. If a psychological disorder is suspected, a full child psychiatric assessment and subsequent treatment is needed. The basic principles, including those of psychotherapy, are outlined. Psychotherapeutic techniques are used in urotherapy, especially cognitive-behavioural elements. Non-pharmacological and non-surgical techniques are most effec-

tive for most forms of incontinence. Therefore, it is important that psychological aspects are integrated into the treatment of children with incontinence problems.

VIII. URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

1. INTRODUCTION

Children with special needs, i.e. intellectually and / or motor disabled, suffer lower urinary tract symptoms (LUTS) than the normal population. Several studies have shown that nocturnal enuresis, daytime urinary incontinence and faecal incontinence are more frequent in children with special needs. Moreover, incontinence has a higher likelihood to persist during adolescence and adulthood. Although LUTS are associated with poor quality of life and health status, they are often less important to parents and physicians who are mainly focusing on physical rehabilitation. Literature on this topic is limited, but illustrates that adequate treatment improves quality of life significantly.

2. CHILDREN WITH SPECIAL NEEDS: GENERAL INFORMATION

2.1. Intellectual disability

Intellectual disability, the former mental retardation, is defined by the American Association on Mental Retardation (AAMR) as a disability characterised by significant limitations both in intellectual functioning and in adaptive behaviour as expressed in conceptual, social and practical adaptive skills. The disability originates before 18 years of age. Limitations in intellectual ability correspond to an IQ less than 70 to 75.

According to DSM -V (Diagnostic and Statistical Manual of Mental Disorders 5th edition. American Psychiatric Association (2013) Washington, DC) intellectual disability involves impairments of general mental abilities that impact adaptive functioning in three domains, or areas. These domains determine how well an individual copes with everyday tasks:

- The conceptual domain includes skills in language, reading, writing, math, reasoning, knowledge, and memory.
- The social domain refers to empathy, social judgement, interpersonal communication skills, the ability to make and retain friendships, and similar capacities.
- The practical domain centres on self-management in areas such as personal care, job responsibilities, money management, recreation, and organizing school and work tasks.

In DSM-V intellectual disability is two standard deviations or more below the population mean, which equals an IQ score of 70.

Severity was defined in the DSM-IV (Diagnostic and Statistical Manual of Mental Disorders 4th edition. American Psychiatric Association (2000) Washington, DC) based on IQ ranges:

- Mild: 50-55 to 70
- Moderate: 35-40 to 50-55
- Severe: 20-25 to 35-40
- Profound: < 20-25

2.2. Motor disability:

Motor disabilities affect a person's ability to learn motor tasks such as walking, running, skipping, sitting, handwriting and others. To be considered a disability, the problem must cause a person to have motor coordination that is significantly below what would be expected for age, and the problem must interfere with activities of learning and daily living.

Although Intellectual disabilities and motor disabilities can stand on their own, in a considerable number of patients, a combination of both is diagnosed.

Intellectual disability is a common problem. Up to 10% of the school-aged children are learning impaired and as many as 3% of children in the US manifest some degree of mental retardation. The prevalence of mild mental retardation is about 1/77 (1.2%) and that of severe mental retardation is 1/300 (0.33%). For the clear majority of individuals with mental retardation (45-63%) no aetiology is identifiable. More than 800 syndromes are associated with mental retardation, of which Trisomy 21 or Down syndrome is the best known. In addition, environmental factors, such as Foetal Alcohol Syndrome and peri- and postnatal conditions, such as CMV, rubella and hypo-ischemic encephalopathy, may also be responsible for mental retardation.

The second most important cause of developmental disability is cerebral palsy (CP). Cerebral palsy encompasses a group of disorders of the development of movement and posture, causing activity limitation, which are attributed to non-progressive disturbances occurring in the developing fetal or infant brain. [1] Often disturbances of sensation, cognition, communication, perception and/or behaviour, and/or seizure disorders accompany the motor disorders. CP is a non-progressive injury of the brain occurring in the perinatal period and persisting through the lifespan.

The incidence of cerebral palsy is about 1.5 per 1000 births.

Twenty percent of the intellectually disabled individuals suffer cerebral palsy and 50% of the cerebral palsy patients are intellectually disabled.

3. LOWER URINARY TRACT SYMPTOMS IN CHILDREN WITH SPECIAL NEEDS: PREVALENCE

Von Wendt *et al.* published that 7-year-old children with mild intellectual disability differ relatively little from healthy children with respect to enuresis, (11.1% versus 9.8%), but suffered significantly more daytime urinary incontinence (16.7%) than the normal population (3.4%). The more severe the intellectual disability the higher the risk of persisting enuresis and daytime urinary incontinence. [2]

In children with CP 55.5% suffer LUTS, of which urinary incontinence is the most frequent with a prevalence rate ranging between 20% and 94%. Urgency and frequency, with a respective prevalence of 38.5% and 22.5%, are also very common in CP patients. Urinary incontinence, urgency and frequency are significantly more common in children with CP compared to a healthy population.

Storage symptoms are more prevalent than voiding symptoms, with a prevalence of hesitancy in children with CP of 16.5%. Urinary tract infections (UTI), with a prevalence rate of 8.5%, are also more common in CP children than in the normal population. [3]

Patients with Down's syndrome also show an impaired ability to become continent. Several studies have illustrated that children with Down's syndrome have a delay in toilet training and are more prone to incontinence afterward. One fifth of the children with Down's syndrome are not toilet trained at the age of five and nearly 50% of the toilet trained children will have incontinence, that even can persist into adulthood. [4]

LUTS are also more common in children with Down's syndrome, with a prevalence around 27%. The LUTS are more common in male (42.8%) than in female (19.6%) patients. These LUTS decrease with age, and patients with Down's syndrome older than 10 years have a five times lower chance of LUTS compared to those who are ten years or younger. [5] Kitamura *et al.* found LUTS to be very common in children with Down's syndrome, but remarkably neither the children nor their environment seemed to be aware of it. [6]

Von Gontard reviewed the association of nocturnal enuresis, daytime urinary incontinence and faecal incontinence in children with intellectual disability in general and in patients with specific syndromes of intellectual disability including Rett's, Angelman's, Fragile-X, Prader Willi, Noonan's and Williams' syndrome. He concluded that people with profound intellectual disability have the highest rate of incontinence, whereas syndromes with mild intellectual disability have much lower rates. [7-12]

Not only intellectual capacity, but also the motor capacity is correlated with the development of continence. The more immobile the higher the prevalence of urinary incontinence. Motor disability, especially the degree of mobility, rather than intellectual disability seems to be the dominant factor determining urinary continence. [13]

4. PATHOPHYSIOLOGY OF LUTS IN CHILDREN WITH SPECIAL NEEDS

a) Urodynamic findings

Samijn *et al.* found in their review on LUTS and Urodynamic Findings in CP patients that 84.5% had an abnormal videourodynamic study. Neurogenic detrusor overactivity (NDO) is the most common urodynamic abnormality, with an average prevalence rate of 59% [3]. The finding of NDO on urodynamics is not synonymous for the prevalence of LUTS. Several authors found pathological urodynamic findings in both symptomatic and non-symptomatic children with CP and *vice versa* [14-17]. Therefore some authors stress on the need for urodynamic examination in this population to discover silent bladder dysfunction or risk factors for upper urinary tract dysfunction (UUTD).

Abnormal uroflow patterns, especially staccato pattern, were found in 36.5% to 66% of CP patients [13, 18, 19]. Van Laecke *et al.* could not establish a correlation between uroflow pattern and urinary incontinence, whereas Silva et al. reported a significant correlation between abnormal uroflow patterns and the presence of LUTS [13, 18].

The average prevalence rate of detrusor sphincter dyssynergia (DSD) is 11% [3].

Comparing urodynamic studies with uroflowmetry showed more pathological findings on urodynamics than on uroflow, which can be explained by the fact that uroflowmetry only measures the voiding phase.

The high prevalence of NDO can be explained by the fact that CP is caused by a cerebral insult, with lesions in the suprapontine circuitry, disturbing the inhibitory control over the pontine micturition centre [20]. Overactivity of the pelvic floor and the urethral sphincter is not expected in patients with a cerebral lesion, and may suggest a lesion of the lumbosacral cord. Severe hypoxia might be the cause of this in CP patients [20-22].

In children with CP, hesitancy is more prevalent than DSD, which may indicate that other factors than DSD contribute to overactivity of the pelvic floor. Mayo *et al.* suggested that hypertonia is the cause of the inability to relax the pelvic floor muscles during micturition, resulting in an increased rate of hesitancy [23]. One might conclude that children with spasticity may suffer pelvic floor overactivity as a voluntary reaction to an overactive bladder.

Kitamura *et al.* found in their study that a significant lower number of children with Down's syndrome had a normal bell-shaped uroflow pattern (18%) than age-matched control children (60%). They concluded that the non-bell-shaped uroflow patterns are due to functional and not to anatomical or organic abnormalities [6].

b) Bladder capacity:

Reduced bladder capacity is a major factor in the pathophysiology of urinary incontinence in children with special needs. Several studies illustrated that 73.5% of the CP subjects have a too small bladder capacity compared to the expected bladder capacity for age (EBC). Mean bladder capacity is 58.5% of the EBC [3]. Bladder capacity can be negatively influenced by uninhibited bladder contractions, characteristic for NDO, inadequate fluid intake due to swallowing problems and inadequate hydration [13, 24-27]. Constipation, which can be due to restricted fluid intake, can negatively influence reduced bladder capacity [28].

c) Inadequate fluid intake

Van Laecke *et al.* found that only 9.9% of the children with a special need included in their study had a normal fluid intake. Although some of these children suffer swallowing problems, the major problem was found to be inadequate drinking. Increasing the fluid intake to a normal level of 1500ml/m² resulted in a significant increase in continence and maximum voided volume [13, 27].

d) Post-void residual

In CP patients, according to the low prevalence of DSD and hesitancy, prevalence of pathologically increased post-void residual is limited [14, 18, 19, 29, 30]. In Down's syndrome patients post-void residual was demonstrated in 7% [6].

e) Intellectual disability and motor dysfunction.

LUTS are less influenced by intellectual disability than by moderate to severe motor dysfunction [13, 31, 32]. Concerning children with CP, continence is less often achieved in subjects with low intellectual capacity combined with spastic quadriplegia than in subjects with high intellectual capacity combined with hemi- or diplegia [33]. The combination of both intellectual disability and spasticity has a bigger influence than both factors independently. Bross *et al*. concluded that urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment [14].

Involuntary spasticity of the pelvic floor, which may be part of a general spasticity, may cause LUT dysfunction [25, 28]. This can also explain the vulnerability to acquire pelvic floor hyperactivity in reaction to NDO in children with spasticity [14, 23].

In subjects with quadriplegia LUTS and abnormal urodynamic findings are found more often than in patients with diplegia, illustrating that not only lower limb impairment, but also upper limb impairment plays a role in achieving continence [33]. The plasticity of the central nervous system enables the unaffected side to assume more control over the bladder during development. This could explain the lower prevalence of LUTS and disturbed urodynamic findings in children with hemiplegia [32].

Poor mobility is an important factor in achieving continence. Inability to reach the toilet, to get adequate on the toilet and to drink enough will influence both urinary incontinence and constipation. Moderate to severe functional impairment (GMFCS III or higher) and the spastic subtype with quadriplegic distribution will negatively influence the ability to become continent [3].

5. COMORBIDITY

a) Constipation and faecal incontinence

Constipation is an important comorbidity in the process of urinary incontinence in children with special needs. There is a proven correlation between constipation and urinary incontinence, detrusor overactivity, dysfunctional voiding and UTI [34]. Intellectual disabled children are more prone to constipation and faecal incontinence. Up to 70% of these children suffer constipation [35]. Up to 90% of the children with CP suffer constipation and 47% faecal incontinence, though most of them to a minor degree [36].

b) Neuropsychiatric disorders

ADHD and autism are more frequent in intellectually disabled children and there is a proven correlation between ADHD and urinary incontinence [37, 38].

c) Sleep disorders

There is increasingly more evidence that there is a relationship between nocturnal enuresis and sleep disorders in otherwise healthy children [39-41]. Sleep is a complex neurological function. In children with brain damage, the autonomous nervous system, which is involved in pineal melatonin secretion and sleep regulation might be affected [42]. Sleep is also vulnerable to several other factors common in CP. Muscle spasms, decreased ability to change body position during sleep, epilepsy and glossoptosis, which can induce sleep disorder breathing, may be the cause of disturbed sleep in these children [43, 44]. Sleep disorders like delayed insomnia, disrupted sleep, early awake or a combination of these are frequently reported in patients with CP. Newman *et al.* found that 44% of the patients presented at least one clinically significant sleep disorder. Nearly 50% of the children with CP have some kind of sleep problem. These problems are more reported in non-walkers (72%) than in walkers (36%) [45]. Also in patients with Down's syndrome sleep disturbances are more common [4].

6. EVALUATION OF THE SPECIAL NEED CHILD SUFFERING LUTS

a) History

History taking in children with special needs is often challenging, and mainly relies on hetero-anamnestic data. Important is that not only parental information but also information from the care givers should be considered, as many of these patients spend a lot of their time in specialised institutions. The questions should include items on nocturnal enuresis, urinary incontinence, lower urinary tract symptoms and bowel function. Attention should also be paid to intellectual and motor development, family disorders, the child's psychosocial and familial situation, neurological and congenital anomalies, urinary tract infections, relevant medication and surgery. Special emphasis should be given to fluid intake and food habits

A voiding and drinking diary, and a dry-wet calendar are essential to determine the child's voiding frequency and voided volumes, to evaluate the number of enuresis and incontinence episodes, to determine the nocturnal diuresis and to evaluate the quantity and quality of fluid intake. The same should be done for stool, registering defaecation frequency, stool consistency and soiling.

b) Physical examination

Theoretically, physical examination should include the assessment of perineal sensation, the perineal reflexes supplied by the sacral segments S1-S4 and anal sphincter tone and control. Practically, as this is confronting for the child, this part of the physical examination is restricted to those where there is a suspiscion of neuropathy.

Special attention should be paid to signs of neuropathy such as: spine deformity, abnormal gait, abnormal deep tendon reflexes, asymmetrical atrophy of the feet, high plantar arches, hammer toes, and signs of occult dysraphism, i.e. skin discolouration, dimples, hairy tufts, subcutaneous lipoma, asymmetrical buttock, legs or feet and oblique gluteal cleft [46]. The abdomen should be palpated to asses a full bladder, full sigmoid or descending colon and flank masses. The external genital region must be inspected for vaginitis and vulvitis, meatal web and a hymen that covers nearly the complete vaginal introitus in girls and for penile anomalies and meatal stenosis in boys. In motor disabled children the locomotor system has to be evaluated according to muscle power, mobility, stability and spasticity In intellectual disabled children the IQ and the functional autonomy has to be estimated.

c) Laboratory tests

Urine analysis to exclude pyuria, proteinuria, glycosuria, haematuria, calciuria and bacteriuria should be done at the first office visit. Urine osmolality and electrolytes should be determined in case of monosymptomatic enuresis with persistent therapy resistant polyuria.

d) Uroflowmetry

Uroflowmetry in children with special needs is often a problem. Intellectual disabled children are often too anxious to perform a uroflowmetry and motor disabled children are often incapable to perform a non-disturbed micturition because of their instable position on the flow chair. Therefor uroflowmetry, especially in moderate and severe patients, should be preferably performed in their own environment on their personal adapted toilet chair.

e) Ultrasound

Ultrasound is used to evaluate the upper and lower urinary tract in children with LUTS especially when they are suffering UTI. It can also be used to measure the post-void residual.

f) (Video-) Urodynamic examination

These urodynamic investigations are invasive, especially in children with special needs who often lack the intellectual capacity to understand what is going to happen, or are physically unable to undergo the examination in a comfortable way. Although some authors are convinced that urodynamics should be performed in the majority of moderate and severe patients to rule out the silent bladder dysfunction or risk factors for UUTD, this examination should be reserved for those patients suffering therapy resistant urinary incontinence and/or recurrent UTI or when obstructive lower urinary tract problems are suspected.

7. TREATMENT OF URINARY INCONTINENCE IN CHILDREN WITH SPECIAL NEEDS

a) Urotherapy

Urotherapy in children with special needs does not differ fundamentally from that used in normally developing children. The aim is also to achieve normalisation of the micturition pattern by a combination of patient education and cognitive, behavioural and physical therapy methods.

The first cornerstone of this therapy is patience. Treating these children will certainly take more efforts and time, but even in severe patients it may lead to an important amelioration or cure of urinary incontinence.

The second is adequate fluid intake. Although often time-consuming, the results are remarkably positive as illustrated in the study of Van Laecke *et al.* [27], Fluid intake does not only positively influence maximum voided volume and continence, but also contributes to an important amelioration of constipation.

The third cornerstone of urotherapy is correct toilet position. Adequate relaxation of the pelvic floor can only be achieved when sitting in a stable position. In many children with CP this can only be the case when using a personal adapted toilet chair.

b) Treatment of Bowel Dysfunction

Constipation and faecal incontinence are common comorbidities in children with special needs. LUT dysfunction and bowel dysfunction often occur concomitant and have been labeled as BBD (Bladder and Bowel Disturbance) by the ICCS [47]. Adequate management of both constipation and faecal incontinence is essential for successful treatment of urinary incontinence in these patients.

Prevention and treatment of milder forms exist of optimisation of food and fluid intake (qualitative and quantitative) and of toilet habits (regular toileting after meals). In case of functional constipation stool masses need to be evacuated with laxatives or enemas. Afterwards laxatives should be continued together with behavioural therapy and dietary interventions for months or even years [48].

c) Alarm treatment

Just like in normally developing children, alarm therapy can be used to treat either nocturnal enuresis or daytime urinary incontinence in children with special needs [49-51]. In the treatment of daytime incontinence, it can be used to achieve active continence, but in some therapy resistant cases it can also be used to achieve passive continence by introducing timed voiding [52]. Again one should be aware of the fact that using an alarm in this population will be more challenging and time consuming.

8. PHARMACOLOGICAL TREATMENT

a) Antimuscarinics

If standard urotherapy fails to achieve urinary continence antimuscarinics are the mainstay of treatment in patients with overactive bladder (OAB). Oxybutynin remains the only FDA approved antimuscarinic for the treatment in children. The major problem with oxybutynin are the side effects; dry mouth, constipation, blurred vision, psychologic and personality changes are common side effects, causing up to 10% of the children to stop their treatment [53]. Especially in children with special needs these side effects are more problematic as tooth decay, constipation, mood disturbances and intellectual delay, which are already relatively common in this population, can get even worse. Therefore, newer, more bladder specific antimuscarinics, only approved for adults, like solifenacin and tolterodine are used off-label in these patients. Propiverine, which is suggested to be better tolerated than oxybutynin, has been approved in some countries for the use in children [54]. When using antimuscarinics strict follow-up, with special attention for side effects and post void residual is necessary.

b) Desmopressin

In case of monosymptomatic enuresis with proven nocturnal polyuria, as in normally developing children, desmopressin is the first line treatment [55]. This treatment should be used with care as excessive fluid intake shortly before or quickly after administration of desmopressin can cause a life threatening water intoxication with hyponatraemia and convulsions.

c) Botulinum toxin

Botulinum toxin has been used off-label successfully for the treatment of children with neuropathic bladder and non-neurogenic bladder dysfunction [50, 56-58]. In accordance with treatment in normally developing children, also in children with special needs it can only be considered in patients suffering OAB or urinary incontinence in whom other treatment options have failed.

9. SURGERY

Children with Down's syndrome have a significantly increased risk of anterior urethral obstruction and posterior urethral valves [59]. In Down's syndrome children, where there is suspicion of obstruction of the LUT, cystoscopy under general anaesthesia with possible incision of the obstructive element should be performed. In those patients with a neuropathic bladder, refractory to conventional therapy, bladderaugmentation, i.e. ileocystoplasty with or without continent catheterisable stoma (Appendicovesicostomy, Monty) can offer the final, non-reversible, solution to achieve continence and to protect the upper urinary tract.

10. CLEAN INTERMITTENT CATHETERISATION (CIC)

Some children do need intermittent catheterisation, especially those undergoing a bladder augmentation. Children with cerebral palsy treated with continuous Baclofen can also suffer urinary retention needing intermittent catheterisation. The problem with some of these children with special needs is that they have a normal genital sensation that makes catheterisation uncomfortable, or even painful. Combined with the reduced intellectual capacities of some this makes CIC nearly impossible. Therefore, incontinent stoma is sometimes the only solution.

11. CONCLUSION

Although often thought to be a minor problem urinary incontinence remains an important issue for every special needs child. Urinary incontinence can lead to limited self-esteem and independence, and may be

challenging health. Often it is a multifactorial problem, but with adequate therapy these children are amenable to continence rehabilitation. The majority can become continent, but some will only achieve a passive form of continence.

I. INTRODUCTION

This chapter deals with neurologic urinary and faecal incontinence; it draws on previous ICI reports, and complements information in other ICI chapters. In developing the content, literature searches were undertaken with the keywords; "neurologic", neurogenic", "bladder", "bowel", "lower urinary tract", "anorectal", "incontinence ", "continence", "urinary", "faecal", "paralysis", "dysfunction", "retention", "constipation". Searches for specific neurologic diseases (section E) were undertaken, looking into selected neurological diseases of particular relevance to neurourology, comprising the more prevalent or more challenging in terms of incontinence diagnosis and treatment.

Continence relates to reservoir functions of the bladder and rectum, and closure of their respective outlets by contraction of smooth muscle (bladder neck and internal bowel sphincter) and striated muscle urethral and anal sphincters. Expulsion requires relaxation of these latter structures, and contraction of the musculature of the respective reservoirs, to permit a physiological reflex evacuation of urine or faeces.

The lower urinary tract (LUT) and the lower bowel tract (LBT) are interrelated structures. Embryologically, bladder and rectum originate from the same basic structure, the cloaca [1]. Anatomically both viscera lie in close proximity to each other, and to the muscular structures of the pelvic floor. Both are innervated by autonomic and somatic nerves (**table 1**), and have similar principles of central control [2, 3]. The LBT differs from the bladder in having an enteric nervous system [4]. Interactions between the two organ systems are increasingly recognised, and their activity is co-ordinated. Voiding can occur without defecation [5], and the initiation of micturition often precedes that of defecation, even if both organs are considered equally full [6]. The filling status of the bladder influences sensation in the rectum and vice versa [7], and the potential for mutual influence in pathology is emerging [8]. Nonetheless, little information is available on co-ordination of both functions in patients with neurological pathology.

Table 1: Overview of function of the abdominal sympathetic, the pelvic parasympathetic and somatic nerves in the LUT and LBT.

	Sympathetic T10-L1	**Parasympathetic S2-4**	**Somatic S3-5**
Bladder	-	+	
Bladder neck	+	-	
External urethral sphincter	exp	exp	+
Bowel		+	
Internal anal sphincter	+	-	
External anal sphincter	exp	exp	+
Pelvic floor			+

Exp= only suggested in animal experiments, no definite clinical evidence.

1. THE EVIDENCE BASE

Neurogenic lower urinary tract dysfunction (NLUTD) is a term that applies to an extraordinarily diverse spectrum of clinical conditions. This heterogeneity can be appreciated by considering the different challenges faced by the infant born with myelomeningocoele and the elderly patient with dementia-associated incontinence. Some order can be imposed by grouping conditions based on their cause and site of impact on the neuraxis (see table 2) [9].

Historical data demonstrates that the management of NLUTD has made huge advances over the last century, largely based on a trial and error approach and the dissemination of expert opinion [10]. Improved outcomes for patients were the result of the development of a urodynamic-based understanding of pathophysiology, the introduction of effective treatments to allow safe and reliable urine storage and intermittent catheterisation, the advent of more effective antibiotics and the development of better catheters and appliances. However, the historical approach is accompanied by significant problems. Dangerous or ineffective treatments can be trialled out-with an appropriate ethical framework and successful therapies can be slow to be introduced because their proponents may not convince their peers of the merits of the new treatment.

Table 2: categorisation of neurological lesions according to time of onset, clinical course and CNS loca-tion, with example conditions.

	Congenital and perinatal lesions	**Acquired, stable conditions**	**Acquired, progressive conditions**
Brain and brainstem	Cerebral palsy	Stroke, Head injury	Multiple sclerosis,* Parkinson's disease, Dementia, Multiple System Atrophy*
Suprasacral spinal cord	Hereditary spastic paraparesis, Spinal dysraphism*	Trauma	Multiple sclerosis*, Spondylosis with myelopathy
Sacral spinal cord	Spinal dysraphism, Sacral agenesis, Ano-rectal anomaly	Conus injury	Tumour
Subsacral	Spinal dysraphism, Familial dysautonomia	Cauda equina injury, Pelvic nerve injury	Tumour, Peripheral neuropathy (e.g. diabetic)

****Conditions that can arise in more than one region of the CNS.***

There is an inherent risk when an area of clinical practice has not been accompanied by a culture of high quality scientific research, and where the data which is available is used uncritically. For example, there has long been concern that management of NLUTD by indwelling catheter drainage results in excessive

morbidity and, at first glance, published data on complication rates between different bladder management systems would appear to confirm that catheters are damaging to upper urinary tract function. However, this is based on cross-sectional data; such studies do not effectively take into account the preceding bladder management methods, the inability to randomise to different management approaches, and that catheters are typically used as a last resort in patients who have already developed problems with their urinary tracts [11]. Prospective longitudinal evaluation accounting for antecedent bladder management actually indicates that indwelling catheterisation is protective for the upper urinary tract [12].

The extensive evidence base concerning NLUTD is clearly demonstrated by the content of this chapter, but much of the evidence is contained in reports of studies which fail to meet contemporary standards for high quality evidence. How then should the clinical community respond to the challenge of improving the scientific foundations of our care for patients with NLUTD?

There are many aspects of modern management of NLUTD which will never be tested in definitive clinical trials because they appear to be of self-evident value. As a result, no trial could be conducted because the hypothesis that was to be tested would lack equipoise. For example, it would be impossible to conduct a trial that randomised spinal cord-injured patients between urodynamic-led and clinical-led treatment planning. However, that does not preclude the need to question these standard approaches. For example, such a study could be conducted in the context of multiple sclerosis where different approaches have been advocated [13, 14].

Despite the difficulties of conducting high quality trials in the field of NLUTD, there are an increasing number of studies that demonstrate the feasibility of such studies. Large, industry-sponsored studies have been conducted and are capable of providing near-definitive data on important clinical questions [15, 16]. However, even where high-quality data exists for some patient groups, there may be little or no data for others; spinal cord-injured and multiple sclerosis patients have been shown to respond to intra-detrusor injections of botulinum neurotoxin A but there is a dearth of data on patients with neurogenic detrusor overactivity (DO) due to intracranial conditions. Extrapolation from one condition to another is inevitably going to be needed but would be aided by even small, well-conceived trials that looked at patients with less common conditions.

There are a large number of interventions that have only been assessed by low quality methodologies, typically uncontrolled case-series. In some cases, such as that of the artificial urinary sphincter, there is sufficient data on which to base an evaluation, whereas other procedures still await a more complete assessment; the majority of alternative operations used to treat neurogenic stress incontinence fall in this category.

Finally, there is the question of how to evaluate new investigative and treatment techniques. Drug therapies are tightly controlled by regulatory authorities but it is common for drugs to be extensively investigated in the non-neurogenic population but not in patients with NLUTD. It is to be hoped that tighter regulation and the demonstration that NLUTD trials are feasible will encourage drug evaluation in this patient group. For devices and surgical procedures, regulation is less tight and it is therefore for the clinical body to resist the premature introduction of techniques that lack an appropriate evidence base. There is a need for multi-centre cooperation in clinical trials that are designed to look, not only at short-term clinical efficacy, but also at long term results, complications and cost-effectiveness of new interventions.

II. PATHOPHYSIOLOGY

With a neurologic lesion the type of dysfunction that follows in LUT (and LBT) will depend on the site, the extent and the evolution of the deficit. Traditionally neuro-urological pathology has been divided into the upper motor neuron lesions (UMNL), comprising suprapontine (cerebral) and suprasacral (brainstem, and spinal cord); and lower motor neuron lesions (LMNL), comprising sacral and subsacral (cauda equina and peripheral nerve). Brainstem lesions are rarely compatible with more than short-term survival, so they are only infrequently encountered in neuro-urological practice.

Very recently Powell proposed a new step in classification of the neurogenic bladder: SALE (Stratify by Anatomic Location and Etiology). The classification is based on seven categories, each having a neurologic defect in a distinct anatomic location. In addition, the presence or absence of bowel dysfunction and autonomic dysreflexia is reported. In the future, as more definite prognostic information can be gleaned from biomarkers, urinary nerve growth factor (NGF) and urinary brain-derived neurotrophic factor (BDNF) levels can be added to the classification. The SALE system should efficiently describe a patient suffering from NGB and simultaneously inform the most appropriate treatment, follow-up regimen, and long-term prognosis. [1]

1. SUPRAPONTINE LESIONS

In suprapontine lesions a neurologic LUTD may be a direct consequence of the neurologic lesion, but may also be due to or changed by other conditions: e.g. motor and cognitive dysfunctions may lead to “functional” incontinence.

There is growing knowledge about how cerebral suprapontine regions are related to the LUT function. The location and extent of a suprapontine lesion will

determine the resulting symptoms and if they are reversible or not. While historically a close clinical observation, post-mortem or surgical evaluation were the main link between LUTD and brain lesions, the modern functional neuroimaging has illustrated such interaction better and has permitted to highlight smaller lesions. [2]

The current model of central LUT control consists of a network of interconnected brain regions involved in the switch between storage and voiding. A recent overview accepts functional roles of the supplementary motor area, dorsal anterior cingulate cortex, lateral prefrontal cortex, thalamus, insula. [3] It is important that there is laterality of cerebral control networks, which can influence the dysfunction in unilateral pathology. Speculations have been made regarding the role of neural circuits but, what is still lacking is a full understanding of connectivity of cerebral control networks.

The cerebral control of the urethral sphincter will depend on voluntary and involuntary control by different parts of the brain. [4]

Supra-Pontine neurologic lesions differ from other neurologic insults because they lead to loss of tonic inhibition of the pontine micturition center (PMC). This can lead to spontaneous involuntary DO, which is different from DO that occurs after supra-sacral SCI. The supra-pontine lesions are overall characterized by storage dysfunction. Normal uroflow and normal post voiding residual (PVR) can often be expected. In some cases detrusor underactivity (DU) has been reported, as well as DO with impaired contraction (DOIC). So it is important to acknowledge that DO is not the only finding in supra-pontine injury. [5] Moreover there may be loss of one or more of the cerebral activities, such as volitional control over timing of emptying, inhibition of bladder, conscious filling and emptying sensations and some integration functions with other organ systems and activities of daily life. One should not overlook the importance of the loss of mobility and of initiative /cognition. This is not seldom the case in such brain lesions as stroke or head injury, which mostly continue to have a synergic LUT function. In many cases there will be OAB syndrome, the patients may purposely increase sphincter activity during an overactive detrusor contraction to prevent urinary incontinence which would otherwise occur. [6] This has been termed “pseudo-dyssynergia” because it is difficult to distinguish from true detrusor sphincter dyssynergia (DSD) on an urodynamic record.

New knowledge is developing. The CNS, once considered to be an immune-privileged area may instead be an active surveillance site, with bi-directional communication with the immune system. This finding has led to a significant interest in neuroimmunological interactions and investigation into the role of the immune system in the pathology of various neurological disorders. The proposal has been made that the relationship between peripheral immune cells, the brain, and the urologic system should be considered as an additional possible mechanism in urologic diseases, and that immunotherapy might be an alternative therapeutic strategy in treating neurogenic bladder dysfunction. [7] [8]

A growing body of evidence suggests that 5-hydroxytryptamine (5-HT; serotonin) has both physiological and pathological functions in the LUT. In the central pathways controlling the micturition reflex, 5-HT1A, 5-HT2A, and 5-HT7 are involved in regulation of bladder and urethral sphincter activities. Their functions, especially that of 5-HT1A, vary in a species- and site (spinal or supraspinal)- dependent manner. [9]

A similar relationship between the bladder and mitochondrial function in the regulation of cellular energetics and metabolism was described as in heart failure. Though there are currently no pharmacologic agents that directly affect mitochondrial biogenesis in organ failure, current advances in the development of therapy including mitochondrial biogenesis, mitochondrial oxidative stress and mitochondrial pore transition proteins might become important in the future. [10]

2. PONTINE LESIONS

The dorsal pontine tegmentum has been established as the seat of the micturition centre. Lesions at that level are rare, but may lead to DO and DSD. This can occur in multiple system atrophy (MSA; formerly known as Shy-Drager syndrome). In view of the crucial role of the pons in key homeostatic and physiological functions, only a limited extent of pontine dysfunction is compatible with life.

3. SUPRASACRAL SPINAL CORD LESIONS

3.1. Complete suprasacral lesions

A lesion resulting in a completely transected spinal cord which occurs above the level of the conus medularis (L1/L2), leads to a cranial cord segment and a caudal cord segment which cease to communicate (Fig 1). The caudal segment therefore becomes autonomous and is known as the **distal autonomous cord**. This leads to an upper motor neurone picture in the affected limbs with hypertonicity, spasticity, absent sensation and hyperreflexia. Occasionally, a lesion above the conus medularis may extend into the lumbar and sacral segments of the conus and lead to lower motor neurone effects in the affected limbs. The

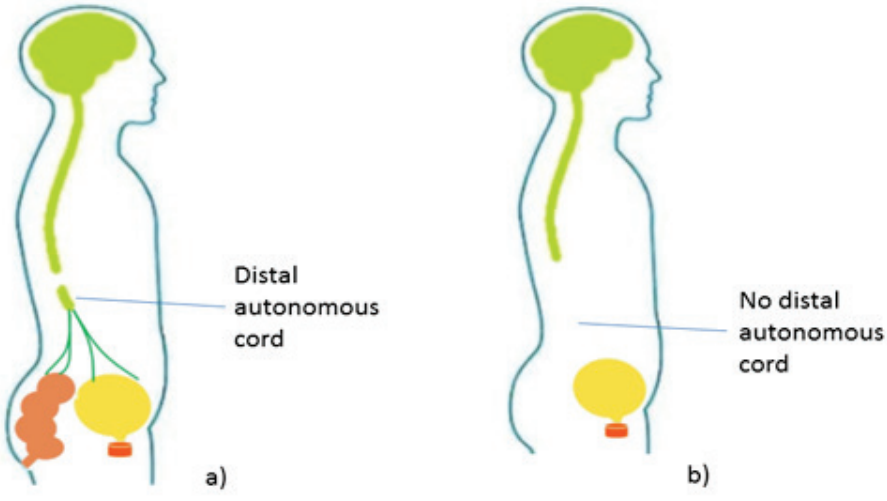

Figure 1: Diagrammatic representation of complete spinal cord injury with a) distal autonomous cord present leads to spasiticity, hypertonicity and hyperreflexia in limbs and reflex activity and DSD for the bladder and sphincter respectively, b) No distal autonomous cord/ sacral lesion leads to flaccidity and areflexlia in limbs and an areflexic bladder with a flaccid sphincter.

resulting LUT dysfunction in this case will follow a sacral pattern rather than a suprasacral pattern. Therefore it is not just the level of injury which is important but the extent of injury and whether it leads to a distal autonomous cord (Fig 1).

With complete suprasacral injury, micturition, which was once controlled by the pontine micturition centre becomes essentially an unmodulated spinal reflex. Previously quiescent, C fibre afferents become activated and the patient develops a **reflex bladder**. As the bladder fills and pressure rises it contracts automatically leading to involuntary urination, seen as neurogenic detrusor overactivity on an urodynamic study. The guarding reflex (which contracts the urethral sphincter on urine entering the bladder neck) is no longer synchronised with voiding (as this is co-ordinated by the pons). This leads to detrusor sphincter dyssynergia (DSD) i.e. concomitant contraction of the urethral sphincter during bladder contraction. [11]

Incontinence is caused by detrusor overactivity when the bladder pressure overcomes the sphincteric resistance or when the sphincter fatigues. The bladder also may not empty to completion as it is reliant on the neurogenic detrusor overactivity (reflex contractions) to empty and is impeded by the DSD.

Another feature of the distal autonomous cord is **autonomic dysreflexia**. This can be potentially life threatening. This occurs due to a painful stimulus occurring in the distal autonomous cord which is above T6. The effect is vasoconstriction, piloerection and sweating in the region supplied by the distal autonomous cord. This leads to the dumping of blood from the areas supplied by this region into the circulation of the regions above the spinal lesion resulting in significant hypertension. The body's response is to precipitate a reflex bradycardia and vasodilatation which can only occur in the areas under suprapontine control i.e. those above the lesion. [12] This results in the visibly characteristic vasoconstriction in the skin below the level of SCI and vasodilation above.

A complete suprasacral cord injury results in a reflex bladder with DSD. The important aspects worth considering are that: [1] bladder contraction involves different afferent fibres (experiments in cats indicate that the relevant afferents are the C-fibres) [13] [2] bladder contractions are poorly sustained, [3] the urethra and bladder become dyssynergic, and [4] previously irrelevant stimuli influence the bladder and/or external sphincter activity. Also voluntary inhibition of the micturition reflex is lost, though some consciousness of bladder sensation may still be present.

Of 489 patients assessed by Kaplan et al. it was shown that all those with suprasacral cord lesions without sacral cord signs (complete SCI) had detrusor overactivity and DSD and in those with sacral cord signs (incomplete injury) 84% had an areflexic bladder. [14] Another study by Weld and Dmochowski of 196 veterans with suprasacral injuries revealed 95% had NDO and/or DSD. [15] Six patients (3%) all with lumbar injuries had bladder areflexia and fit the subsacral pattern described below.

DSD may cause incomplete emptying and with prolonged detrusor contractions structural bladder changes may occur resulting in bladder fibrosis and poor compliance with vesico-ureteric reflux. When combined with recurrent urinary tract infections, renal failure may result. This is more common with continuous than intermittent DSD although both require long term follow-up. [16] More than half of men develop urological complications and are considered to be at high risk of upper tract damage.

3.2. Incomplete suprasacral lesions

Incomplete suprasacral injuries can take many forms but four common patterns of injury have been described. **Anterior cord syndrome**, usually occurs due to disruption of the anterior spinal artery leading to reduced or absent motor activity and pain/ temperature sensation but proprioception is retained. In contradistinction, **posterior cord syndrome** for example due to tabes dorsalis affects only proprioception. **Lateral cord syndrome** also known as Brown Sequard leads to ipsilateral loss of power and proprioception and contralateral loss of pain and temperature sensation. The most common pattern however, is seen due to traumatic neck hyperextension during a fall and is termed **central cord syndrome**. [17] Due to lamination in the spinal cord, the upper limbs are more affected than lower limbs (as they lie closer to the central canal) and the former are more likely to show lower motor neurone features compared to the latter which demonstrate spasticity. Sensation also disproportionately affects the upper limbs. Recovery is also more likely in the less affected lower limb. [18]

Incomplete suprasacral lesions lead to variable bladder and sphincteric function. Anterior cord injury leads to detrusor overactivity in the majority of patients, and DSD is also a possibility dependent on how extensive the injury is and which parts of the cord are affected. The pathways co-ordinating the bladder and sphincter are located mostly in the lateral columns and if these are affected DSD may occur. [19] If the dorsal columns are unaffected, bladder sensation is spared. [20] The risk of upper tract injury is based on the individual circumstances.

A urodynamic study of 22 veterans with central cord syndrome revealed normal findings in three men, detrusor areflexia in four, DSD in 11, detrusor overactivity without DSD in one and detrusor underactivity in one, also two men had BOO due to BPH. [21] Therefore it is clear that the LUT function in central cord syndrome will be variable and the risk of upper tract damage due to DSD or poor compliance needs to be considered but is not common and also sensation is reported to be preserved. [22]

With Brown Sequard syndrome, urodynamic studies in eight patients revealed detrusor overactivity in four, an areflexic detrusor in three and DSD in four patients. [23] In a study of 269 patients with spinal cord lesions, those with unimpaired sensation and younger age were most likely to recover acceptable bladder function. [24] Brown Sequard and central cord syndromes carried the best prognosis for recovery of bladder function.

4. SACRAL AND SUBSACRAL LESIONS

Lesions of the conus medullaris and cauda equina are characterized by motor and sensory symptoms in the lower limbs, buttocks, perineum accompanying the dysfunctions of bladder, bowel and sexual activity: the “cauda equina syndrome”. [25] As the axons with roots from cauda equina extend into the spinal cord, dysfunctions caused by a lesion of conus or cauda are similar thus making distinction between them on clinical grounds difficult. [26]

4.1. Sacral (conus medullaris) lesions

The intermediolateral nucleus contains the motor nuclei of the autonomic nervous system. In the sacral spinal cord, this region is parasympathetic, and damage to the nucleus renders the detrusor areflexic. Resulting retention of urine can cause incontinence (formerly termed overflow incontinence). Onuf’s nucleus, located medially in the ventral horn of the sacral spinal cord, is a mixed autonomic/ somatic nucleus containing the motor nuclei for the LUT and LBT outlets. Damage to this structure affects sphincters (and some pelvic floor musculature), and thus stress incontinence may result. If the pudendal nerve is also impaired, there is an increased risk for incontinence.

The functioning of a sacral or areflexic bladder depends on the sphincteric resistance (detrusor leak point pressure). The bladder will fill up to the detrusor leak point pressure and empty by over flow. There will be no detrusor contraction. The bladder may develop poor compliance and pose some risk to the upper tracts. The symptoms can be acute with motor and sensory changes as when central large lumbar disc herniation occurs. Chronic symptoms may occur when degenerative disc disease and osteoarthritis of the spine create gradually narrowing of the spinal canal and/or foramina.

4.2. Subsacral lesions (cauda equina or peripheral nerves)

The same effects as seen with lesions of the conus medullaris can result from lesions of the subsacral nerves (the cauda equina, or the peripheral nerves-including the pudendal nerves). The main function of peripheral nerves is the communication between the CNS and peripheral effector organs. Lesions at that level can occur by different causes as infections (cytomegalovirus, herpes), fractures, surgery, radiotherapy and many more. Peripheral neuropathies are found in a long list of conditions as diabetes, alcohol abuse, Guillain-Barré et al. [27] [28] Both parasympathetic and somatic motor function will potentially be impaired; the detrusor can be underactive or areflexic and the external sphincter can be paralyzed. These lesions can also cause a variety of sensory deficits. Some pain and/or filling sensation can be retained because of intact sympathetic hypogastric nerves, which enter the spinal cord in thoracic roots. The bladder neck is predominantly innervated by sympathetic pathways, and so it can retain some function in sacral injury. If there is extensive autonomic damage, the bladder neck remains open. [29]

Iatrogenic causes of focal pelvic nerve lesions have been described with abdominoperineal resection,

though these are probably less frequent with intraoperative neuro-monitoring. It has been studied in hysterectomy, where nerve sparing techniques offer a better outcome. [30] [31] Also in radical prostatectomy enhanced attention to the innervation at the time of surgery may result in improved preservation. [32] Complete lesions of all local innervation, are followed by a silent, painless distension of the bladder. Urinary retention follows, leading to incontinence by overfilling, though if the external urethral sphincter is also denervated stress urinary incontinence (SUI) and even continuous urine leakage may occur. When lesions are partial, sensory symptoms may predominate. But patients, especially women, can report "spontaneous voiding" with Valsalva. In patients with a presumed isolated PNS involvement (as in Guillain-Barré syndrome), DO with or without DSD has been described. [33] [34]

In patients with a complete cauda equina or a lower conus lesion, a sensory input from the bladder can be preserved and is possibly transferred through the intact hypogastric plexus to the thoracolumbar segments of the spinal cord. [35]

Conclusions (LOE = 1)

- With a neurologic lesion the type of dysfunction that follows in LUT (and LBT) will depend on the site, the extent and the evolution of the deficit.
- Distinction is made between suprapontine, pontine, surpasacral spinal cord, sacral and subsacral lesions.

Recommendations (grade A)

- It seems worthwhile to further evaluate the classification of the neurogenic bladder: stratified by Anatomic Location and Etiology (SALE). Beside classifying into seven categories, each corresponding with a neurologic defect in a distinct anatomic location, the presence or absence of bowel dysfunction and autonomic dysreflexia is reported.
- In the future, if further evaluation confirms their importance, prognostic information as from biomarkers, NGF and BDNF, can be added to the classification and will be an important avenue for further research.
- As such the classification describes a patient suffering from NGB and simultaneously informs about the most appropriate treatment, follow-up regimen, and long-term prognosis

III. NEUROLOGICAL URINARY INCONTINENCE

1. EPIDEMIOLOGY (INTRODUCTION)

NLUTD may be caused by a variety of neurological diseases and/or events affecting the various parts of the nervous systems controlling the LUT. The resultant dysfunction depends grossly on the location, extent, and nature of the causative neurological lesion or lesions. Overall prevalence estimates for NLUTD in the general population are scarce, but data are available on the prevalence of the underlying conditions and, in some cases, the relative risk for the development of NLUTD. It is important to realise that most of these data show a very wide range of prevalence figures, due to low level of evidence in most published data and smaller sample sizes.

Nevertheless, worldwide estimates of the prevalence of spinal cord injury (SCI) are at over 2.5 million, multiple sclerosis (MS) considerably greater than 1.5 million and Parkinson's disease (PD) approximately 3 million [1-3]. Spinal cord injuries are common, with an estimated 50 people per million sustaining a traumatic spinal injury every year in the Western world [4]. Non-traumatic injury (vascular, infection, tumour) is more common, and cancer alone is estimated to cause more SCI than trauma [5]. Traumatic injury mostly affects young men, and advances in rehabilitation medicine mean that the longevity of paraplegics is similar to the general population while that of tetraplegics is 10 years shorter [9]. The prevalence of MS is approximately 1 per 1 000 [2].

Mobility, pain and bladder dysfunction in neurological patients has been relatively well studied, while the bowel and pelvic floor dysfunction has been neglected by comparison. With rapid advances in rehabilitation medicine resulting in increased survival of patients, these individuals are experiencing bladder and bowel symptoms for ever-longer periods.

As in previous International Consultations on Incontinence reports published data on epidemiology were reported both in a separate section and in each specific neurological condition, it seemed more appropriate for the 2016 ICI report to present updates of epidemiology only with each specific neurological condition. The general conclusions and recommendations on epidemiology of the previous ICI report remain unchanged.

Conclusions

- Dysfunction of the LUT occurs in patients with a variety of neurologic diseases but precise epidemiological data is seldom available

- Common manifestations of NLUTD include urinary incontinence, voiding difficulties, and urinary retention.
- Because neurological disease is often present in elderly populations, it is frequently difficult to discriminate if LUTS are due to aging alone, or due to the presence of neurological disease. This difficulty is reflected in widely varying prevalence estimates.

Recommendations

- Patients with neurologic disease known to be associated with NLUTD should be evaluated for the presence of lower urinary tract symptoms.
- In certain neurologic disease states, NLUTD may be relatively asymptomatic, yet represent a risk of upper urinary tract impairment.
- In the appropriate clinical setting, a neurological evaluation may be recommended in a patient with unexplained LUTS and no known neurological disturbance. This is particularly true in the case of a young patient with idiopathic severe LUTS after proper office evaluation for common etiologies.
- Prevalence estimates of NLUTD would be improved by multicenter co-operative studies from large tertiary centers utilizing established outcomes and evaluation tools.

2. SPECIFIC DIAGNOSTICS

Before any functional investigation is planned, all "basic" data should be gathered and used for further interpretation of the NLUTD [1,2]. Relevant investigations include; history and physical examination, questionnaires, urine tests, voiding diary, urodynamic studies (cystometry, electromyography (EMG), videourodynamics, uroflowmetry, pressure-flow study), diagnostic imaging with voiding cystourethrography and ultrasonography. In this chapter are highlighted some data specially related to NLUTD. Some tests developed for the diagnosis of neurologic dysfunction are considered specifically; the bethanechol supersensitivity test, and the ice water or bladder cooling test. Neurophysiologic studies are discussed in the chapter "Clinical Neurophysiological testing", and only some data for NLUTD is given here.

2.1. History

The *general history* aims at gathering information on the neurological and congenital abnormalities, previous urinary complications or treatments. The use of medication with known or possible effects on the LUT, menstrual, sexual and bowel function, and obstetric history are also important. Hereditary or familial risk factors, metabolic diseases and other must be known. Lifestyle factors such as smoking, alcohol, or addictive drug use should be assessed as well as an evaluation of Quality of Life. Social impact and the degree of disability have to be taken into consideration. Patients with a spinal cord lesion above Th6 may develop autonomic dysreflexia, so a history of severe headaches should be explored.

The signs and symptoms that bring the patient to consultation must be documented. Symptoms related to storage and voiding, continence and /or retention, as well as onset and nature of the NLUTD (acute or insidious) should be determined. If appropriate this information should be compared with the patient's condition before the NLUTD developed. Bladder sensation and mode and type of voiding (catheterization) should be considered. Validated questionnaires are useful for recording symptoms, their frequency, severity and bother, and the impact of LUTS on QoL. Some instruments were not validated in NLUTD or are impossible to implement because of sensory or motor deficiency in NLUTD. An excellent review of available tools for neurological disease and urinary-specific instruments used to assess QOL associated to bladder symptoms has been written by Clark and Welk [3]. Results are summarized in Table 3 at the end of this paragraph. Warning signs and symptoms that warrant early further investigation include; fever, pain, hematuria, catheterization problems, clinical infections and signs of autonomic dysreflexia. Individuals with NLUTD may not be accurate at determining whether they have a UTI based on their symptoms [4]. UTI management is not standardised and clinical practice suffers from a weak evidence base [5].

Table 3: Disease- and urinary-specific instruments used to assess QOL associated to bladder symptoms (adapted from [3])

Scale	Population	Original purpose	Item generation	Internal validity	Reliability	External validity	Responsiveness and MDC*
Qualiveen [6]	SCI/MS	Cross-sectional and longitudinal examination of SCI patients	Patient interview and expert review	α >0.80	ICC: 0.85–0.92	Consistent with predicted correlations with SQLP	SRM >0.75 (in patients with MS) [7] MDC: 32
SCI-SCS [8]	SCI	Cross-sectional and longitudinal examination of SCI patients	Adapted from the SCQ	α >0.76	ICC: 0.56–0.80	R: 0.31–0.64 between total score and 6 SF-12 domains	SRM: NE MDC: NC
SCI-QOL bladder management difficulties bank [9]	SCI	Cross-sectional and longitudinal examination of SCI patients	Adapted items from Neuro-QOL with patient interview and expert opinion	α: 0.74	ICC: 0.74	Study in progress	SRM: NE MDC: 12
SCI-FI [10,11]	SCI	Cross-sectional and longitudinal examination of SCI patients	Interviews with patients, literature review and expert consensus	α: 0.85–0.95	ICC: 0.90–0.99	Not evaluated	SRM: NE MDC: NC
I-QOL [12]	SUI/SCI/MS	Cross-sectional and longitudinal examination of SCI patients	Patient interview and expert review	α >0.79	ICC: 0.89–0.99 [13]	R: 0.36–0.59 for SF-36 mental health, social functioning and vitality domains	SRM: NE MDC: NC MID: 11 with medium effect size estimation
NBSS [14]	SCI/MS/SB	Cross-sectional and longitudinal examination of SCI and MS patients	Interviews with patients, literature review and expert consensus	α: 0.89	ICC: 0.91	R: 0.52–0.59 with AUASS, ICIQ-UI, GBA and SF-Qualiveen total	SRM: NE MDC: 9
MSQOL-54 [15]	MS	Cross-sectional and longitudinal examination of MS patients	Adapted from SF-36 with literature and expert review	α >0.75	ICC: 0.66–0.96	Varying degrees of correlation with SF-36, MOS, and faces scale	SRM: 0.71 for physical health SRM: 0.57 for mental health [16] MDC: 67

Scale	Population	Original purpose	Item generation	Internal validity	Reliability	External validity	Responsiveness and MDC*
MSIS-29 [17]	MS	Cross-sectional and longitudinal examination of MS patients	Interviews with patients, literature review and expert consensus	α >0.91	ICC: 0.65–0.90	Consistent with predicted correlations with SF-36, FAMS, EQ-5D, GHQ-12, postal Barthel Index	Effect size: 0.66 (psychological scale), 0.82 (physical scale) MDC: 2
FAMS [18]	MS	Cross-sectional and longitudinal examination of MS patients	Interviews with patients, literature review and expert consensus	α >0.82	ICC: 0.85–0.91	Consistent with predicted correlations with SF-36, HADS, MDI, PSR and MCSDS	SRM: 0.58 [9] MDC: 29
HAQUAMS [19]	MS	Cross-sectional and longitudinal examination of MS patients	Items adapted from FAMS and SF-36 and expert opinion	α >0.68	ICC: 0.75–0.94	Consistent with predicted correlations with EDSS, T8, SDMT, 9HPT, FAMS, HADS	SRM: −0.55 in worsening patient SRM: 0.30 and 0.59 in patient undergoing intervention [20] MDC: 2
MSQLI [21]	MS	Cross-sectional and longitudinal examination of MS patients	Conglomeration of 10 scales [22]	α >0.70	ICC: 0.83–0.92 (for bladder scale)	R: 0.45–0.58 (for bladder scale)	SRM: NE MDC: NC
ABSST/-SF [23,24]	MS	Cross-sectional and longitudinal examination of MS patients	Interviews with patients, literature review and expert consensus	α: 0.85–0.90	ICC: 0.80	Long form R ≥0.782 with OAB-q SF and HRQOL scores	SRM: NE MDC: 12
QOLSB [25]	SB	Cross-sectional and longitudinal examination of children with SB	Interviews with patients/parents, literature review and expert consensus	α: 0.93–0.94	ICC: 0.37–0.63	R: 0.26 (children) and 0.89 (adolescent) with Piers-Harris Children's Self-Concept Scale	SRM: NE MDC: NC
IIQ-7 [26]	UI			α >0.88	ICC >0.8		SRM: NE

Scale	Population	Original purpose	Item generation	Internal validity	Reliability	External validity	Responsiveness and MDC*
		Cross-sectional and longitudinal examination of adults with UI	Adapted from the IIQ			Consistent with predicted correlations with EORTC QLQC30	MDC: NC
KHQ-LUTS [27]	UI	Cross-sectional and longitudinal examination of adults with UI	Adapted from the KHQ	α >0.72	ICC: 0.93 [28]	Consistent with predicted correlations with SF-36 [29]	SRM: NE MDC: 39
ICIQ-OAB [30]	OAB	Cross-sectional and longitudinal examination of adults with over active bladder	Interviews with patients/parents, literature review and expert consensus	α >0.86	ICC: 0.91–0.95 [31]	Consistent with predicted correlations with SF-36	SRM: 0.6 [32] MDC: NC

A urinary diary can be used to capture information on the number of voids (frequency and nocturia), the sensation at each void, volumes voided, incontinence, and volume/ time of fluid intake. Little information is available on optimal diary duration in NLUTD, considering information captured balanced against inconvenience to the patient [33]. However general recommendation is to do it at least for 3 days [34]. Some information could be difficult or impossible to collect because of sensory or motor deficiency in NLUTD. Nonetheless, such diaries deliver useful assessment for evaluating treatment outcomes [35].

A Urinary diary can be subdivided into:

1. Micturition Time Chart: this records only the times of micturitions, day and night, for at least 24 hours.
2. Frequency Volume Chart (FVC): It records the volumes voided as well as the time of each micturition, day and night, for at least 24 hours.

Bladder Diary: it records the times of micturitions and voided volumes, incontinence episodes, pad usage and other information such as fluid intake, the degree of urgency and the degree of incontinence.

2.2. Physical examination

A general impression of patient's physical and mental possibilities is relevant to the choice of investigations and treatment. Severely impaired mobility, extreme spasticity, severe mental disorder and general weakness are all important in this respect. The physical examination evaluates the lower abdomen, external genital organs and perineal skin. Palpation per vagina or per rectum is done in search of pelvic organ descent, or cervix-uterus/ prostate disease. The strength of the pelvic floor muscles should be assessed. Cardiovascular function should be considered. Patients with very high neurological lesions may suffer from a significant drop in blood pressure when changing position.

Specific examination of the lumbo-sacral innervation includes: sensation of fine touch and pin-prick in the different perineal dermatomes (Figure 2), evaluation of bulbocavernosus/ anal/ cremaster reflexes, tone of anal sphincter and voluntary contraction of the anal sphincter / pelvic floor muscles (Figure 3). Clinical neurological findings correlate well with NLUTD in some types of neuropathy such as single level traumatic spinal cord lesions [36] but less in other types like meningomyelocoele or combined traumatic spinal cord lesions [37,38]. Urinary symptoms and pathological urodynamic findings increase along with the degree of motor function impairment in infantile cerebral palsy [39] The levels of vertebra lesions does not correspond to the level of nerve damage (Figure 4) [40]

2.3. Urine tests

Tests for bacteria or pyuria do not establish a diagnosis of urinary tract infection (UTI), but are helpful in the context when symptoms are present. The urine sample should be collected with sterile catheter and taken to the laboratory immediately. Colony forming units $\geq 10^5$ cfu/L in an intermittent catheter specimen with symptoms present, represents sufficient diagnosis of UTI's. In clean-voided specimens from catheter-free men using condom catheters, $\geq 10^7$ (cfu/L) is a sufficient level [41]. There is however lack of other high level evidence to define UTI's in patients with NLUTD.

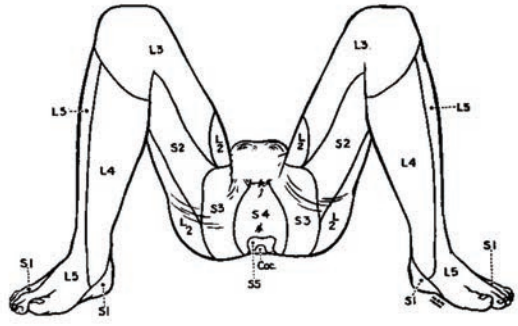

Figure 2: Dermatomes of spinal cord levels L2-S4

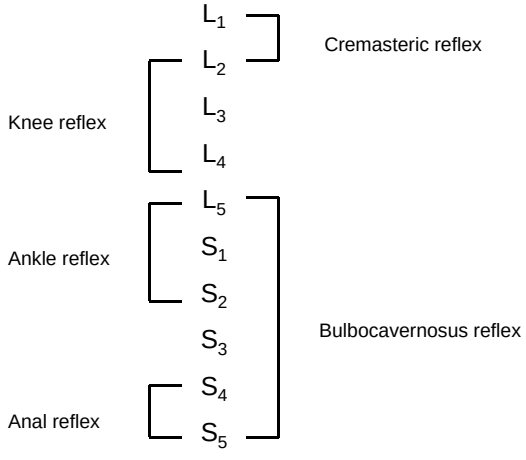

Figure 3: Urogenital and other reflexes in lower spinal cord

2.4. Urodynamic tests

Urodynamic techniques evaluate multiple functional parameters in NLUTD [42]. The International Urodynamic Basic Spinal Cord Injury (SCI) Data Set sets out data to be included in the urodynamic evaluation of patients with SCI. Variables included are; bladder sensation during filling cystometry, detrusor function

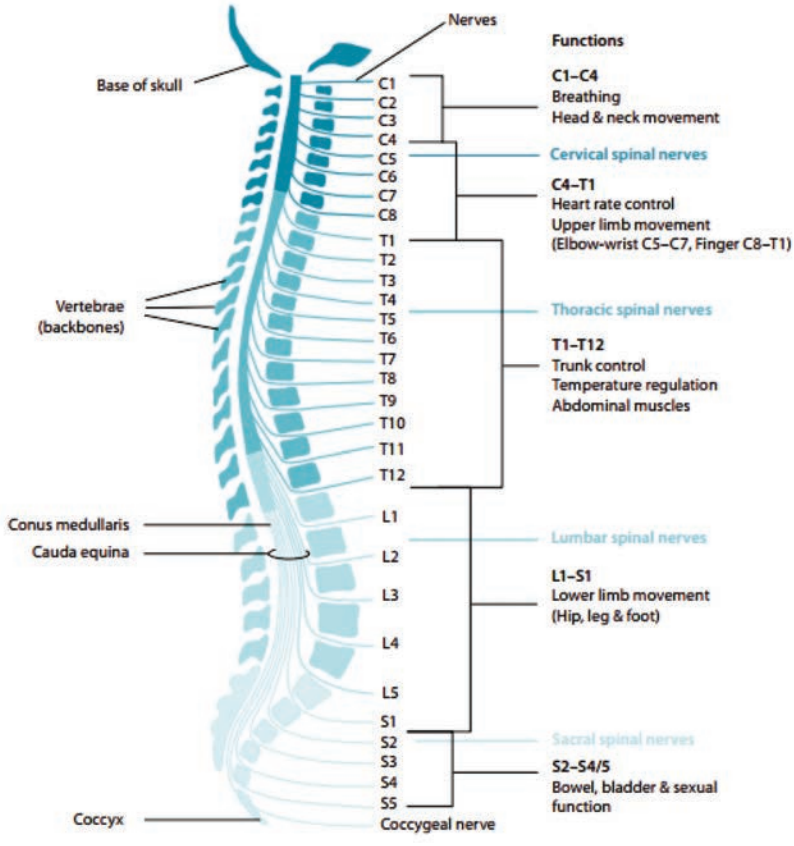

Figure 4. Levels of spinal cord injury

and compliance during filling cystometry, detrusor function during voiding, detrusor leak point pressure, maximum detrusor pressure, cystometric bladder capacity and post-void residual [16].If the study is under taken with video control then one has to look for reflux, bladder trabeculations and sphincter dyssynergia.

Often, the nature of NLUTD is impossible to anticipate from clinical assessment alone, exemplified by CNS tumours in children [43]. Likewise, severity of NLUTD does not necessarily correspond with severity of neurological lesion.

Electromyography (EMG) during cystogram and pressure flow studies

The basis of EMG has long been a question of debate [44, 45]. Sundin and Petersen [46] used cystometry (EMG) investigation in NLUTD for patients with an active detrusor contraction associated with impaired bladder emptying. A voluntary control of external urethral sphincter relaxation was found in most of the healthy volunteers, and cystometry-EMG gave reliable information on DSD in patients. .On the other hand Kirby et al showed that perineal surface patch EMG did not measure expected pelvic floor and urethral sphincter relaxation during voiding [47]. De et al found significant disagreement between needle EMG and VCUG for a positive diagnosis of DESD and suggested a combination of EMG and VCUG for diagnosis of DESD [48]. Perkash [49] found rhythmic detrusor contractions on cystomanometry with associated marked increase in EMG activity on attempted voiding to be relevant characteristics of patients with DSD. Rodriquez et al. [50] used EMG-gas cystometrogram to select SCI patients for removal of a Foley catheter. Important factors governing success were the amplitude of the detrusor contraction, the presence of detrusor-sphincter synergy and the presence of a flaccid sphincter. Mayo and Kiviat [51] used multichannel urodynamic studies in patients with incomplete bladder emptying secondary to suprasacral spinal cord lesions. They found that bladder pressure and sphincter EMG measurement during voiding, combined with fluoroscopy, are ideal methods to identify the factors responsible for incomplete emptying in problem cases. Perlow and Diokno [52] and Koyanagi et al. [53] found cystometry-EMG informative in SCI patients.

Blaivas et al. [54] described three types of dyssynergia. Type 1 had a crescendo increase in EMG activity that reached a maximum at the peak of the detrusor contraction, type 2 had clonic sphincter contractions

interspersed throughout the detrusor contraction and type 3 was characterized by a sustained sphincter contraction that coincided with the detrusor contraction. There was no correlation between the clinical neurologic level and the type of dyssynergia. In DSD, Rudy et al. observed clinically that increases in EMG activity and external urethral sphincter pressure were associated clearly with a positive slope of the intravesical pressure trace, whereas decreases in both parameters were associated with a negative slope [55].

Simultaneous recording of intravesical pressure, sphincter electromyography and uroflowmetry was compared by Aoki et al. [56] with cystometry EMG. They found some influence of the catheter in the urethra. Micturition pressure and opening pressure were larger with cystometry EMG, and incidence of DSD was greater. The authors also found that the Credé manoeuvre exaggerated the DSD. Urodynamics with needle electrode EMG permitted Kirby [57] to differentiate between patients with pelvic nerve injury, distal autonomic neuropathy, progressive autonomic failure - multiple system atrophy, and idiopathic Parkinson's disease. This influenced the selection of patients for transurethral surgery. Pavlakis et al. [58] studied cystometry concomitant with perineal floor and rectus abdominis EMG and were able to improve the recognition of intravesical pressure elevation owing to voluntary contraction of the abdominal musculature. EAS motor unit potential (MUP) analysis and EMG cystometry were used to differentiate multiple system atrophy (MSA) from Parkinson's disease in the first five years after disease onset. It showed that involvement of Onuf's nucleus in MSA is time-dependent; before the fifth year of illness, the prevalence of neurogenic change does not seem to be high, so a negative result cannot exclude the diagnosis of MSA [59]. Rapidi et al. used combined urodynamic and electrophysiological study in diabetic cystopathy [60].

Filling parameters

The importance of detrusor pressure has been acknowledged for many years. Filling rate is important in NLUTD, and slow filling is recommended by the International Continence Society to minimise artefactually affecting compliance [61].

Bruschini et al. [62] undertook clinical, urodynamic and imaging evaluation of the upper and lower urinary tract in inadequately managed myelomeningocele patients. The urodynamic data correlated with the status of the upper urinary tract (UUT). The cystometry showed detrusor overactivity (DO), poor compliance, increased bladder capacity and normal cystometry in 48, 49, 2 and 1% of the patients, respectively. Detrusor leak point pressure (DLPP) over 40 cm H_2O was associated with UUT damage. Patients with decrease of functional bladder capacity (FBC) had more renal scars than their counterparts. Incomplete SCI patients with neurogenic DO should be evaluated with the same caution as complete SCI patients, as there can be little difference in cystometric capacity and leak point pressure between complete and incomplete spinal cord injury patients [63].

The importance of urodynamic tests for diagnosis and follow up was demonstrated in the study by Abrahamsson et al. [64] on urodynamic changes with untethering in myelomeningocoele children. After untethering, 35% experienced improved bladder function and 5% deteriorated. All of the patients who deteriorated before untethering improved afterward, and 90% of those who were stable preoperatively continued to be stable postoperatively. Regular evaluation of bladder function in children with myelomeningocele is recommended. Kang et al. [65] used urodynamic tests to determine prognostic factors affecting urological outcome after untethering surgery for lumbosacral lipoma.

Perkash and Friedland [66] found simultaneous transrectal ultrasonography helpful. They recommended not to irritate the bladder when introducing the urodynamic catheter, and to examine the entire curve of the CMG, not simply the initial rise [67].

Filling technique

In SCI patients with neurogenic LUT dysfunction, Ko et al. [68] determined whether cystometry performed by filling using diuretics (FMCG) reveals different findings compared with conventional CMG. Significant differences between the two techniques were found in pressures and compliance in neurogenic DO, but not in hyporeflexic or areflexic bladders. Natural filling by the production of urine can change the results of cystometry considerably, and should be considered when performing urodynamic investigations and interpreting the results.

De Gennaro et al. [69] performed continuous urodynamic monitoring over six hours in children and compared this with standard urodynamics. They found continuous monitoring feasible, permitting a better diagnosis than standard cystometry in some cases. Zermann et al. [70] investigated the diagnostic value of natural fill cystometry (NFC) in children with neurologic bladder in comparison to conventional videocystometry. In 45%, NFC detected additional findings. The extra value of ambulatory urodynamics as compared to conventional urodynamics in spinal cord injury patients was investigated by Martens et al. They concluded that ambulatory urodynamics do not seem necessary for diagnosis and risk assessment in SCI patients suspected for DO when conventional urodynamics are done properly [71].

The outlet during voiding

Pressure-flow study can demonstrate an obstructive pattern (high pressure voiding) in neurologic patients due to urethral relaxation failure [72,73]. Videourodynamics (VUDS) offers visualisation of bladder neck and urethral sphincter activity during filling and voiding [74,75]. Accordingly, VUDS is a test that can determine the site of obstruction. Zerin et al. [76] found

that the urographic position of the bladder neck in relation to the pubic symphysis was correlated with lower motor neuron (LMN) denervation of the urethral sphincter as detected with electromyography in infants and children with myelodysplasia. They concluded that, although not as precise as urodynamic testing, significant descent of the bladder neck is a reliable urographic finding of complete LMN denervation of the external urethral sphincter in infants and children with myelodysplasia. In men with SCI, some cystometric variables and detrusor overactivity may remain consistent over sequential studies [77].

Bladder sensation

In a large cohort study it was shown that impaired perception of bladder filling during CMG is a sign of neuropathy [78]. Nonetheless, despite spinal abnormality, patients can experience bladder filling sensation, signifying the presence of afferent pathways joining the spinal cord at higher levels. In 52 SCI patients, 26 % of those with a supposed complete lesion had sensation of bladder filling during cystometry [79]. In 41 patients with myelodysplasia the perception of bladder filling was present in a majority [80]. In a study of 26 SCI patients, bladder sensation was reported by 73% of patients in daily life. However, only 41% of patients had analyzable bladder sensation concomitant with detrusor overactivity during ambulatory Urodynamics [81].

Ersoz and Akyuz [82] investigated bladder filling sensation in 73 SCI patients with complete lesions above T11 and below T10 and with incomplete lesions. Bladder filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and in 38.9% of the patients with complete lesions above T11. Bladder-filling sensation investigations were reproducible in terms of bladder filling sensation category in 36 SCI patients who had a second CMG. The authors concluded that presence of bladder-filling sensation in many SCI patients reveal the potential for sensation-dependent bladder emptying, especially in the ones with complete lesions below T10 and the ones with incomplete lesions. The safe use of sensation-dependent bladder emptying was shown to be dependent on the urodynamic situation [83].

The amplitude of the first overactive contraction and the maximal detrusor contraction were found to be statistically greater in female patients with multiple sclerosis and neurogenic detrusor overactivity compared to women with idiopathic overactivity. The threshold volume for detrusor overactivity was greater, likely secondary to the elevated post void residual urine volume in the MS patients. In this study using a cut off value of 30 cm H2O for amplitude of the first overactive contraction achieved a positive predictive value of 88% for identifying multiple sclerosis [84].

Complications of urodynamic testing

Complications of cystometry include hematuria due to the urethral catheter, the development of oedema in the urinary bladder wall and urinary bladder spasm as a result of catheter irritation. One case report of twist and knot formation in the double lumen urethral catheter after cystometry of a patient with a hypocompliant bladder has been published [85]. Another case report describes bladder rupture during filling cystometry many years after bladder augmentation in a girl with meningomyelocoele [86].

Symptomatic urinary tract infections after cystometry are not infrequent and antibiotic prophylaxis has been advocated [87]. Randomised controlled trials (RCTs) comparing effectiveness of prophylactic antibiotics with placebo or nothing in reducing bacteriologically proven UTI after invasive cystometry have been done for all patients, including NLUTD [88]. The use of prophylactic antibiotics in urodynamics reduced the risk of significant bacteriuria but there was not enough evidence to suggest that this effect reduced symptomatic urinary tract infections [89].

Conclusions

- Findings of Urodynamic tests can be difficult to anticipate from clinical assessment alone in NLUTD (LOE 2)
- A combination with EMG and /or imaging adds to the diagnostic possibilities (LOE 2)
- Filling rate can influence the outcome of several urodynamic parameters (LOE 2)
- Pressure development in the bladder is one of the important parameters to be studied and high leak point pressure is a risk factor for renal deterioration (LOE 2)
- Sensation of filling may be preserved despite spinal abnormality (LOE 2)
- Complications of urodynamic testing are rare, but antibiotic prophylaxis in NLUTD can be considered (LOE 1)

Recommendations

- There is currently inadequate data (LOE3-4) to support recommendations for the use of urodynamics in each specific neurological condtion. However, the use of invasive urodynamics is recommended in neurological conditions associated with ‘high-pressure bladders’ which may place renal function at risk (A), as opposed to ‘urodynamically safe’ bladder conditions (C)
- Methods of Urodynamic testing in NLUTD should follow International Continence Society recommendations (A)

2.5. Special tests

Bladder-cooling reflex; the ice water test (IWT)

The ice water test (IWT) is a C-fiber mediated reflex, first described as a way to differentiate upper from lower motor neuron lesions. It is based on the principle that mucosal temperature receptors can elicit a spinal reflex contraction of the detrusor, a reflex that is normally inhibited by supraspinal centers. An upper motor neuron lesion interrupts these inhibitory pathways, resulting in manifestation of the reflex, whereas a lower motor neuron lesion does not. A positive test should therefore theoretically occur in patients with upper motor neuron lesions, whereas those with lower motor neuron lesions and neurologically normal patients should have a negative test. Simultaneous measurement of intravesical pressure with cold fluid instillation enables evaluation of the response. Patients without neurogenic disease have a greater perception of cold during the IWT than neurogenic patients; this must be considered when evaluating test results [90]. The bladder cooling reflex was blocked in 16 out of 17 neurogenic patients when 30 mg intravesical oxybutinin was instilled [91].

There is a significant correlation between a positive IWT with abnormal sensation of bladder filling and inability to inhibit micturition voluntarily. A negative IWT also corresponded with the occurrence of phasic detrusor contractions during cystometry. The IWT may be useful for functional subdivision of overactive bladders. In patients with voiding dysfunction in the absence of LUT inflammation, a positive test is an indicator of a silent or overt neurological disorder. Geirsson [92] reported positive or a false negative IWT in a large cohort study. Geirsson and Fall [93] used the IWT in patients suspected of DSD (cystometry and needle EMG). A positive test with a high detrusor pressure was stated to indicate DSD, whereas the contrary applies to the negative test. All patients who responded to cold stimulation with detrusor contraction but without fluid leakage (called positive nonleakage IWT), manifested DSD on EMG. The authors concluded that the simpler IWT could substitute for a needle EMG study.

Ishigooka et al. [94] evaluated urinary bladder sensation to ice water instillation in patients with diabetes mellitus. There was no apparent relationship between prevalence of peripheral neuropathy and that of negative sensation of IWT. Impairment of ice water perception was less frequent than that of mechanoreceptor sensation in patients with diabetic cystopathy.

Ronzoni et al. [95] studied the IWT in 148 patients with neurologic bladder dysfunction resulting from a traumatic lesion and in 130 patients with neurologic bladder dysfunction and multiple pathogenic disorders. IWT was positive in 95% of patients affected by complete and in 86% of patients with incomplete medullary lesions. The IWT in patients with lower motor neuron medullary lesions was always negative. The test was used diagnostically in patients with lower motor neuron lesions. In those with upper motor lesions it was used as a rehabilitation method during the medullary-shock phase to accelerate the appearance of the micturition reflex. In 9% of patients it was used to induce micturition during cystography. The authors consider IWT as a useful complement to urodynamic examinations in patients with neurological bladder disease. By contrast, Chancellor et al. [96] found lack of sensitivity and specificity of the IWT in SCI patients and concluded it did not contribute to their management. Autonomic dysreflexia can occur during evaluation. Since the IWT is an unphysiological investigation that might significantly bias subsequent urodynamics, Kozomara et al. suggest that the IWT should not precede more physiological standard urodynamic invastigation [97].

Repeating the IWT has been shown to increase its positivity [98]. Combining the IWT and electrical perception threshold (EPT) testing will reinforce the results of both tests and can indicate more clearly the possibility of an unsuspected neurologic pathologic finding in patients with idiopathic DO. In multiple sclerosis it may have pathophysiological value, indicating a spinal rather than cerebral mechanism of overactive bladder, and diagnostic value, indicating multifocal demyelination [99].

Conclusions:

- The majority of published studies show value of the IWT in the diagnosis of NLUTD and in the differentiation between reflexic and areflexic neurologic bladder (LOE 2)

Recommendation:

- The ice water test is an optional test which should be interpreted in the context of all data from the diagnostic evaluation, but should not precede regular UDS (B)

Bethanechol supersensitivity test (BST)

Bethanechol is a muscarinic agonist which may improve bladder emptying in some non neurologic patients, and correspondingly increase bladder sensitivity [100]. The BST was developed by Lapides et al. in 1962 [101] to try to distinguish between a neurologic and a myogenic aetiology in an acontractile bladder. It is based on the observation that after an organ is deprived of its nerve supply, it develops hypersensitivity to the normal excitatory neurotransmitters. A neurologically intact bladder should have a pressure increase of less than 15 cm H_2O above the control value, whereas a denervated bladder shows a response greater than 15 cm H_2O. The clinical utility has not been studied in detail recently.

The test is considered unreliable by some [102]. Penders [103] considered the test reliable when the indications are good (large capacity, hypotonic bladder, clinical suspicion of lower neuron lesion) and when the interpretation is based on a right under-

standing of its mechanism. Pavlakis et al. [104] suggest that the BST is more sensitive and more specific than perineal floor electromyography in corroborating bladder neuropathy. Sidi et al. [105] studied patients with neurologic or non-neurologic detrusor areflexia with the BST, EMG of the urethral rhabdosphincter and bulbocavernosus reflex latency and found the sensitivity of these tests in detecting neurologic mechanisms to be 90, 87.5 and 78.1%, and the specificity 96, 76 and 80%, respectively. When all three tests were performed together, the combined accuracy approached 100 %. They conclude that these combined tests are useful in the diagnosis of patients with equivocal bladder neurologic conditions and in those with subtle neurological lesions. Denervation supersensitivity to bethanechol was demonstrated in acute idiopathic autonomic neuropathy [106] .

Wheeler et al. [107] found the positive BST not diagnostic of neurologic detrusor areflexia because of the many variables that can influence the test. In a later study, the same group [108] suggested that flow rate, surface electromyography, and bethanechol supersensitivity test cannot help differentiate neurologic from non-neurologic detrusor failure. Although no test can accurately differentiate neurologic from non-neurologic female urinary retention, careful neurourologic evaluation will help guide to more appropriate management.

Conclusion:

- The literature on the value of the bethanechol test for the diagnosis of neurologic pathology is contradictory. The test may contribute to overall evaluation of neurologic LUT dysfunction. (LOE 2)

Recommendation:

- The bethanechol supersensitivity test has limitations, and results should be interpreted in conjunction with established diagnostic results. (B)

Electrodiagnostic tests

EMG of the urethral sphincter

EMG of the urethral sphincter has been used for decades in the diagnosis of NLUTD; its value in practice remains uncertain. Use of needle or surface electrodes is debated. Urethral concentric needle electrodes were found to be superior to surface patch electrodes for evaluating relaxation of the muscle during voiding in neurologically intact women [109]. Nordling and Meyhoff [110] used cystometry in combination with urethral and anal sphincter EMG in patients with suspected NLUTD and found anal sphincter EMG to be highly unreliable. Koyanagi et al. [111] also found discordant activities between the anal and the external urethral sphincters in 39 % of male patients with SCI. The degree of bladder dysfunction was related more to the degree of dyssynergia of the urethral than the anal sphincter. Nevertheless, Podnar states that anal sphincter EMG is the most useful diagnostic test, particularly for focal sacral lesions, and atypical Parkinsonism [112]. Fowler et al. [113] introduced a technique of recording EMG activity of striated muscle in the urethral sphincter by using a concentric needle electrode and an oscilloscope with a delay line and trigger. Individual motor units were isolated and measured. Vodusek also studied individual motor units [114]. Both conclude that quantitative EMG may be a helpful technique in the investigation of patients with disorders of micturition.

Ziemann and Reimers [115] found the sphincter EMG the most sensitive technique in the diagnosis of chronic pudendal lesions. However, pure afferent lesions cannot be detected by the sphincter EMG. In this case, the BCR, using unilateral stimulation of the dorsal nerves of the penis, provides the opportunity to distinguish between afferent and efferent lesions of the sacral innervation. Fowler [116] concluded that sphincter electromyography (EMG) is valuable for identifying patients with Parkinsonism who have multiple system atrophy. Tests which examine aspects of nerve conduction velocity have proved to be of lesser value both because such investigations test conduction of nerve fibres rather than levels of innervation. Furthermore, they examine large myelinated fibre conduction, rather than the unmyelinated fibres which comprise the autonomic innervation. Sphincter EMG is a diagnostic test of Fowler's syndrome in young women with urinary retention [117]. Sphincter EMG can be used in gauging timing of stimulation for suppressing DO [118].

De E J et al. [119] found a significant disagreement between needle EMG and voiding cystourethrogram (VCUG) for diagnosis of DSD. A combination of EMG and VCUG may identify more cases of DSD than either modality alone and underscores the need for more strict criteria when defining this entity from a urodynamic standpoint.

Anal sphincter EMG as well as external urethral sphincter EMG can be used to detect the onset of detrusor contractions in patients with both neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD) opening a door for the use of triggered devices to inhibit unwanted contractions through continuous electrical stimulation of sensory nerves [120,121]. Light et al. [122] found in patients with detrusor areflexia and a high spinal cord lesion, EMG of the pelvic floor muscles is the neurophysiological test which best predicts detrusor contractility.

EMG of the urethral sphincter has been used to investigate retention in multiple-system atrophy [123], LUT function in Machado-Joseph disease [124], the impact of pregnancy and delivery on vesico-urethral disorders in patients with multiple sclerosis [125] and children with cerebral palsy [126].

ICS Guidelines on urodynamic equipment standardization recommend that EMG during urodynamics should have high input impedance greater than 100 MOhms, a common-mode rejection (CMRR) greater

than 80, and a filtering program to best produce a consistent EMG during testing [127].

EMG of Detrusor muscle

Detrusor EMG has not been widely studied in neurologic patients. La Joie et al. [128] recorded simultaneous EMG recordings from the bladder detrusor muscle and the inferior rectus abdominis muscle in 6 normal subjects, in 4 patients with LMN bladder disease and in 2 patients with an UMN type of bladder lesion. The bladder electrodes did not appear to record muscle activity remote from the abdominal muscles so that any increased detrusor electrical activity with abdominal contraction must have some other explanation. Kaplan and Nanninga [129] analysed detrusor EMG in upper motor neuron type NLUTD. Kinder et al. did not advocate detrusor EMG [130]. Recent data are lacking and so the technique cannot be considered a standard diagnostic test.

Conclusion

- Sphincter EMG can be valuable in the diagnosis of patients with neurologic bladder dysfunction (LOE 2).
- Detrusor EMG is not established as a diagnostic test

Recommendation:

- EMG of the urethral sphincter can be considered as a specialized diagnostic method in patients with neurologic LUT dysfunction and neurologic urinary incontinence (B B)

Dynamic Bulbocavernosus reflex (BCR)

Walter et al. [131] studied dynamic BCR during micturition induced by using periodic dorsal penile nerve stimulation; the evoked reflex response was recorded with an anal sphincter pressure sensing balloon. Results indicate that an enhanced BCR is a factor contributing to increased urethral resistance during micturition.

Kaiho et al. [132] recorded the evoked potential of the BCR (BCR-EP) with a concentric needle electrode at the periurethral striated muscle. They found BCR-EP was suppressed during voluntary voiding in normal subjects, but it was insufficiently suppressed in the patients with NLUTD. It was suggested that the measurement of BCR-EP could distinguish involuntary voiding caused by pathological urethral sphincter relaxation from voluntary voiding. The same group [133] investigated the change of sacral reflex activity of the striated urethral sphincter in the urine storage phase with BCR-EP in normal male subjects and male patients with NLUTD due to suprasacral spinal cord injury. Sacral reflex activity was accelerated by bladder filling in both the normal subjects and SCI patients, particularly in the latter. In addition to the conventional evaluation of the integrity of sacral reflex arc by BCR examination, the observation of changes of BCR affected by bladder filling may provide information on the continuity of sacral segment and supraspinal micturition centre. Niu et al. showed that in 8% of patients with SCI and in 70% of patients with peripheral nerve lesions the BCR was abnormal [134].

Motor evoked potentials

Motor evoked potentials (MEP) has been used to assess neurogenic lesions affecting the urethral compressive musculature with simultaneous recording of evoked pressure curves [135]. MEP recording is an accurate and easily applicable test for the diagnosis of lumbosacral spinal cord lesions [136].

Nerve conduction studies

In patients with diabetes mellitus, conduction velocities are decreased [137]. Vereecken et al. [138] found urethral and anal responses produced by electrical stimulation of penis, bladder neck and anus were delayed and the duration reduced. Carbone et al. [139] assessed the effect of urinary bladder filling on the excitability of somatic spinal motor neurones in patients affected by neurogenic and non-neurogenic DO and proposed that H-reflex modulation may be considered a tool in the differential diagnosis of voiding dysfunctions.

Somatosensory evoked potentials

In the committee's literature search, no recent publications were found on somatosensory evoked potentials (SSEP). Badr et al. [140] described techniques of recording evoked potentials in humans in response to stimulation of the urinary bladder. Galloway et al. [141] described a method of sacral evoked response to measure the integrity and function of the lower sacral segments by stimulation at the urethral and anal sphincters.

Mochida et al. [142] studied evoked spinal cord potentials (ESCP) in surgical patients with cervical myelopathy. The presence of NLUTD was closely correlated with severe limb symptoms and with relatively slow ESCP velocity. However, for 47% of the patients with urinary complaints, findings of urodynamic examinations were negative; these patients may have had pathologic or psychosomatic factors other than neurogenic bladder due to cervical myelopathy.

Curt et al. [143] studied the significance of SSEP recordings in predicting the recovery of bladder function in acute, traumatic spinal cord injury (SCI). They found a good correlation with the recovery of the external urethral sphincter function, but not with the urodynamic impairment. SSEP in response to stimulation of the tibial nerve have been studied in patients with hyperactive urinary bladder to clarify their role in prognosis of tibial neuromodulation efficacy [144].

Afferent nerve recording on sacral roots

Afferent nerve activity from the sacral dermatome, bladder and rectum can be recorded using cuff elec-

trodes placed on the extradural S3 sacral root in humans, but improvements in recording quality and sophisticated signal processing methods are needed for chronic application. The applicability in clinical practice is very limited [145, 146].

Conclusions:

- Detrusor EMG, BCR-EP and MEP are techniques of experimental interest, but with insufficient basis for use as standard clinical diagnostic tests.
- There are some arguments that nerve conduction studies can be useful in the further differentiation of the nerve deficits in cases of neurologic pathology of the bladder (C)
- Direct measurement of sacral afferent nerve activity is still experimental

Recommendation

- Somatosensory evoked potentials can be of use in the further diagnosis of nervous deficits related to LUT dysfunction (C).

Electrosensation in the LUT

Measurement of the sensory threshold of the LUT towards electrical stimulation was attempted as early as 1899 [147]. After re-introduction of the technique by Markland et al. [148] several authors have studied its value in neurologic bladder dysfunction. Kieswetter [149], and Powell and Feneley [150] demonstrated abnormal electrosensation in patients with NLUTD. Frimodt- Möller [151] described pathological electrosensation in patients with Parkinson's disease, multiple sclerosis and meningomyelocoele. He also found abnormal electrosensation in half of patients with diabetes and generalized sensory neuropathy, but only in 10% of the diabetic patients with a neurologic bladder. Electro sensation was present in many meningomyelocoele patients with absent skin sensation and absent reflexes, and in many patients with suspected complete spinal cord injury on clinical evaluation [78,79].

Wyndaele [152] determined the threshold of sensitivity to electrical stimulation in several parts of the LUT in 436 consecutive patients. In the groups with different patterns of disturbed sensation a higher incidence of neuropathy was found than in the group with a normal sensation. Further neurological investigation revealed abnormal innervation in 29% of patients who lacked electrosensitivity in one or more parts of the LUT but who had no previous evidence of neuropathy.

Standardization is necessary to develop the technique and achieve reproducible results [153]. While it is a constructive concept to be able to determine threshold of different fibre types selectively [154], so far no such fibre selectivity has been demonstrated in the bladder [155]. In the committee's literature search, no recent publications were found.

Conclusion:

- To determine the electrosensation in the LUT might be valuable to evaluate the afferent innervation in cases of neurologic bladder.
- Absent electrosensitivity might guide further neurologic tests in patients with LUT dysfunction (LOE 2)
- Further development and standardisation is needed for the use of electrosensation test to become established as a clinical test.

Functional Magnetic Resonance Imaging (fMRI)

fMRI has been used as a research tool in patients with overactive bladder [156-158].but only a single study has been conducted in SCI patients with neurogenic LUTD [159]

Neuroimaging-positron emission tomography (PET) and single-photon emission computerized tomography (SPECT).

Novel functional brain imaging study (PET) showed evidence for the existence of abnormal interaction between brainstem and cortical centers in women with urinary retention [160]. There are however only limited reports on using these studies in NLUTD, mainly in Parkinson's disease [161-165]. A report on using SPECT brain imaging with special reference of bladder function, performed in eight multiple system atrophy (MSA) patients suggested that the decrease in tracer activity in the cerebellar vermis during urinary storage and micturition is contributing to the micturitional disturbance in this disorder [161].

Conclusion

- These tests are still restricted to specialized centres and are considered as a research tool rather than diagnostic test.

Sympathetic skin response

Schurch et al. [166] assessed the descending sympathetic spinal tract and correlated these findings with bladder neck function in SCI patients. Evidence was presented that the integrity of the descending sympathetic spinal tract is necessary for a synergic function of the vesicourethral complex and that sympathetic skin responses (SSR) are of value in the diagnosis of bladder neck dyssynergia. SSR's are absent in case of bladder neck dyssynergia. For lesions below the T12 level, other investigative methods to exclude bladder neck dyssynergia are necessary. Rodic et al. [167] found that recording the perineal SSR in addition to that of the hand and foot represents a sensitive diagnostic tool for assessing sympathetic nerve function within the thoracolumbar spinal cord, representing a reliable and accurate diagnostic tool for assessing bladder neck competence and incompetence.

Emad et al. showed abnormal suprapubic, palmar, and plantar SSR in urinary incontinence patients due to incomplete SCI. They considered an abnormal SSR from the suprapubic area as another way to show bladder sympathetic system involvement [168].

SSR recordings above a spinal lesion level after urethral electrostimulation might provide a useful and technically simple objective diagnostic tool to assess integrity of autonomic (visceral) afferent nerves from the LUT. Somatosensory deficits are not always paralleled by viscerosensory loss and vice versa. SSR may be superior to visceral sensory evoked potentials, which are more difficult to record. The clinical utility needs to be further studied.

Conclusion

- Sympathetic skin responses may help evaluate the integrity of LUT-related sympathetic function, including bladder neck competence and synergia (LOE 2)

3. CONSERVATIVE TREATMENT

Therapeutic principles in different patterns of NLUTD depend on the underlying processes: dysfunction of the detrusor, dysfunction of the sphincter or a combination of both. Neurogenic detrusor overactivity leads to "reflex-incontinence", detrusor acontractility with incontinence due to retention (overflow incontinence). An acontractile (incompetent) sphincter causes neurogenic stress-incontinence, an overactive sphincter overflow-incontinence. Quite often detrusor and sphincter are affected simultaneously by the neurogenic lesion. In most patients the storage problem, leading to incontinence, is associated with an emptying problem; therefore both aspects have to be considered at the same time. Therapy of neurogenic incontinence is primarily a conservative one. Timed bladder emptying, by whatever means, controlled fluid-intake and avoidance of urinary tract infections are the prerequisites for successful treatment.

If incontinence persists, and if operative procedures are not indicated or possible, containment products will be needed. The indwelling catheter remains an option for conservative therapy, and can offer acceptable quality of life outcomes [1]. However, most experts regard indwelling catheterisation as being associated with significant problems [3]. While suprapubic catheters are generally preferred over urethral, there is little evidence on which to base practice [4]. Urethral leakage can persist despite continuous drainage with a SPC either due to persisting detrusor overactivity (DO), induced or aggravated by UTI, then pharmacological inhibition of DO as well as UTI treatment/prophylaxis need to be considered. Bladder neck closure is rarely indicated [5].

3.1. Overview according to type of lesion

The aim of neurogenic bladder management is to preserve kidney function and to control incontinence resp. to restore continence.

Supraspinal lesions (previously included in upper motor neuron lesions)

In supraspinal lesions**,** neurogenic DO is mostly combined with normal sphincter function; overactivity incontinence is the main symptom and behavioural treatment together with antimuscarinic therapy is the method of choice, especially in patients with cognitive impairment. Antimuscarinics are able to increase the bladder capacity but are not able to change the underlying pathophysiology.

Spinal lesions

They mostly cause simultaneous dysfunction of the detrusor and the sphincter.

Suprasacral spinal lesions (previously included in upper motor neuron lesions)

In suprasacral lesions, the spinal reflex bladder manifests the combination of DO with an overactive/ dyssynergic sphincter. For these patients, spontaneous reflex voiding may be possible. However, detrusor contractions may be inadequate and detrusor striated sphincter dyssynergia present, both potentially leading to inefficient voiding. Triggered reflex voiding is recommended only if it is urodynamically safe and reflex incontinence is manageable; accordingly, careful support is needed to achieve adequate symptom control [6] and long-term renal safety [2]. The method of choice nowadays is – at least in complete lesions – to circumvent the spastic sphincter by intermittent catheterisation. Treatment to lower tone and spasticity of the urethral sphincter can be used to aid emptying, especially in incomplete lesions using sphincterotomy [7], stenting [8] or repeated botulinum toxin injections into the sphincter [9. Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia. Sphincterotomy may help in reducing episodes of autonomic dysreflexia [11].

The mainstay of treatment in current practice is intermittent catheterization (IC) [12], undertaken by the patient or carer. However, to achieve low pressure LUT urine storage and continence between catheterisations, additional pharmacotherapy may be necessary. If bladder inhibitory agents fail or are not tolerable, electrotherapy is an alternative in incomplete lesions: ano-genital electrostimulation (penile, clitoral, vaginal and anal) can inhibit neurogenic detrusor overactivity by stimulating pudendal nerve afferents (see Electrical neuromodulation section).

Sacral/subsacral spinal cord lesions (previously called lower motor neuron lesions)

For complete conus lesions, acontractility of the detrusor with acontractility of the sphincter is character-

istic. Sphincter incompetence causes neurogenic urinary stress incontinence and may be combined with dribbling incontinence if adequate emptying is not achieved. Conservative treatment to achieve continence is often unsuccessful. Bladder expression is potentially dangerous, and pharmacotherapy is not helpful in this situation. Accordingly, appliances and condom catheters are often necessary, and consideration of suitability of surgery may be needed [9].

Acontractility of the detrusor combined with overactivity of the sphincter may occur in epiconal lesions. This pattern may also result from decompensation of a neurogenic overactive bladder after chronic urinary retention. With this combination, overflow incontinence can be controlled by intermittent catheterization- mostly without adjunctive additional pharmacotherapy. If intermittent catheterization is not possible, an indwelling catheter, preferably suprapubic (expert opinion), may be needed. If overactivity of the detrusor is combined with acontractility of the sphincter, reflex incontinence is combined with neurogenic stress incontinence. This pattern is sometimes found in epiconal lesions, especially in myelomeningoceles. Agents inhibiting abnormal bladder pathways may diminish neurogenic detrusor overactivity. In incomplete lesions, electrical stimulation of the pelvic floor musculature may improve sphincter function. However, with this type of neurogenic LUT dysfunction, conservative treatment alone is generally unable to restore continence; therefore either appliances or operative treatment must be considered.

Cauda equina and peripheral nerve lesions are often incomplete. Hypoactivity or acontractility of the detrusor may also be combined with a normally functioning external striated sphincter, a combination which can be seen after intrapelvic surgery, when the pudendal nerves remain intact. Conversely, pudendal nerve lesions in which the pelvic plexus remains intact, a combination of a normally functioning detrusor with a hypo- or acontractile external sphincter may be present. If there is DO, pharmacotherapy is the first choice treatment. For some lesions, intravesical electrotherapy has been reported to increase detrusor contractility [13]. Repeated injection of botulinum toxin in the striated sphincter is a potential treatment option, not well accepted as retreatment may be necessary maybe already after three months.

3.2. Specific interventions

During the acute period of spinal or cerebral shock, bladder management comprises proper bladder drainage. For the post shock period, or for non-acute neurogenic dysfunctions, several conservative treatments are in use [14, 15]:

a. Behavioral therapy

   a.1 Triggered reflex voiding

   a.2 Bladder expression (Crédé and Valsalva maneuver)

   a.3 Toileting assistance

b. Catheters and appliances

   b.1 Intermittent catheterization

   b.2 Indwelling catheterization

   b.3 Condom catheter and external appliances

c. Pharmacotherapy

Triggered reflex voiding

"Automatic" or spinal "reflex" bladder behaviour can occur following recovery from spinal shock in suprasacral spinal cord lesions. This can be used as a means to empty the bladder, using voluntary approaches to provoking a bladder contraction by stimulation of the sacral and lumbar dermatomes. The most commonly used manoeuvres are suprapubic "tapping", thigh scratching and anal/rectal manipulation. A quadriplegic patient who is unable to perform ISC or has nobody who can do it for him may choose this option, however, mostly incontinence aids are necessary and post-void residual urine is present (see below).

If the efferent branches of the pelvic nerve are impaired, reflex emptying is much less complete, and considerable voluntary straining is additionally required to empty the bladder to a satisfactory degree. Integrity of the sacral reflexes predicts the potential to use this approach.

The aims of regular triggered reflex voiding are to achieve "balanced voiding", decreasing incontinence but ensuring safe (low pressure) urodynamic function. The possibility of collecting the urine in a socially acceptable way and a reasonable time period for bladder emptying are needed. Frequency of emptying has to be specified for each patient. Whether bladder outlet obstruction is present also has to be considered; this is not often considered in published literature. To improve emptying, control autonomic dysreflexia related to bladder filling and contraction, and avoid upper tract damage, the effect of alpha-blockers is still discussed controversially, botulinum toxin sphincteric injections have to be repeated periodically. Sphincterotomy and/or bladder neck incision may sometimes be needed. Regular follow-up is essential, though the frequency of check-up appointments is not validated.

Triggered voiding should not be recommended as first line management; in current practice, IC is the accepted standard for continence, upper urinary tract protection and improvement of quality of life.

Conclusions

- Reflex voiding is based on an unphysiological sacral reflex. It is potentially dangerous and has a limited role in managing the reflex bladder (LOE3).
- Costs of appliances and of adjuvant therapies (pharmacotherapy, surgery, urethral prosthesis etc) have to be evaluated (LOE 2).

- Treatment of co-existing sphincteric spasticity/ bladder neck obstruction and co-morbidity should be taken into consideration (LOE 1 and 2)

Recommendations

- Triggered voiding could be recommended only for patients whose situation has proven to be urodynamically safe and stable, and who can manage reflex incontinence.
- Triggered voiding can be considered for patients after sphincterotomy and/or bladder neck incision and/or alpha-blockers and/or intrasphincteric botulinum toxin injections, in order to improve spontaneous reflex voiding (C).
- Reflex voiding can be recommended only if an adequate follow-up is guaranteed (C)
- Any unit managing patients with SCI should be appropriately set up to manage acute autonomic dysreflexia.

Bladder expression (Crédé and Valsalva)

Bladder expression comprises various techniques aimed at increasing intravesical pressure in order to facilitate bladder emptying. The most commonly used are the Valsalva (abdominal straining) and the Crédé (manual compression of the lower abdomen). It has been recommended for a long time for patients with a combination of an acontractile detrusor with an acontractile sphincter or with an incompetent urethral closure mechanism of other origin (e.g. after sphincterotomy). Difficulties in emptying the bladder by expression may either be due to an inability to open the bladder neck or due to compression of the membranous urethra on its way through the pelvic floor even if it is flaccid during these manoeuvres. Therefore, especially in men, these techniques may induce a functional obstruction at the level of the membranous urethra despite complete paralysis of the musculature of the pelvic floor. Over time, patients may manifest problems such as reflux into the prostate and seminal vesicles, or epididymo-orchitis. Moreover, the high pressures could cause reflux into the upper urinary tract. The stress to the pelvic floor with these techniques several times a day also can make incontinence worse, and causes additional genital-rectal prolapse and haemorrhoids.

Adjunctive therapy to decrease outflow assistance includes alpha-blockers, sphincterotomy or botulinum toxin injections. If effective, they usually cause or increase neurogenic urinary stress incontinence. Expression of the bladder for voiding by Crédé and Valsalva can be effective. To empty the bladder, the pressures measured may be high and potentially dangerous for the upper urinary tract. Bladder expression is often not safe. Sphincter-hyperreflexia and detrusor-sphincter dyssynergia are contra-indications for bladder expression.

Conclusions

- Bladder expression by Valsalva or Credé is potentially hazardous for the urinary tract due to functional obstruction at the level of the pelvic floor (LOE 3).
- It is contraindicated if it creates a high intravesical pressure, particularly in association with reflux into the ureters or seminal vesicles. Hernias, pelvic organ prolapse, haemorrhoids and urethral pathology (strictures) are relative contraindications (LOE 3).
- Bladder expression may adversely affect a flaccid pelvic floor, potentially exacerbating incontinence (LOE 3).
- Alpha-blockers, sphincterotomy or botulinum toxin may reduce the outflow resistance, but may also induce or increase urinary stress incontinence (LOE 3).

Recommendations

- Before recommending bladder expression by Valsalva or Credé, it must be proven that the LUT is urodynamically safe. (B)
- Exclude contraindications, such as vesico-ureteric reflux, pelvic organ prolapse, hernias, urethral pathology and symptomatic UTIs before recommending this type of bladder emptying. (B)
- In general, bladder expression should be replaced by CIC in most patients with neurogenic bladder-sphincter dysfunction. (B)
- Adjunctive therapy of outflow obstruction can be considered. (B).

Toileting assistance: timed voiding, habit retraining, prompted voiding

See also the chapters on adult conservative treatment and frail elderly.

Adaptation of the drinking and voiding regimen requires education and can be implemented by the patient and/or caregivers. The aim of the behavioural process in adults is to re-establish the control of urinary continence. The goals include correcting faulty habit patterns of frequent urination, improving ability to control bladder urgency, prolonging voiding intervals, increasing bladder capacity, reducing incontinent episodes, and building a patient's confidence in controlling his/her bladder. In dependent patients all these techniques can be proposed and tried, provided that caregivers (physiotherapist, nurse, family members, etc.) are supportive.

Timed voiding is characterized by a fixed interval between toileting, e.g. every two hours. It is a passive toileting assistance program, initiated and maintained by caregivers. It is considered appropriate for patients who cannot participate in independent toileting. It has

been used where incontinence is associated with cognitive and/or motor deficits. Its aim is more to avoid incontinence than to restore a normal bladder function. For neurologic patients it has also been considered as an adjunct to tapping and/or Crédé manoeuvre and/or intermittent catheterisation. Timed voiding can also be recommended in the management of patients with excessive bladder volumes, exemplified by diabetic patients with impaired bladder filling sensation. With habit retraining the intervals between toileting are based individually on the voiding diary. As with timed voiding also theaim of habit retraining is to help patients to avoid incontinence by decreasing voiding intervals. Prompted voiding is used to teach people to initiate their own toileting through requests for help and positive reinforcement from caregivers.These techniques are more suited to patients with brain diseases than spinal cord diseases, and for patients with cognitive and/or motor deficits.. Such a program is very useful for institutionalised patients, there are no specific evaluations on neurologic patients in the literature.

Conclusions

- Behavioural techniques should be used in conjunction with other therapies (pharmacological treatment, catheterisation) (LOE 2)
- When appropriate, toileting assistance should be used to improve continence of neurologic impaired patients (LOE 3)
- Timed voiding, habit retraining and prompted voiding may be able to decrease incontinence episodes. Patients likely to benefit from the technique are those with less cognitive impairment and higher dependency (LOE 2/3)

Recommendations

- Behavioural techniques are a suitable component of the rehabilitation program for each individual. (C)
- There are no guidelines or consensus on suitable intervals for bladder emptying. They should ideally be derived from the voiding diary and other related factors (bladder volume, fluid intake, post-void residual urine volume, urodynamic parameters). (C)
- The mental status of a patient must be taken into consideration, and a rehabilitation program realistically tailored to the patient's possibilities. (B/C).

Intermittent catheterization

Intermittent catheterization (IC), including intermittent self-catheterization (ISC), aims to resume normal bladder storage and regularly complete urine evacuation. They avoid some of the complications of indwelling catheterization (IDC). IC can improve incontinence, or make patients with neurogenic bladder continent, if; bladder capacity is sufficient, bladder pressure is kept low, urethral resistance is adequate, and fluid intake is balanced with frequency of catheterization. In children with SCI, IC used with anticholinergic drugs appears to minimise upper urinary tract deterioration, improve continence and decrease infections; safe increase in capacity appears to increase with growth [16, 17]. Post-void residual signifying the need to institute IC remains to be clarified. However, Dromerick et al. [18] (LOE 2) demonstrated in a series of stroke patients that a post-void residual greater than 150 ml is an independent risk factor for development of UTI.

Most appropriate technique and catheter depend on individual anatomic, social and economic possibilities [19] (LOE 1). Two main techniques have been adopted, aseptic IC (IC) and clean IC (CIC). The aseptic non-touch technique involves the use of sterile materials each time and insertion of the catheter "out of the sheath" without touching it directly ("non-touch technique"). In an intensive care unit, some advocate wearing a mask and a sterile gown as well [20]. De Ridder et al. [21] compared SpeediCath hydrophilic-coated catheters versus uncoated polyvinyl chloride (PVC) catheters, in SCI patients. This 1-year, prospective, open, parallel, comparative, randomised, multi centre study included 123 male patients injured within the preceding 6 months. Primary endpoints were occurrence of symptomatic UTI and hematuria. Secondary endpoints were development of urethral strictures and convenience of use. The results indicate a beneficial effect regarding UTI when using hydrophilic-coated catheters. Bjerklund-Johansen et al. evaluated patient willingness to change and satisfaction with catheters for IC in neurogenic bladder dysfunction. They also compared patient response to conventional catheters and a packaged hydrophilic catheter: LoFric Primo [22]. 409 neurogenic patients were recruited and 378 (283 males, 95 females; mean age 43.5 years) completed a short-term trial. Patient satisfaction was expressed on a Visual Analogue Scale for seven topics covering use and general satisfaction. Differences regarding satisfaction, handling, time spent, and ability to cope with daily life were reported. Kovindah and Madersbacher investigated whether a silicone catheter reused over years for clean IC was safe for men with SCI [23]. Reused silicone catheter appeared to function as well as disposable. However, to reuse urinary catheters, one should consider the increased risk of infection. The authors suggest that for SCI patients in developing countries, CIC with a reusable silicone catheter may be a suitable and safe choice if one cleans and applies it. In the same way, Getliffe performed a systematic Cochrane review summarizing current evidence on the relationship between sterile single-use catheters or clean reused catheters and the incidence of UTIs [24]. 13 trials met the inclusion criteria. There was considerable variation in length of follow-up, definitions of UTI, and numbers of subjects. Attrition was a problem for several studies, and all were underpowered. Several studies were more than 10 years old,

and outcome measures were imprecise, making it difficult to draw conclusions on the benefit of one catheterization method over another. They concluded that there are no definitive studies illustrating that incidence of UTIs is affected by sterile single-use or coated catheters compared to clean reused catheters. However the current research base is weak and design issues are significant. Based on the current data, it is not possible to state that one catheter method is better than another and further research is needed (LOE1). Research to evaluate clean vs. sterile PVC catheter use, and coated vs. uncoated catheter use (both sterile and reused), is needed. It seems that single or multiple use silicone catheters are becoming more popular especially in Asian countries, studies are available only from the Japanese silicone catheter [25].

Frequency of catheterization depends on many factors, e.g. bladder volume, fluid intake, post void residual, and urodynamic parameters (compliance, detrusor pressure). Usually it is recommended to catheterize 4 – 6 times a day during the early stage after spinal cord lesion. Some will need to keep this frequency if IC is the only way of bladder emptying. Others will catheterize 1 – 3 times a day to check and evacuate residual urine after voiding. To overcome high detrusor pressure, adjunctive therapy with antimuscarinic drugs or other bladder relaxants can be indicated. For those who develop a low compliance bladder, upper tract deterioration or severe incontinence, injection of Botulinum toxin in the bladder wall or surgery, such as bladder augmentation, may be necessary.

If catheterization is begun by patients with recurrent or chronic UTI and urinary retention, the incidence of infection usually decreases. If symptomatic infections occur, improper CIC or misuse should be considered. Chronic infection persists if the cause of the chronicity remains. Treatment of UTI is necessary if the infection becomes symptomatic. Lindehall et al. evaluated the rate of complications associated with catheterization and the risk of urethral lesions in myelomeningocele treated with clean IC for a minimum of 10 years. They found that there were remarkably few problems [26]. The incidence of major urethral lesions did not increase during puberty. Larger catheters seemed to be protective against major lesions [27] (LOE3). In contrast, Chen et al. found that the incidence of urethral strictures increases with a longer follow-up, and bladder stone formation is associated with long-term use of CIC in SCI patients [28] (LOE3).

Oh et al. evaluated health-related quality of life (HRQOL) with IC in neurogenic bladder. They conducted a prospective trial involving 132 patients (81 men and 51 women, mean age 41.8 years, range 18 to 80 years) with SCI and 150 age and sex-matched controls [29]. Patients using IC have a reduced quality of life in all health domains, as assessed by the SF-36 (LOE2). In another prospective, cross-sectional study involving 102 SCI patients and 110 controls, the same group of researchers found that the risk for depression was 4.6-fold higher in patients unable to perform CIC (LOE2) [30].

Conclusions

- IC in the neurogenic bladder is effective and safe in short- and long- term use. (LOE 1)
- Complications such as UTI are regularly seen and seem to be related to both, the catheterization itself (technique and materials) and the pre-existing LUT condition (LOE 2)
- Urethral and bladder complications seem to increase in the long- term (LOE 3)
- In order to reduce and prevent complications, appropriate materials and correct techniques should be taught, performed and controlled (LOE 3)
- Adequate frequency of IC, a non-traumatizing technique and suitable materials are the key factors for a successful outcome (LOE 2)

Recommendations

- IC is the first choice treatment for those with inability to empty the bladder adequately and safely in neurogenic voiding dysfunction. It is a valuable tool for achieving continence. (A)
- Proper education and teaching are necessary to achieve a good outcome. (B)
- To prevent and reduce complications, a non-traumatizing technique (external lubricant or lubricant coated catheters) with adequate frequency of catheterization and complete emptying should be achieved. (B)
- Annual follow-up is needed. (B/C)
- Due to the poor quality of studies it is currently not possible to state whether any IC method or catheter type is advantageous (Grade D) and further research on the topic is strongly recommended.

Indwelling Catheter (IDC)

The Foley catheter was developed in the early 20th century. After the World War I, most SCI and other neurologic patients were treated with indwelling urethral catheterization (IDUC) or suprapubic catheterization (SPC) due to difficulty in voiding or urinary incontinence. While IC is nowadays recommended for neurologic patients, many still choose IDC due to difficulty in performing IC, or persistent leakage between catheterizations. In developing countries, IDC can still be the method of choice for those with urinary retention or incontinence.

IDUC placement requires meticulous technique. More frequent catheter changes may be needed in patients with recurrent UTIs. IDUC can cause various complications, such as; urethral trauma and bleeding,

urethritis, bladder stones, cystitis, acute and chronic UTI, bladder neck incompetence, meatus and urethral sphincter erosion, and bladder carcinoma. Fistulas can result from pressure effects, caused by improper catheter size and inadequate securing technique, particularly with long-term use. Therefore many experts advocate removal of an IDUC as soon as possible, and usage of other methods such as IC or SPC. Nowadays the complications of IDUC seem less, presumed due to better materials, judicious size selection and a proper technique of securing the catheter. For CIC wet patients, overnight IDUC self-placement seems to decrease risk of febrile episode due to UTI, as compared to CIC alone [31]. In the morning, the catheter was removed, washed with tap water and stored in disinfectant (LOE3).

The study by Pannek (LOE 3) reported an incidence 0.11% for bladder cancer in catheterised SCI individuals (48 out of 43,561 patients), similar to that observed in the general population [32]. However, more than 60% of the patients with SCI initially presented with muscle-infiltrating bladder cancer. Hypothetically, the expression of inducible nitric oxide synthase with IDUC [33] might predispose to formation of potentially carcinogenic nitrosamines in the bladder. Hamid et al. [34] did not find bladder cancer on bladder biopsies in patients with SCI and a mean IDUC use of 12.1 years. Literature remains conflicting as in a recent series of 129 consecutive patients suffering from NLUTD for at least 5 years, investigation with bladder washing cytology and urethrocystoscopy identified a range of relevant histological findings (bladder melanosis, nephrogenic adenoma, keratinizing squamous metaplasia, intestinal metaplasia, and muscle-invasive adenocarcinoma) in 5% of them [35]. Nevertheless, both general guidelines on bladder cancer (EAU)[36] and more specific spinal cord medicine guidelines [37] recommend urethrocystoscopy and/or cytology as part of routine follow-up for patients with NLUTD.

Routine antibiotic prophylaxis for patients with IDC is not recommended. Attempts at eliminating bacteriuria associated with indwelling or intermittent catheters are generally unsuccessful [38, 39] (LOE 4). For prevention of UTI, general cleanliness and local hygiene should be encouraged. In symptomatic UTI, it is important to consider catheter blockage and problems such as urinary stones. Symptomatic UTIs have to be treated with the most specific, narrowest spectrum antibiotics available for the shortest possible time. Guidelines for selecting antimicrobial agents in SCI patients are similar to guidelines for the treatment of complicated UTIs in the general population. Characteristics of the quinolones make them well suited for treating UTI in SCI patients [40] (LOE 4). Recommendations of the local microbiology department should be sought.

The benefit and risks of SPC are similar to IDUC, including the risk for UTI, stone formation and maintenance cost of catheter and bag. Advantages include: minimized risk of urethral trauma and pain- in neurologically impaired women with even relatively short-term IDUC, urethral destruction is a significant risk. The key disadvantage is that SPC placement requires a minor 'surgical' procedure to insert the suprapubic catheter, with potential to injure nearby organs [41]. In this respect, if the SPC is displaced, unless replaced promptly, reinsertion may be a problem through the same tract. While most centres favour SPC use, complications are well-recognised and literature is limited. Most publications are old, there are no prospective studies and no RCTs on SPC.

Conclusions:

- Long-term IDUC use in neurologic patients can predispose to complications. (LOE 2)
- Catheters should have as large a lumen as possible to maximise time to blockage by encrustation (12-14 Fr silicone catheters in men and 14-16 Fr silicone catheters for women), and 5-10 ml self-retaining balloons to minimise the pressure effect on the bladder neck. (LOE 4)
- Closed drainage systems are associated with lower infection risk. (LOE 1)
- Frequency of change largely depends on time to blockage, which is influenced by catheter materials and lumen, patient factors and infection. (LOE 3)
- SPC is a reasonable alternative to IDUC, but IC is the first line intervention (LOE 3).
- SPC is a safe and effective short-term management of urinary retention. (LOE 3)

Recommendations:

- Silicone or hydrogel-coated catheters are preferable. (A/B)
- Use sterile materials and aseptic technique, and routine catheter care in the context of a closed drainage system. (C/D)
- Catheters should be changed regularly, to try to pre-empt obstruction or infection. (C/D)
- Bladder irrigation and antibiotic prophylaxis are not recommended as a routine infection-control measure. Symptomatic UTI should be treated with narrowest spectrum antibiotic possible, according to local microbiology practice. (B)
- Patient education on daily cleanliness (meatus) and hygiene care are mandatory. (C)
- Short-term IDC during the acute phase of neurological injury is a safe management for neurologic patients. (B)
- Long-term IDC should be the last resort and may be safe only if a careful check-up of urodynamic,

renal function, and upper and lower tract imaging are performed. (B)

- Bladder screening for bladder cancer is strongly recommended, especially those with IDC more than 5-10 years. (C) Annual bladder washing cytology is recommended after the 5th year, which should be combined with urethrocystoscopy after year 10 (B)
- Annual cystoscopy and biopsy may be necessary for those with gross hematuria, or chronic symptomatic UTI refractory to therapy. (C)
- Consider the use of antimuscarinic drugs in individuals with suprasacral lesions using chronic indwelling catheters. (C)
- Patient comfort, convenience, sexuality and quality of life need to be considered. (C)

Condom catheters and external appliances

Male patients with neurogenic bladder and chronic urinary incontinence can be candidates for a condom catheter connected to a collection bag. However, some men have difficulty in applying condom catheters, e.g. due to obesity, penile atrophy or retraction.

Conclusions

- Condom catheters facilitate urinary containment in neurologic male patients (LOE 3)
- Long-term use does not increase the risk of UTI when compared to other methods of bladder management. (LOE 3)
- Complications may be less if technique, hygiene, replacement and maintenance of low bladder pressures are optimised. (LOE 3)
- Due to possible Latex allergy especially in children with congenital NBD silicone condom catheters are to be preferred.

Recommendations

- Size selection should consider control of leakage, and prevention of penile compressive effects. (B)
- Regular bladder emptying with low bladder pressures and low post void residual should be confirmed (B)

4. PHARMACOTHERAPY

This chapter deals primarily with specific issues of continence pharmacotherapy in neurologic patients. For a fuller description of the drugs in use, see chapter 8. The principal causes of urinary incontinence in this subpopulation are neurogenic DO and/or incompetence of urethral closing function. Accordingly, treatment aims to decrease storage-phase detrusor activity, increase bladder capacity and/or increase bladder outlet resistance. This picture is blurred by the occurrence of DSD, which can be present concomitantly with DO. Pharmacologic therapy alone is particularly helpful in relatively mild degrees of neurogenic bladder dysfunction. Patients with more profound neurogenic bladder disturbances may require pharmacologic treatment to improve results of other forms of management, such as IC.

In 2013 Madersbacher et. al published a review on efficacy, tolerability and safety of oral antimuscarinics in patients with neurogenic detrusor overactivity, based on thirty studies, thereof 16 randomized controlled trials , enrolling 1479 patients.

The following conclusions were made: Only oxybutynin, propiverine and trospium were evaluated in large-placebo controlled studies, demonstrating a decrease in the maximum detrusor pressure by 30 - 40 % and an increase of maximum cystometric bladder capacity 30 - 40 %. Antimuscarinics were able to normalize the intravesical pressure and to increase cystometric bladder capacity. Self selected dosing of AM, exceeding the recommended doses, improve efficacy and tolerability.

However other important parameters were not adequately investigated so far as e.g. achievement of continence inbetween catheterizations in patients on IC, also long-term data were not assessed, despite the fact that most patients with NDO are on antimuscarinic medication life-long.

Therefore the authors proposed that any further study should aim at incorporating not only urodynamic, but also crucial clinical parameters as achievement of continence and long-term results.

In 2016, three years later, an integrative review of standardized clinical evaluation tool utilization in anticholinergic drug trials for neurogenic lower urinary tract dysfunction published by Stothers et al. identified infrequent use of standardized clinical evaluation tools and reporting measures state, that data from future trials evaluating therapies for neurogenic bladder would likely be more applicable to specific patient groups, if current standardized classification and descriptors are used consistently.[1] Still the “ideal” studies are not yet available.

Also between 2013 and 2016 only a comparatively small number of relevant papers were published: 6 with Oxybutynin (Oxy.), 4 of them dealing with children, 3 with Solifenacin, 1 with each Fesoterodine, Propiverine, Imidafenacin and 1 with the “newcomer” Mirabegron. There was no study published during these years with Trospium (only in a study in combination with Oxybutynin [2] and no study with Tolterodine, only in one study with Solifenacin as active control [3].

4.1. Drugs for neurogenic storage dysfunction

Oral bladder relaxants

Antimuscarinics

General indications of pharmacological treatment in neurogenic DO are to improve reflex incontinence, decrease high intravesical storage and voiding pressures and support other interventions e.g. IC and IDC. Antimuscarinic therapy is a symptomatic treatment. In neurogenic DO, antimuscarinics may increase post void residual urine.

The evidence base for the use of antimuscarinics in patients with a neurogenic bladder is limited. In fact, in a recent Cochrane review performed on all current literature regarding anticholinergic therapy for MS-related incontinence, only five usable studies were found, and no conclusion supporting benefit could be drawn from the analysis [4].

Oxybutynin

Oxybutynin hydrochloride is a moderately potent antimuscarinic agent with a pronounced muscle relaxant activity and local anesthetic activity as well- the clinical relevance of the latter is debatable. In a prospective, 12-week dose titration trial of controlled release oxybutynin (OXY-XL), Bennett et al. [5] evaluated the efficacy and tolerability of higher dose oxybutynin chloride in patients with neurogenic bladder and multiple sclerosis, spinal cord injury or Parkinson's disease. A 7-day washout period was used before initiation of the starting dose of 10 mg OXY-XL. Doses of OXY-XL were increased by 5 mg at weekly intervals to a maximum dose of 30 mg per day guided by patient perception of efficacy versus side effect. At the end of the study statistically significant decreases in the number of voids in 24 hours, episodes of nocturia and incontinence episodes were observed. Residual urine remained unchanged. No patient experienced serious adverse events (LOE2). In a prospective, open label trial of 3 formulations of oxybutynin (tablets, syrup and extended release tablets), Franco et al. [6] evaluated the efficacy and safety of oxybutynin in children with neurogenic DO. The effect of treatment on average urine volume per catheterization and on secondary urodynamic outcomes was evaluated. Maximal cystometric capacities increased, and mean detrusor and intravesical pressures were significantly decreased at week 24. Improvements in bladder function were consistent across all oxybutynin formulations (LOE 2). Gajewski et al. demonstrated in a prospective randomized study that oxybutynin was more effective than propantheline in the treatment of DO in patients with multiple sclerosis (LOE 1) [7].

More recently two Oxybutynin papers deal with intravesical application (0,1%), one in adults, one in children (see topic Antimuscarinics Intravesical Bladder Relaxants).

Lee et.al (2014) published a retrospective, multi-centre, observational study with Oxybutynin in paediatric neurogenic bladder due to spinal dysraphism: of 121 patients 41 (34 %) received OXY. at less than 5 years of age. During a mean observation time of 19 months (range 0,3 to 111 months) there was a significant improvement of both primary efficacy outcomes, MCC increased about 8 %, mean EFP was reduced from 33 to 21 cm H2O. No serious AEs were reported; constipation and fascial flushing consisted of the major AEs. (LOE3) [8].

Propiverine

In a randomized, double-blind, prospective multicenter clinical study, Stöhrer et al. [9] compared the efficacy and tolerability of propiverine and oxybutynin in patients with neurogenic detrusor overactivity. Propiverine and oxybutynin were equally effective in increasing bladder capacity and lowering bladder pressure. The trend for better tolerability of propiverine compared to oxybutynin achieved significance for dryness of the mouth (LOE1). Propiverine hydrochloride has also been shown to be effective in neurogenic detrusor overactivity in children and adolescents, even in some of those cases unresponsive to other anticholinergics [10, 11]. The low incidence rate of adverse events evidenced a favourable risk-benefit profile of propiverine hydrochloride (LOE3).

In 2013 a review on Propiverine, of its use in the treatment of adults and children with overactive bladder associated with idiopathic or neurogenic detrusor overactivity, as well as in men with lower urinary tract symptoms was published by McKeage [12].

Propiverine is now also produced in an extended release (ER) formulation. Comparing patients with neurogenic detrusor overactivity in a double-blind randomized multi-centre study, comprising 66 patients with proven NDO Stöhrer et. al (2013) demonstrated, that both galenic formulations are equi-effective, However following propiverine ER 45 mg s.i.d higher continence rates compared with propiverine ER 15 mg t.i.d were achieved, indicating most probably more balanced plasma-levels with the ER formulation [13]. A slight tendency for superior tolerability outcome with ER compared with IR was demonstrated; however it did not reach statistical significance. (LOE2)

Trospium

Trospium is a quaternary ammonium derivative with mainly antimuscarinic actions. Trospium has been shown to significantly reduce the number of urinations, increase cystometric capacity and mean effective volume of the bladder, and reduce the incidence of urgent voids in neurogenic patients [14, 15] (LOE1). It is the only antimuscarinic which does not pass the healthy blood-brain-barrier as proved by Staskin et al. (2010) comparing the trospium levels in the blood and the CNF after trospium treatment in a group of healthy elderly people [16]. Since 2013 no further study with trospium in NDO was published.

Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist. Tolterodine has a high selectivity in vitro and exhibits selectivity for the urinary bladder over the salivary glands in vivo. Several phase II studies have demonstrated the efficacy and safety of tolterodine in patients with overactive bladder [17]. Ethans conducted a prospective, randomized, double-blind, crossover trial plus open-label comparative stage, aiming at comparing tolterodine with oxybutynin and placebo in people with neurogenic DO. Tolterodine, when used at self-selected doses (SSDs) was comparable with oxybutynin at SSDs in enhancing bladder volume and improving continence, but with less dry mouth. It seems that larger doses of tolterodine are needed to achieve best effect on neurogenic bladder [18, 19] (LOE3). Since 2013 no study with tolterodine in NDO was published.

Solifenacin succinate

Solifenacin has been extensively studied in OAB [20, 21] (LOE1). In a prospective, open-label study of solifenacin for the treatment of OAB in MS patients, van Rey et al. demonstrated a significant improvement in number of micturitions, number of pads used per day and severity of urgency compared to baseline following eight weeks of treatment [22] (LOE 2).

Three studies were published between 2013 and 2016 using Solifenacin. Krebs and Pannek (2013) report on the effects of solifenacin in patients with neurogenic detrusor overactivity as a result of spinal cord lesion. In this retrospective analysis of case histories and urodynamic data (35 SCI patients) solifenacin (dosage unknown) resulted in significant improvements in bladder capacity, decrease in maximum detrusor pressure (median -7 cm H20), reflex volum (median + 62, 5 ml) and detrusor compliance (median +25.0 ml/cmH20). The findings indicate that solifenacin significantly improves bladder capacity, detrusor compliance, reflex volume and maximum detrusor pressure. Res. two patients discontinued Solifenacin treatment due to insufficient efficacy or intolerable adverse event. [23] (LOE3)

The second study is a double-blind, randomized, active- and placebo-controlled urodynamic study (SONIC), in which 189 patients with neurogenic detrusor overactivity-NDO due to multiple sclerosis (MS) or spinal cord injury (SCI) were randomized to placebo or active treatment (solifenacin 5 mg, 10 mg and oxybutynin 15 mg) for four weeks [3] . In the primary analysis solifenacin significantly improved mean change from baseline MCC vs. placebo and was associated with improvements in bladder volume at first contraction and at first leak as well as detrusor pressure at first leak. Similar results were obtained for oxybutynin versus placebo. However the study was not powered for the comparison of Solifenacin with oxybutynin. Solifenacin 10 mg was more effective than solifenacin 5 mg in most of the parameters. (LOE1)

The third trial with solifenacin is a double-blind, randomized, placebo-controlled, 3-site study with an open label extension phase to determine the efficacy of Solifenacin in idiopathic PD patients with OAB (Zesiewicz et.al., 2015). The primary outcome measure was the change in the mean number of micturitions per 24 h period, secondary outcome measures included the change in the mean number of urinary incontinence episodes. In this pilot trial Solifenacin treatment led to an improvement in urinary incontinence, despite persistence in other OAB symptoms. Adverse events included constipations and xerostomia, central nervous system side effects are not mentioned, however in a study on patients with cerebral diseases the tolerability and safety of antimuscarinics should include systemic evaluation of central nervous system side effects. [24] A good example how to do it, is the paper of Sakakibara et al. (2013), with Imidafenacin (see below) [25]. (LOE2)

Darifenacin

Dariferacin has a higher relative selectivity for the M3 receptor compared with other anticholinergics. Darifenacin has been extensively studied in OAB, but not in neurogenic bladder dysfunction.

Fesoterodine

Fesoterodine acts functionally as a prodrug, hydrolysed by nonspecific esterases to 5-hydroxymethyl tolterodine (5-HMT). This active metabolite, responsible for the antimuscarinic activity of fesoterodine is also an active metabolite of tolterodine. Phase 3 trials have evaluated fesoterodine in OAB. There is one dose-escalating study on the pharmacokinetics and tolerability of Fesoterodine in children with overactive bladder. Of 21 children enrolled, 11 had neurogenic detrusor overactivity. Treatment-related adverse events (all mild or moderate) including 1 event each of dry mouth, constipation, dry eyes and blurred vision, and 2 events each of nausea and increased post-void residual volume. Moreover, oral administration of Fesoterodine in children produced steady-state plasma 5-hydroxy-methyltolterodine exposures similar to those in adults. [26] (LOE3)

Imidafenacin

A study by Sakakibara et. al with 62 patients, mean age 70 years (25-86) with OAB due to neurologic diseases investigated the urinary symptoms survey, moreover cognitive tests (MMSE, FAB, ADAS-cog) were performed in all patients. Urodynamics were conducted in 35 patients and real-time near-infrared spectroscopy (NIRS)-urodynamics in eight patients before and after Imidafenacin for 3 months at 0,2 mg/day. [25]

Imidafenacin significantly ameliorated urinary urgency, night-time urinary frequency, and quality of life and - most important - the three cognitive measures did not change significantly. Urodynamics showed increased bladder capacity, but detrusor overactivity did not change significantly. NIRS showed changes

in the bilateral prefrontal area but without statistical significance. It is concluded, that imidafenacin effects on bladder and brain function, ameliorated bladder sensation without cognitive worsening, with a trend of prefrontal activation. Imidafenacin seems safe in treating OAB patients with or due to neurological diseases.

The long term results of double anticholinergic therapy for refractory neurogenic and non-neurogenic detrusor overactivity were reported in a paper by Nadeau et.al. (2014) in a prospective open-label study. Results showed that with DO or NDO refractory to anticholinergic monotherapy double anticholinergic therapy is feasible and efficient approach. Side effects were reported by half of the patients (28/56) light by 20, moderate by 8 and severe in 2 with withdrawal from the study. [27]

Dual therapy with antimuscarinics

Dual therapy (between combinations of oxybutynin, tolterodine and trospium) has been shown to be effective and well tolerated in a few patients with neurogenic bladder dysfunction [28] (LOE 2).

Hadiji et.al (2014) evaluated efficacy of anticholinergic agents in the treatment of neurogenic overactive bladder and neurogenic detrusor overactivity in spinal cord injury patients on clean intermittent catheterization. Neither the monotherapy nor a combination of Oxybutynin with Trospium was not always satisfactory in terms of control of NDO and rarely allowed full continence. [2]

Antimuscarinics in neurological patients with cognitive impairment

In the cognitively impaired, antimuscarinics should be prescribed with a warning about possible deterioration in memory or the onset of confusion. It would appear sensible to recommend the use of antimuscarinics that are likely to have less impact on cognition, either by lower propensity to cross the blood–brain barrier (e.g. trospium chloride) or by relative selectivity for the M3 receptor (e.g. darifenacin) which is not known to be involved in cognition; evidence affirming these considerations is limited. Only one study by Sakakibara et al. (2009) with results on the management of overactive bladder in elderly individuals with dementia, the combined used of donepezil (a central acetylcholinesterase inhibitor) and propiverine (a peripheral muscarinic receptor antagonist) showed by evaluated MMSE and mean ADHS-coc that there was no significant change in these parameters when propiverine was added to cholinesterase inhibitor therapy. The authors conclude that this combination of therapy - acetylcholinesterase inhibitor plus propiverine could become an option in patients who suffer from dementia and OAB together.[29] In a randomised, double-blind, parallel group, multicentre study of 3 weeks treatment with darifenacin in the healthy elderly, no significant effects on memory compared to placebo was observed, in comparison to oxybutynin ER which caused significant memory deterioration [30] (LOE 1). In a single-centre, non-comparative, pre-post dose intervention phase IV study of healthy elderly that was primarily designed to evaluate CSF trospium levels after orally dosed trospium , no decline in performance on tests of learning and memory was observed following ten days [31] (LOE 2).

Recommendations

- The evidence demonstrating the efficacy of oral pharmacotherapy in the management of storage NLUTD symptoms concerns mainly the older antimuscarinics. More large-scale randomised controlled studies are needed to evaluate this further.

Beta-3-Andrenoceptor agonists – Mirabegron

Only one study is so far published reporting the initial experience with the treatment of neurogenic detrusor overactivity with the β-3 agonist Mirabegron as monotherapy in patients with spinal cord injury in a retrospective chart analysis comprising 15 patients with NDO during a period of at least 6 weeks. There was a significant reduction of the frequency of bladder evacuation per 24h (8,1 vs 6,4, P = 0,003) and incontinence episodes per 24h (2,9 vs. 1,3, P=0,027). Furthermore there was a improvement in bladder capacity (from 365 to 419, of compliance and of detrusor pressure during storage phase (45,8 vs. 30 cm H_20). However, due to the limited number of patients and the retrospective nature of the study, prospective, placebo-controlled studies are needed. In regards to tolerability it is mentioned, that NDO treatment with Mirabegron in patients with NLUTD due to SCI is feasible and well tolerated, without giving any further details on tolerability and safety. [32]

The different working mechanisms of antimuscarinics and the beta-3-adrenoceptor agonist Mirabegron let us assume that a combination of both could have synergistic effect. In a study by Wada et. al (2015, phase IV study, article in Japanese) efficacy and safety of Mirabegron in patients with neurogenic bladder, who had detrusor overactivity or a low compliance bladder despite taking anticholinergic medications are reported. Mirabegron was added to the anticholinergic medication (Solifenacin 5 mg, 10 mg and Tolterodine 4 mg). After 7 months of the combination with Mirabegron (50 mg, once daily) together with the anticholinergics, incontinence improved in all patients, bladder deformity improved as well, VUR disappeared in all 3 patients. The authors conclude that combination therapy of Mirabegron with anticholinergics is effective and beneficial for neurogenic bladder resistant to anticholinergic monotherapy. [33]

Based on these however limited results Mirabegron is an alternative in NDO if antimuscarinics are contraindicated, not effective or cause intolerable side effects. Cognitive impairment should not occur. Beta-3-

receptors are also in the brain, however, their functions is unknown.

Oral cannabinoid agonists

The cannabinoid system comprises exocannabinoids and endocannabinoids. Both anecdotal reports of MS patients [34] and clinical trials [35-37] suggest that cannabis and cannabis-based medicinal extracts (CBME) improve skeletal muscle spasticity as well as bladder and bowel dysfunction. An open-label (LOE3) study using sublingual spray of extracts containing delta-9-tetrahydrocannabinol (THC) and/or cannabidiol (CBD) in patients with advanced MS and NLUTD concluded that both extracts significantly reduced urinary urgency, the number of incontinence episodes, daytime frequency, nocturia, daily total voided and catheterized urine volumes as well as incontinence pad weights [35]. *Freeman et al.* (2006) investigated the effect of a CBME (Δ9-THC) on urgency incontinence in a large multi-center, randomized, placebo controlled trial (the CAMS-LUTS study) involving 647 patients with MS. The study demonstrated a significant effect of CBME on incontinence episodes compared to placebo (LOE1)[36]. Another multicentre double-blind, placebo-controlled trial specifically studying LUTS in 135 patients with advanced MS used an endocannabinoid modulator comprising THC and CBD in a 1:1 ratio (Sativex). The active treatment improved daytime frequency, nocturia, and Patient's Global Impression of Change significantly more than placebo (LOE1)[37]. Improvements in urgency and urgency incontinence episodes did not reach statistical significance over placebo.

With regards to endocannabinoids, Strittmatter et al. (2012) investigated the distribution of fatty acid amide hydrolase (FAAH; cannabinoid degrading enzyme) immunoreactivity in the human urothelium [38]. Aizawa et al. (2014) demonstrated in a rat experiment that inhibition of peripheral FAAH suppresses the A-delta and C-fiber activity of primary bladder afferents via CB1 and CB2 receptors, a promising finding for further research [39].

Intravesical bladder relaxants

Antimuscarinics

Since the first use of the intravesical application by Brendler et al. in 1989 [40], there have been several articles reporting successes of intravesical oxybutynin to treat OAB and neurogenic DO. The main findings were, at least at short term follow up; improved LUTS, fewer incontinence episodes, an increase of maximum bladder capacity and decreased DO. George et al. 2007 compared the therapeutic response of intravesical oxybutynin, propantheline, and capsaicin in the treatment of neurogenic DO [41]. Oxybutynin 5 mg in solution or propantheline 15 mg in solution and capsaicin were instilled intravesically in each patient. Urodynamic studies were done before and after the intravesical instillation of each drug. There was a significant difference in therapeutic response between intravesical oxybutynin, propantheline, and capsaicin in the treatment of detrusor overactivity for leak volume (LV) and leak frequency at 2nd week. When comparing responses of oxybutynin and propantheline, more subjects demonstrated improvement with intravesical propantheline than oxybutynin for reflex volume, detrusor leak point pressure, clean intermittent catheterization volume, and LV (LOE3). However, there is no standard instillation protocol concerning the use of intravesical oxybutynin; doses used range between 5-30 mg, diluted in 30-40 ml saline [41, 42]. Also the instillation frequency is not standardized and varies between 1 to 3 times /d. Small case series report on long-term success of intravesical oxybutynin (up to 3 years in adults, up to one year in children with NDO (LOE4) [43, 44]. Despite favourable results on urodynamic parameters, there is also a low level of evidence for the use of intravesical oxybutinin in low-compliance neurogenic bladders [45]. Modulation of the ice-water test and suppression of the electrical perception threshold by oxybutynin has been studied [46]. An animal experiment suggested that early administration of oxybutynin might have a protective effect on structural bladder alterations, at least in obstructed animals [47].

Fader et al. 2007 [48] tested the efficacy and side effect profiles of intravesical atropine compared to oxybutynin immediate release (IR) in MS. They performed a study to determine the most effective dose of atropine. Eight participants used increasing doses of intravesical atropine (2 to 6 mg in 20 ml saline) during a 12-day period. Bladder diary data showed that the instillation of 6 mg atropine 4 times daily was most effective for increasing bladder capacity (voided/catheter volumes). Afterwards they performed a randomized, double-blind crossover trial. Participants received 14 days of treatment with oral oxybutynin IR 5 mg twice daily (range 2.5 twice to 5 mg 4 times daily) or with intravesical atropine, followed by 14 days of alternative treatment. Participants recorded a bladder diary and rated side effects and quality of life. The primary outcome variable was bladder capacity. 57 participants with MS completed the study. Average change in bladder capacity was higher in the atropine arm. Changes in incontinence events and voiding frequency were not statistically different between the arms. Changes in total side effect and dry mouth scores were significantly better in the atropine treatment arm. These findings suggest that intravesical atropine is as effective as oxybutynin IR for increasing bladder capacity and has less antimuscarinic side effects (LOE2). However, no further results of clinical trials with intravesical atropine have been published since. Since 2013 two papers deal with intravesical application of oxybutynin (0,1 %), one in children and one in adults:

In the paediatric long-term study with evaluation 15 ± 1 years after the switch from oral to intravesical, bladder compliance shows a statistically significant increase; pyélonéphritic episodes decreased, from 10

during the 2 years on oral to 3 over 15 years with intravesical oxybutynin indicating that intravesical oxybutynin provided more than adequate suppression of detrusor activity without side effects for a period of 15 years [49] (LOE3).

The adult study is a randomized, prospective, controlled multi-centre trial comparing intravesical 0,1 %, oxybutynin 3 times per day with a group on oral oxybutynin 5 mg, 3 times a day, each for a period of 28 days: There was a statistically significant increase in maximum bladder capacity with intravesical application compared to oral oxybutynin ADR were reported by 55,6 % with intravesical and 82,5 % with oral administration. Significant differences in favour of intravesical application were observed in ADR affecting vision, gastrointestinal tract, nervous system, skin and subcutis [50]. ADR from the nervous systems are reported 2/10 with intravesical vs 8/14 with oral OXY. But also in this study as in others (exception a study of Sakakibara on Imidafenacin [25]) no systematic evaluation of CNS effects using relevant cognitive tests was undertaken. (LOE 2)

Nociceptin/orphanin FQ (N/OFQ)

Nociceptin is a peptide that exerts several physiologic actions at both the central and the peripheral level by activating a specific G-protein-coupled receptor named nociceptin orphan peptide (NOP) receptor. Animal studies have demonstrated that N/OFQ inhibits the micturition reflex in the rat [51]. Lazzeri et al. recently studied the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of the endogenous peptide N/OFQ in a selected group of patients who performed CIC for neurogenic DO [52]. A total of 18 patients were randomized to receive 1 mg nociceptin/orphanin FQ in 10 ml saline or placebo (saline) at the first catheterization for 10 days. Mean daily urine leakage episodes significantly decreased from 2.18 at baseline to 0.94 during nociceptin/orphanin FQ treatment, while no significant changes were reported in the placebo group. The bladder capacity significantly increased in patients receiving nociceptin/orphanin FQ. The urodynamic parameters showed an increase in cystometric capacity and a decrease in maximum bladder pressure. Although these findings supported the use of nociceptin/orphanin FQ peptide receptor agonist as an alternative approach for controlling NDO incontinence (LOE2), no further study results have been published since 2006.

Compounds acting via the transient receptor potential (TRP) channels

The vanilloids, capsaicin (CAP) and resiniferatoxin (RTX), desensitize afferent nerves by binding TRPV1 receptors. CAP has been the subject of small, short-lasting placebo-controlled trials in patients with SCI or MS [53] (LOE1-2). Thus, the use of CAP is still largely experimental and limited by the fact of prolonged and painful excitation of the sensory c-fibers. The alcoholic solvent may be a major factor in the poor tolerability of alcoholic CAP instillation, as suggested by the result of one placebo controlled study showing that side effects appeared to be the same after intravesical instillation of CAP diluted in 30% ethanol as after instillation of ethanol alone (LOE2).

RTX acts without the potent neuronal excitatory effect of capsaicin, and therefore elicits less discomfort. The difference in tolerability of the 2 vanilloids (CAP vs. RTX) was usually attributed to the differential pungency of the 2 agents. Nevertheless, because we know the role of the solvent in the irritative effect on bladder mucosa, it is reasonable to assume that differential effects could be related to the use of different vectors. From a technical point of view the choice of the solvent is limited because of the poor hydrosolubility of CAP, imposing the use of an alcoholic, lipidic or glucidic vector. The safety of the lipidic solution could be imperfect because of difficulty of achieving complete elimination of lipidic solution from the bladder. On the contrary, a glucidic solution may represent a safe and valuable alternative to the alcoholic vector. De Seze et al. [54] compared the efficacy and tolerance of intravesical instillations of CAP and RTX using a glucidic solvent for CAP and the 10% ethanol solvent for RTX in a controlled randomized, double blind study in patients with severe urinary incontinence due to spinal cord injury. On day 30, improvement was found clinically and urodynamically in 78% and 83% respectively of patients treated with CAP vs. 80% and 60% treated with RTX. No significant difference between the 2 groups was observed. The benefit remained in two-thirds of the 2 groups on day 90. There were no differences in regard to incidence, nature or duration of side effects in CAP vs. RTX treated patients. These results once more strongly argue for the importance of accounting for the role of vanilloid solute when interpreting efficacy and tolerance of vesical vanilloid instillation in neurogenic DO cases. They suggest that a glucidic solution is a valuable solvent for CAP instillation (LOE2).

RTX seems to have a beneficial effect on neurogenic DO (LOE 2). However, good randomized controlled studies are needed to determine its place in the treatment of NDO. Also the optimum doses (concentration) as well as the inter treatment intervals need to be determined. Moreover, the long-term safety of vanilloid agents, particularly concerning mutagenic and carcinogenic effects on the bladder wall is not perfectly known. RTX belongs to the family of tumor promoting phorbol esters, strengthening the need to ensure the safety of RTX before extending its therapeutic applications.

Initial interest in RTX has declined following the introduction of intradetrusor Botulinum toxin injections in the treatment of intractable neurogenic DO. In a randomized trial comparing onabotulinumtoxinA injection to resiniferatoxin intravesical instillation in 25 patients with spinal neurogenic DO [55] there was a significant decrease in catheterization and incontinence episodes for both treatments at 6, 12, and 18-months of follow-up. However, onabotulinumA injections provided superior clinical and urodynamic benefits as compared to intravesical resiniferatoxin, although

RTX did not necessitate subsequent intermittent catheterisation (LOE1-2).

Transient receptor potential channels are being increasingly investigated as targets for the treatment of detrusor overactivity. Piperine, a novel vanilloid compound, was found to have both acute and prolonged in vitro effects [56]. In an animal model of chronic spinal NDO, systemic administration of GRC-6211, a novel TRPV1 antagonist, could abolish DO [57]. An antagonist of another TRP channel, the ankyrin-repeat transient receptor potential 1 channel (TRPA1), could decrease the number and amplitude of non-voiding bladder contractions in SCI rats [58]. Finally, nitro-oleic acid, an electrophilic fatty acid nitroalkene derivative which modulates gene transcription and protein function via post-translational protein modification demonstrated TRP-agonist actions affecting both the TRPV1 and the TRPA1 receptors in rat bladders [59].

For both vanilloids no clinical studies were published between 2013 and 2016.

Potential intravesical treatments with Cannabinoid modulators

While orally administered cannabinoid modulators appear to improve neurogenic OAB symptoms, particularly in MS patients [60], the identification of functional cannabinoid receptors (CBs) in the human bladder urothelium [61, 62] has intensified research in intravesical cannabinoid agonists for bladder dysfunctions. To date, only preclinical studies exist, and in non-neurogenic bladder models. Cannabinor, a selective CB2 receptor agonist, was found to affect bladder function in both normal rats as well as rats with bladder outlet obstruction, by increasing intervals between bladder contractions as well as flow pressures [63, 64]. In rats, but not humans, a Cannabis sativa extract enriched in cannabidiol drug substance reduced cholinergic-mediated bladder contractility in vitro [65]. Intravesical application of a non-selective cannabinoid agonist suppressed afferent activity via activation of CB1 receptors [66]. Finally, intravesical administration of the fatty acid amide hydrolase, the enzyme responsible for the degradation of the endocannabinoid anandamide, altered afferent-related urodynamic parameters in normal rats [67]. In a single study using a spinal cord injury model, systemic administration of a CB2-selective agonist could improve spontaneous voiding, possibly via a positive effect on inflammatory responses in the spinal cord [68].

4.2. Drugs for sphincter deficiency

Several drugs, including alpha-adrenergic agonists, estrogens, beta-adrenergic agonists and tricyclic antidepressants, and duloxetine have been used in an effort to increase outlet resistance. No adequately designed controlled studies of any of these drugs for treating neurogenic sphincter deficiency have been published.

4.3. Drugs for treating voiding dysfunction

Alpha-adrenergic antagonists (alpha-blockers)

Alpha-adrenoceptors are present in the bladder base, posterior urethra and prostate. Alpha-blockers have been already reported to be useful in neurogenic bladder by decreasing urethral resistance during voiding. Tamsulosin has been shown to improve bladder storage and emptying in MS and SCI [69]. Abrams et al. [70] evaluated the efficacy and safety of tamsulosin in patients with neurogenic lower urinary tract dysfunction secondary to suprasacral spinal cord lesions in a 4-week randomized controlled trial (RCT) followed by a 1-year, open label, long-term study. A total of 263 patients were randomized to 4-week double-blind therapy with placebo, or 0.4 or 0.8 mg tamsulosin once daily. The primary efficacy parameter was maximum urethral pressure (MUP). In the long-term study, but not in the RCT trial, there was a statistically significant mean decrease in MUP from baseline to end point. In the long-term study tamsulosin also improved several cystometry parameters related to bladder storage and emptying, e.g. decreased maximum urethral closure pressure. It also increased mean voided volume based on the micturition diary. There was statistically significant improvement for the International Prostate Symptom Score Quality of Life. Both doses were effective and well tolerated. (LOE1).

The value of alpha blockers with neurogenic LUT dysfunction is still discussed controversially. The efficacy of selected alpha-blockers in the treatment of children with neurogenic bladder dysfunction is investigated by Kroll et.al. (2016). The aim was to assess the usefulness of selective alpha-1-blockers in children with neurogenic urinary tract dysfunctions and increased leak point pressure (LPP). 14 children from age 6 to 16 years with LPP higher than 40 cm H_20 were enrolled in the study. All patients received the selective a1-blocker doxazosin for 6-8 weeks (initial dosage 0,03 mg/kg). The differences both in LPP and LPV before and after treatment were not statistically significant. This observation is consistent with the conclusions from other studies and showed no evident efficacy of doxazosin in children with neurogenic bladder. [71]

Conclusions

- Antimuscarinic drugs improve storage function (LOE 1).
- Antimuscarinic drugs have a high incidence of side effects (dry mouth, constipation, urinary retention, etc.). Tolterodine, propiverine, trospium and controlled-release oxybutynin have significantly less side effects compared to immediate-release oxybutynin (LOE 1).
- High doses of oxybutynin have been used to treat patients with neurogenic bladder dysfunction (LOE 3)

- Intravesical instillation of oxybutynin may be an alternative route of administration (LOE 4).
- An alternative to antimuscarinics is the beta-3-agonist Mirabegron, however, only one study was published so far. The advantages in regards to side effects compared to antimuscarinics are evident.
- There is LOE1 data to support a beneficial effect of oral cannabinoid agoinsts on neurogenic lower urinary tract dysfunction in patients with MS
- Intravesical instillation of capsaicin/resiniferatoxin has been reported to improve spinal reflex incontinence. Resiniferatoxin is preferable (LOE 3). Recent results supporting their use are lacking.
- Long-term alpha adrenergic antagonists are effective and well tolerated in patients with MS and suprasacral spinal cord lesion with neurogenic lower urinary tract dysfunction (LOE1)
- There is no adequately designed controlled study of any drug for neurogenic sphincter deficiency.

Recommendations

- Antimuscarinic drugs should be recommended for the treatment of neurogenic detrusor overactivity (A). Titration of the dosage of these drugs individually should be done to optimal balance of therapeutic and adverse effects. If one drug is not tolerated, another drug should be tried (C/D).
- The use of oral cannabis-based medicinal extracts can be recommended for MS patients with NLUTD, currently in specialized research centres (C). Further research is needed on oral and intravesical cannabinoids in patients with NLUTD
- Vanilloid intravesical therapy still remains experimental and therefore is not recommended except within clinical trials (C/D)
- For decreasing outlet resistance in neurogenic bladder a-adrenergic antagonists may be used (B/C).
- For neurogenic sphincter deficiency, no effective drugs are available up to now; further research is needed (D).
- For detrusor acontractility no effective drugs are available up to now; further research is needed

5. MINIMALLY INVASIVE TREATMENTS

5.1. Botulinum neurotoxin type A injections

Botulinum neurotoxin type A for neurogenic incontinence

Efficacy. Botulinum neurotoxin type A (BoNT/A) intradetrusor injections has become the newest approved treatment for urinary incontinence in adult neurological patients with inadequate response to (or reduced tolerance of) an anticholinergic medication (U.S. Food and Drug Administration approval) in the OnabotulinumtoxinA (BOTOX®) format. Similar approval has been granted in European countries. Several systematic reviews [1-4] [5, 6], meta-analyses [7] and randomized, controlled trials (LOE1) [8-14], an active comparator-controlled trial (LOE1-2)[15], four LOE2 studies [16-19], as well as numerous LOE3 studies have confirmed the efficacy of BoNT/A in the treatment of refractory neurogenic DO incontinence. Clinical improvement is accompanied by significant ameliorations in bladder function, as urodynamic parameters that matter in the management of NDO, namely maximum cystometric capacity, maximum detrusor pressure and reflex volume, appear to gain substantial benefits [1-3, 20]. Almost all studies have published on two BoNT/A preparations, onabotulinumtoxinA (Botox®) and abobotulinumtoxinA (Dysport®)[3, 5]. The two formats are not interchangeable and there are no direct comparisons for dose, efficacy and safety, at least in urological indications. Although both products appear to be efficacious in NDO, onabotulinumtoxinA has been more comprehensively studied than abobotulinumtoxinA [3]. Two LOE1 studies have been published reporting abobotulinumtoxinA [14, 17]. An LOE3 study suggests that onabotulinumtoxinA may be more efficacious than a novel BoNT/A preparation, Prosigne, in the treatment of refractory NDO [21].

The mean duration of efficacy of a single injection is 6-16 months for onabotulinumtoxinA and 5-12 months for abobotulinumtoxinA [3]. The FDA regulatory trials (275 and 416 patients, respectively) demonstrated a mean duration of effect of 37-42 weeks for onabotulinumtoxinA compared to 13 weeks for placebo [10, 12]. Complete continence was achieved in 36-38% and 40-41% respectively with the 200U and 300U doses of onabotulinumtoxinA as opposed to 7.6-10% with placebo. Interestingly, significantly higher post-treatment continence rates have been reported in single-centre studies with both preparations (a mean 71% with onabotulinumtoxinA and 65% with abobotulinumtoxinA) [3]. Similarly, reduction in the number of daily leaks was significantly superior in LOE3 compared to LOE1&2 studies (80% vs 63%, p=0.01) [5], but the majority of LOE3 studies had used 300U onabotulinumtoxinA. The concomitant use of anticholinergics does not appear to provide additional benefit [22], although this needs to be

confirmed in specifically-designed studies. In those taking anticholinergics, onabotulinumtoxinA initially reduces the dose of anticholinergics needed, but this tends to increase again at longer follow-ups [23] [24]. A single real-life study has investigated the effect of switching from the earlier used 300U to the newly approved 200U onabotulinumtoxinA [25]. Although 94% of patients continued to experience symptomatic improvement, 25% reverted back to the original 300U dose. Somewhat greater reductions in daytime frequency and nocturia were recorded with 200U vs. 300U (87.5% and 81.3% respectively *vs*. 75% and 75%) but lesser urgency improvements (75% vs 81). At three year follow–up, 82% of patients who had switched to the lower dose were happy and keen to continue receiving 200IU OnabotulinumtoxinA. Several retrospective studies [19, 26-36] and a single prospective trial [37] now attest to the sustained efficacy of repeat treatment sessions with either of the two formulations. In prospectively followed-up patients opting for repeat injections, the median duration of effect was ≥9 months, with one in four patients enjoying an even more lasting effect of at least one year [37].

Reported failure rates are 5-25% for onabotulinumtoxinA and 10-32% for abobotulinumtoxinA [3] [39]. Clinical predictors of success/failure in NDO have little been studied. A study of spinal cord injured patients proposed that the level of injury may be important as patients with thoracic and lumbar injury had better clinical and urodynamic outcomes compared to cervical injury patients [38]. A longer duration of MS has been proposed as a predicting factor for treatment failure [9] (LOE3). To date there is no robust evidence to link treatment failure with the formation of neutralizing BoNT/A antibodies, but a wide range of antibody formation rates following treatment has been reported (0-35%) [40-43] and its clinical significance needs further investigation. A small, midterm, controlled study in children (LOE1-2) found no association between antibody formation and treatment failure, but reported an increased rate of antibody formation in those receiving repeat versus single injections (71% vs. 38%) [44] up to 4 months post treatment. In the long-term, antibody titers returned to control levels. Patient-related factors also affect adherence to treatment; in a long-term study with a mean 12-year follow-up, 21% of patients discontinued treatment due to inadequate efficacy, but another 19% opted for other treatments (antimuscarinics, sacral neuromodulation) despite the toxin's efficacy [36]. In another study, only 59.3% of spinal cord injured patients were satisfied with repeat treatments and only 20% continued after a fourth injection, with 33.9% reporting inadequate efficacy and 6.8% discontinuing due to adverse events [35]. Nevertheless, in treatment failures toxin switch could be more effective than re-injection with the same toxin (51.7% vs. 24.1%). Patients treated with a switch from abobotulinumtoxinA to onabotulinumtoxinA and those treated with a switch from onabotulinumtoxinA to abobotulinumtoxinA had similar success rates (52.9% vs. 50%)[45].

Patient populations. The majority of the studies involved participants with neurogenic bladder due to SCI or MS, often mixed, while only small case series investigated efficacy in patients with Parkinson's disease, multiple system atrophy or cerebrovascular accident (CVA) [46-49]. Comparisons of efficacy between neurological subpopulations are generally lacking, although a small LOE3 study suggested better continence outcomes and more significant improvements in maximum detrusor pressures in SCI patients compared to those with CVA [49]. The largest RCTs which involved MS and SCI patients conclude that the toxin is highly efficacious in both subpopulations [10, 12]. A lower placebo effect in the SCI subpopulation could be noted, although the studies were not designed for head-to-head comparisons.

Doses. The FDA registration studies demonstrated a similar efficacy and adverse event profile for the 200U and 300U onabotulinumtoxinA (BOTOX) doses, suggesting a plateau in the efficacy of the toxin. Similar conclusions were drawn by a smaller randomized study [19]. Providing the best benefit/risk ratio, the 200U onabotulinumtoxinA dose was recommended for the treatment of refractory NDO incontinence [10] [12]. A LOE2 study suggested a trend towards better clinical and urodynamic improvements with 750U as opposed to 500U abobotulinumtoxinA [46]. Other, non-randomized and inadequately powered studies (LOE3)[16, 17, 50] could not identify a clear dose-response for higher doses of abobotulinumtoxinA, although 1000U abobotulinumtoxinA might produce a beneficial effect of greater duration than that with 500U[17].

Little data exists on lower doses. A pilot LOE3-4 study suggests that 100U onabotulinumtoxinA could be effective in MS patients and minimize unfavourable side-effects, particularly the need for IC [51], while a LOE1 dose-response study confirms a more significant clinical benefit of the 200U dose as opposed to the 50U and 100U doses of onabotulinumtoxinA in patients with SCI [13].

Effect on quality of life (QOL). Both preparations have been shown to improve patients' QOL in RCTs. The I-QOL questionnaire has been used in the majority of LOE1 studies. Patients with NDO-associated incontinence receiving a single injection of 500 units abobotulinumtoxinA, diluted in 25 ml saline and injected into 25 injection sites, had a more significant change in clinical, QOL and urodynamic parameters when compared to placebo at 26 weeks, in addition to reduced use of anticholinergics [9]. Similarly, 200U and 300U onabotulinumtoxinA administered into 30 injection sites improved QOL scores significantly more than placebo in all LOE1 studies [10-12, 52][53, 54]. Moreover, OnabotulinumtoxinA-treated patients achieve their treatment goals at significantly higher proportion than placebo-treated patients (LOE1) [55]. Fully published data on QOL following repeat treatments is sparse; in a 3-year extension study of the registration trials, QOL improvement was sustained

with repeat injections (up to six) in parallel with clinical benefits [56].

Administration technique. A large variance in the number and volume of injections has been described. However, in the majority of studies onabotulinumtoxinA was given at 30 injection sites (range 10–40) at a dilution of 10U/1ml per injection site (total volume of 30 ml, range 3–30 ml), as described in the original publication by Schurch et al. [57]. The same dilution and number of injection sites was used when administering either 300U or 200U onabotulinumA in the regulatory trials. Administration of abobotulinumtoxinA is less standardized (10–30 injection sites, total volume of 5–30 ml), but a total 30 ml given at 30 injection sites appears to be the most common again [3]. The effect of these variables on outcomes has little been studied. A recent LOE1 study compared 15 to 30 injection sites (Dysport 750 U or the equivalent placebo) and concluded that a reduction of injection sites does not affect efficacy [14]. Urodynamic results were more robust than the clinical ones, the small sample size possibly affecting the statistics. A randomised, non-controlled study on OnabotulinumtoxinA only exists in short report format [58]. Comparing 10 to 30 injection sites (300 U Botox), *Karsenty et al*. found no significant difference in number of incontinence episodes or cystometric capacity, but a significant reduction in post-procedure pain was noted in the 10 injection-sites group.

The vast majority of studies reported injections into the detrusor muscle sparing the trigone, as in the original technique [57]. There is, however, LOE2 evidence to suggest that trigonal injections may produce better continence rates than detrusor injections alone; urodynamic parameters were affected to a lesser extent, as only reflex volume was improved more significantly in patients who received trigonal injections [18]. There is also LOE1-2 evidence suggesting that submucosal injections are comparable in efficacy to intradetrusor injections, with the exception of voided volume [59] and detrusor compliance [60]. An impressive difference was found, however, in patient satisfaction favouring the suburothelial injections (88.8% vs. 64.3% of patients satisfied) [60].

Alternative delivery techniques are being investigated including intravesical instillation of BoNT/A encapsulated in liposomes [61] or via electromotive drug administration (EMDA) [62]. The former has only been tested in non-neurogenic patients in small, short-term, placebo-controlled trials [63, 64](LOE1-2) with inconclusive results. In the largest trial (n=62 patients), intravesical instillation of liposomal onabotulinumtoxinA (200U) improved micturition frequency and urgency severity scores over placebo at 4 weeks, but not urgency episodes or urgency incontinence [64]. No urinary retention episodes were reported though. The EMDA method has been tested in a pilot LOE3-4 study in children with myelomeningocele. Significant improvements were reported in maximum cystometric capacity, detrusor pressure, urinary incontinence, vesicoureteric reflux and even fecal incontinence [65], but results need to be confirmed in controlled trials.

Safety. The treatment appears to be overall safe in currently used doses and techniques. The most common adverse event is the significant increase in post-void residual in patients not using CIC prior to treatment. In onabotulinumtoxinA placebo-controlled trials, 12-22%, 30-47%, and 42-49% of patients in the placebo, 200U, and 300U groups, respectively, initiated CIC post-treatment [10] [12]. Rates of de novo CIC appear to be reduced after repeat treatments: in a 4-year study with up to six onabotulinumtoxinA injections, de novo CIC rates were 29.5, 3.4, and 6.0% (200U), and 43.0, 15.0, and 4.8% (300U) for treatments 1-3, respectively; de novo CIC rates were 0% for treatments 4-6 [56].

Although earlier studies had reported a reduced incidence of UTIs in NDO patients treated with BoNT/A [31, 66, 67], recent large RCTs [10][12] as well as systematic reviews [6] and meta-analyses [7] suggest a higher incidence of UTIs in those treated with onabotulinumtoxinA as opposed to placebo-treated patients. This might be associated with the increased rate of *de novo* CIC in the Botox®-treated population. In prospective, long-term, follow-up trials UTIs remained the most common adverse event, but with no increased incidence over time [37, 56]. Long-term controlled trials could clarify these apparent discrepancies.

Haematuria, constipation and flu-like symptoms have also been described [3, 10, 12] , while inclusion of trigonal injections does not appear to produce vesicoureteral reflux (LOE2-3) [18][68][69]. A study in SCI male patients found a post-treatment decrease in the volume of ejaculate accompanied by improvements in semen quality, sperm mobility and vitality, as well as semen culture [70]. Further research is needed to confirm these results and explore whether they are due to local re-organization of autonomic function which also affects the reproductive system.

The most serious adverse event is generalized paraparesis/ fatigue, which has been described in 0.005% of patients receiving onabotulinumtoxinA and in 0.026% of patients receiving abobotulinumtoxinA [3]. The effect resolves spontaneously after 4-6 weeks and appears to be dose-related, with most cases reported in those patients injected with 750-1000U abobotulinumtoxinA or 300U onabotulinumtoxinA [12, 29, 71].

As BoNT/A studies in skeletal muscles have identified autonomic, histological and other secondary effects [72, 73], further investigation is needed on safety issues, especially after repeat injections [2]. Preclinical studies provided evidence for transport of the toxin from the bladder to the CNS and vice versa [74, 75]. A single study to-date prospectively examined distant effects post-BoNT/A bladder injection using single-fibre EMG; one-third of the patients had findings of neuromuscular jitter post-treatment, but there was no

placebo arm or pre-treatment data for comparison [76] (LOE3). Frequency and severity of autonomic dysreflexia episodes were reported to be reduced following onabotulinumtoxinA bladder injections (LOE3)[77]. Other studies produced histological evidence of reduced or no additional fibrosis after one or multiple injections, including in children [78-80].

Future research should highlight the gaps in our knowledge of long-term treatment with focus on patient-reported outcomes and satisfaction, safety and tolerability issues as well as technical aspects such as alternative techniques of application, ways to minimize post-treatment voiding dysfunction in patients who void freely and larger studies in select patient populations.

Botulinum neurotoxin type A for neurogenic voiding dysfunction

Sphincter injections were historically the first application of BoNT/A in the lower urinary tract [81], but there is still inadequate evidence to support its use. The most commonly injected volume is 4ml of either the onabotulinumtoxinA or the abobotulinumtoxinA preparations. Usually 100U onabotulinumtoxinA or 150U abobotulinumtoxinA have been delivered transperineally or transurethrally [82, 83]. No direct comparison of injection techniques exists; there is low evidence (LOE4) to suggest the two delivery approaches are equally effective [82].

In a LOE1 study, the effects on DSD of botulinum toxin versus placebo was studied in 86 multiple sclerosis (MS) patients [84]. The study employed a single transperineal injection of onabotulinumtoxinA, 100 U in 4 ml normal saline, or placebo, into the striated sphincter with EMG guidance. The primary endpoint was post void residual volume at 30 days. The secondary endpoints included voiding and urodynamic variables. OnabotulinumtoxinA failed to decrease post-void residual volume in this group of MS patients, although it increased voided volume and reduced pre-voiding and maximum detrusor pressures. These findings differ from those in patients with spinal cord injury and may be due to lower detrusor pressures in MS patients. A small LOE1-2 study (n=13 patients) showed a superior effect of onabotulinumtoxinA over lidocaine 0.5% injected in the urethral sphincter in MS patients [83]. Another small (n=21 patients), controlled study (LOE1-2) in CVA patients with urethral sphincter pseudodyssynergia reported superior clinical efficacy in the active treatment group (91% response rate and higher improvements in QOL and symptom scores with 100U OnabotulinumtoxinA) despite highly significant urodynamic benefits noted in the control group (reduction in voiding pressures and increase in maximum flow rates) [85]. In MS patients there is also LOE3 to suggest that a combination of detrusor and sphincter injections may facilitate bladder emptying [86]. In children with NDO and DSD due to myelomeningocele there is LOE1-2 from a single study to suggest that sphincter injections additional to the detrusor injections accomplish significant improvements in post-void residuals, as well as more significant benefits in urinary incontinence, constipation, vesicoureteral reflux and creatinine levels [87].

Since the last ICI update (2012) there has been a single LOE3 study in SCI patients with NDO and DSD comparing urethral injections of 100U onabotulinumtoxinA to detrusor injections of 200U onabotulinumtoxinA depending on the main symptoms (voiding dysfunction vs. NDO-associated incontinence) and found less patient satisfaction in the urethral injection group (60.6% vs. 77.3% in the detrusor injections group) as well as greater improvements in the UDI-6 and IIQ-7 scores in the detrusor injection group, despite significant urodynamic benefits in both groups [88]. Not unexpectedly, patients in the urethral injection group were dissatisfied due to increased degree of post-Botox incontinence whereas the detrusor injection group suffered higher rates of post-treatment voiding difficulty.

Overall, randomized controlled trials (RCTs) or quasi-RCTs investigating the use of BoNT/A in patients with neurogenic DSD in comparison to placebo or active comparators were reviewed by the Cochrane database. Published data were found to be of limited quality due to the small sample sizes, the heterogeneity in the protocols, and with a high risk of bias. Nevertheless, the authors conclude that intraurethral BoNT/A injections improve some urodynamic parameters at 30 days post-injection and propose future high-quality research to address the optimal dose and mode of injection for neurogenic DSD [89].

Conclusions

- Botulinum neurotoxin A (BoNT/A) injection into the detrusor muscle improves clinical and urodynamic parameters (LOE1) as well as the quality of life (LOE1), and has been approved as second-line treatment for urinary incontinence associated with neurogenic detrusor overactivity in patients with inadequate response to or intolerance of an anticholinergic.
- Both the OnabotulinumtoxinA and the AbobotulinumtoxinA formats are effective (LOE1), but the vast majority of currently published data concerns OnabotulinumtoxinA
- Repeat intradetrusor injections of BoNT/A provide sustained clinical benefits (LOE3)
- Published LOE1 data almost exclusively concern intra-detrusor injection administration, but there is limited LOE2 data to favour trigonal and submucosal over detrusor injections
- Treatment with intradetrusor BoNT/A is considered overall safe, with increased post-void residual and need for post-treatment CIC being the most common adverse event (LOE1). A higher incidence of UTIs in those treated with the toxin has become apparent in LOE1 studies.

- Antibody formation is not associated with treatment failure, but may be increased after repeat injections (children)(LOE1-2)
- BoNT/A is probably safe and effective for the treatment of DSD in spinal cord injury patients (LOE2). However, on the basis of one LOE1 study,
- BoNT/A does not provide significant benefit for the treatment of DSD in MS patients.

Recommendations

- BoNT/A should be offered as a treatment option for incontinence associated with neurogenic detrusor overactivity (A).
- Further research is needed on long-term outcomes and safety, administration techniques, the bio-equivalence of the various preparations, the concomitant use of anticholinergic drugs or β3-agonists, mechanisms of action, and wider effects (A)
- BoNT/A may be considered for DSD in spinal cord injury patients (B)

5.2. Electrical Neuromodulation

In the last decade, sacral nerve neuromodulation (SNM) has been established as a treatment option for patients with OAB. The success with SNM has increased the interest in other neuromodulation techniques. Additional methods include; (a) anogenital stimulation (b) pudendal nerve stimulation, (c) dorsal genital nerve stimulation (d) percutaneous tibial nerve stimulation, (e) magnetic stimulation and (f) deep brain stimulation. It is not really known how neuromodulation works, but there is evidence that sites of action are spinal and supraspinal [90]. Firstly the non-surgical ways of neuromodulation will be presented, followed by the surgical techniques.

Anogenital Stimulation

This has been applied in children with OAB complaints. Gladh et al. found a response for anogenital stimulation in 53% of the children [91]. Trsinar and Kralj used an endoanal electrode and reported a complete or partial response to the treatment in 75% of the patients [92]. In a control group of patients who had the endoanal electrode introduced but not activated, no patient had the symptoms resolved completely. No recent publications could be found.

Pudendal Nerve Stimulation

Pudendal nerve stimulation and electrode positioning can be carried out under neurophysiological monitoring (using a St. Mark's electrode) in order to guide the electrode in Alcock's Canal as close as possible to the pudendal nerve [93]. Electrode implantation can also be carried out by a rear approach under local anesthesia according to the method described by the same team [94, 95]. On the other hand, an anatomical study demonstrated that the technique for implanting electrodes at the pudendal level may carry some risk [96].

Direct pudendal nerve stimulation has beneficial effects on numerous pelvic floor function impairments such as urinary and/or fecal incontinence, retention, and constipation. In preceding literature the implant technique required a fairly complex and invasive procedure, although recent advances with percutaneous placement of the lead through an introducer have made the procedure much less invasive. Electrical stimulation of pudendal nerve afferents can inhibit bladder contractions in patients with SCI, and bladder capacity can be increased [97] (LOE3). Implants such as the InterStim system have made this treatment modality commercially available (see sacral nerve stimulation). Common to these implantable systems is that they use continuous stimulation. Detrusor inhibition is in principal only necessary during an involuntary contraction and, thus, stimulation could be turned off between contractions (i.e. conditional stimulation) [98]. Such a stimulation scheme could have a number of advantages. Power consumption may be decreased and, thus, extend battery lifetime. Furthermore, continuous stimulation of a reflex may lead to habituation, which would be minimized or prevented by conditional stimulation. Hansen et al. [99] examined the effect of the automatic, event driven electrical stimulation of pudendal nerve afferents on bladder capacity in patients with SCI. The study included two women and 14 men older than 18 years with NDO, bladder capacity below 500 ml and complete or incomplete suprasacral SCI. Detrusor pressure (P_{det}) was recorded during natural bladder filling. In a similar subsequent recording P_{det} was used to trigger electrical stimulation when pressure exceeded 10 cm H2O. Of the 16 patients enrolled in this study, 13 had increased bladder capacity and reduced storage pressure decrease achieved by event-driven electrical stimulation. During stimulated filling, P_{det} never exceeded 55 cm H2O. An average bladder capacity increase of 53% was achieved (LOE 3). Ohlson et al. treated eight patients with NDO in whom vaginal/rectal stimulation failed, with acute pudendal nerve stimulation. Five achieved a decrease in urinary frequency and four had an increase in cystometric capacity [100].

Spinelli et al. [94] performed a staged procedure similar to that of sacral neuromodulation (SNM) to place a tined lead near the pudendal nerve, using neurophysiological guidance. They named this approach chronic pudendal nerve stimulation (CPNS). Fifteen neurogenic patients (eight male, seven female) with urgency incontinence underwent CPNS. All patients had complete neurophysiological and urodynamic evaluation at baseline and follow-up and were asked to complete a voiding and bowel diary for 7 days. During screening, the average number of incontinent episodes per day decreased from 7+/-3.3 to 2.6+/-3.3

(P<0.02, paired t-test). Eight patients became continent, two improved by more than 88% (from 9 to 1 daily incontinence episodes) and two patients reduced the number of incontinence episodes by 50%. The implantable pulse generator (IPG) was subsequently implanted in those 12 patients. Three patients without improvement did not continue to second stage. In implanted patients with 6 months follow-up, urodynamic evaluation showed an objective improvement in the maximum cystometric capacity which increased from 153.3+/-49.9 to 331.4+/-110.7 ml (P<0.01, paired t-test). The maximum pressure decreased from 66+/-24.3 to 36.8+/-35.9 cmH2O (P=0.059, paired t-test). Eight patients reported significant improvement in bowel function (LOE3).

Another elegant way to approach the pudendal nerve is the laparoscopic one as described by Possover et al. [101].

Only recently in 2016 an experimental study with electrical stimulation of dog pudendal nerve is showing that stimulation of the pudendal nerve trunk is a promising method to modulate bladder function. It can well be that in medium term sacral neuromodulation could be replaced by pudendal nerve stimulation, a method which was described already in 1986 by Vodusek et al. [102] and more recently, also Spinelli et al. (2006) reported success with pudendal nerve stimulation by a minimally invasive procedure in 15 patients with failed previous SNM [103].

Dorsal Genital Nerve (DGN) stimulation

DGN stimulation can be continuous or conditional. Goldman et al. used continuous stimulation for one week [104]. They found a 55% increase in cystometric capacity. In 47% there was >50% reduction in incontinence episodes, and in 81% there was >50% reduction in number of urgency events. Increases in cystometric capacity vary significantly between studies using continuous stimulation (range 11-177%) and also conditional stimulation (range 37-144%). Horvath et al. and Oppisso et al. showed that DO was suppressed conditionally, with a subsequent increase in bladder volume and postponement of incontinence [105, 106]. Martens et al. found with conditional stimulation that an increase in stimulation current results in a more pronounced detrusor inhibition [107]. Besides DO suppression, increases of the pressure at the bladder neck and the urethral sphincter contribute to continence [108]. In general, patients tolerate conditional stimulation well and they adapt to the sensation in long-term use [109]. Stimulation effectively suppresses urgency and decreases urgency episodes. Suppression of urgency during stimulation might contribute to tolerance of stimulation. This might enable stimulation at higher current to increase effectiveness when stimulation is applied conditionally.

Posterior tibial nerve stimulation

Percutaneous posterior tibial nerve stimulation (PTNS) was described 20 years ago as a minimally invasive treatment for urge incontinence due to neurogenic detrusor overactivity (NDO) in spinal cord injury (SCI) patients. Interestingly, the location where the tibial nerve is stimulated is in the same area as the Sanyinjiao (SP6) point used in Chinese acupuncture to treat pelvic floor organ dysfunctions. The PTN is derived from the L4-S3 nerve roots and therefore shares common roots with those serving bladder functions. SCI and Parkinson patients with neurogenic DO have been treated with PTNS. PTN seems to increase cystometric bladder capacity and bladder volume at which DO and associated leakage occurs [110, 111] (LOE3). Gobbit et al. looked at the effect in 21 MS patients. Eighty-nine percent of patients reported a treatment satisfaction of 70%. Significant improvement in QoL was seen in most domains of the King's Health QoL questionnaire [112]. Kabay et al. looked at the clinical and urodynamic effects in MS and Parkinson's disease [113, 114]. They found significant clinical and urodynamic improvements, although it was impossible to completely suppress DO. De Seze et al. looked at transcutaneous PTNS in 70 MS patients [115]. With daily stimulation sessions, they showed clinical improvement in urgency and frequency in more than 80% of patients at three months. They also observed an initial acute cystometric response in > 50% of the patients without correlation with clinical efficiency. There still is debate about the possibilities to really influence voiding behavior via the posterior tibial nerve [116]. PTNS is a stimulation technique that allows for sham comparison. It should therefore be tested in this fashion.

As in SNM, the literature reports of PTNS in the neurogenic bladder population is complicated by limited number of studies, small sample sizes, non-standard treatment plans, poor descriptions of the extent and severity of neurologic disease, and heterogeneous patient populations. A recent meta-analysis by Gaziev et al. (2013) including MS and Parkinson's disease showed mixed findings on success rate ranging from approximately 40 % to 100 % for neurogenic overactive bladder or urinary retention [117] (LOE3). In 2015 *Kabay et al*. published the results of a retrospective case-controlled study with 34 patients enrolled to PTNS treatment. 21 patients completed the one year PTNS treatment with controls at 6, 9 and 12 months of therapy. After 12 weeks of therapy, PTNS was applied at 14-day intervals for 3 months, then 21-day intervals for 3 months, and in the end for another 3 months with 28-day intervals. The improvements for all voiding diary parameters were significant at each control when compared to the baseline. Daytime frequency decreased by 5.4 voids daily, urgency incontinence decreased by 3.4 episodes daily, urgency episodes decreased by 7.4 episodes daily, nocturia decreased by 2.6 voids, and voided volume improved by a mean of 72.1 cc. The reported results demonstrate an excellent durability of PTNS over 12 months [118] (LOE3).

Repetitive transcranial magnetic stimulation

Repetitive transcranial magnetic stimulation (rTMS) of the motor cortex induces a long-lasting modulation of spinal cord excitability [119]. Thus, it represents a potentially useful tool for the treatment of neurogenic urinary disturbances. Centonze et al. [120] investigated the effects of low frequency (5 Hz) excitatory rTMS over the motor cortex on LUT dysfunction in 10 MS patients complaining of urinary symptoms. All but one of the patients reported an improvement of voiding phase LUT symptoms and a significant reduction of post void residual volume. In patients with pure detrusor underactivity, there was increase of $P_{det}Q_{max}$ and Q_{max}. In patients with DSD, on the other hand, rTMS produced negligible effects, although the observation of a reduction of $P_{det}Q_{max}$ in this context seems to suggest a better relaxation of the urethral sphincter (LOE3). Brusa et al. also observed positive effects lasting 2 weeks after rTMS in 8 patients [121].

Deep brain stimulation

Subthalamic nucleus deep brain stimulation (STMN-DBS)

A large proportion of patients suffering from Parkinson's disease present with urinary dysfunction including urgency, increased frequency or incontinence [122]. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been established as a surgical treatment of motor symptoms in Parkinson's disease patients [123]. However, data from experimental urodynamic measures in men [124] and animal models [125] have also demonstrated a significant influence of STN-DBS on urinary bladder function. In these studies, the main effect of STN-DBS appeared to be a normalization of urodynamic parameters in the storage phase with a delayed first desire to void and an increased bladder capacity. Herzog et al. investigated the effect of STN-DBS on the neural mechanisms underlying cerebral bladder control. Using PET to measure changes in regional cerebral blood flow (rCBF), 11 patients with bilateral STN-DBS were studied during urodynamic bladder filling in STN-DBS ON and OFF condition. A filled bladder led to a significant increase of rCBF in the anterior cingulate cortex, which was further enhanced during STN-DBS OFF. A significant interaction between bladder state and STN-DBS was observed in lateral frontal cortex with increased rCBF when the bladder was filled during STN-DBS OFF [126, 127] (LOE3).

Thalamic deep brain stimulation

The precise mechanisms underlying cerebral regulation of lower urinary tract function are still poorly understood. Essential tremor (ET) is not known to induce lower urinary tract symptoms (LUTS) or neuropathological changes in the thalamus. Consequently, DBS in patients with ET offers the unique opportunity to investigate the role of the thalamic ventral intermediate nucleus (VIM) nucleus in lower urinary tract function. Kessler at al. [128] evaluated the effect of thalamic DBS on urodynamic parameters in patients with ET. Seven patients were examined (two females, five males) with ET 15–85 months after implantation of DBS leads into the VIM. They compared urodynamic parameters during thalamic DBS (ON state) and 30 min after turning the stimulator off (OFF state). In the ON compared with the OFF state, there was a significant decrease in bladder volume at first desire to void (median, 218 ml vs. 365 ml, $p = 0.031$), at strong desire to void (median, 305 ml vs. 435 ml, $p = 0.031$), and at maximum cystometric capacity (median, 345 ml vs. 460 ml, $p = 0.016$). No significant differences between the ON and OFF state were detected for changes in detrusor pressure during filling cystometry, bladder compliance, maximum detrusor pressure, detrusor pressure at maximum flow rate, maximum flow rate, voided volume, and postvoid residual (LOE3).

Conclusions

- Electrical neuromodulation is not first line treatment for neurogenic DO. There are some limited reports showing that it may be beneficial (LOE 3).
- Automatic, event-driven electrical stimulation in the treatment of neurogenic DO is feasible (LOE 3).
- Chronic pudendal nerve stimulation is feasible. Neurophysiological guidance seems to be mandatory to place the lead near the pudendal nerve (LOE3).
- Percutaneous Tibial Nerve Stimulation gives improved clinical and urodynamic parameters. (LOE3), but its role is not established.
- Enhancing corticospinal tract excitability by rTMS might be useful to ameliorate detrusor contraction and/or urethral sphincter relaxation in MS patients with bladder dysfunction (LOE3).
- Thalamic deep brain stimulation resulted in an earlier desire to void and decreased bladder capacity, suggesting a regulatory role of the thalamus in lower urinary tract function (LOE3).
- STN-DBS appeared to tend to normalization of urodynamic parameters in the storage phase, with a delayed first desire to void and an increased bladder capacity (LOE3).

Recommendations

- If pharmacotherapy fails to relax the overactive detrusor, electrical neuromodulation may be optional in patients with neurogenic DO (C/D)
- Although the setup for conditional, event-driven electrical stimulation is not suitable in a clinical setting, the treatment modality is promising and it warrants further investigation (D).
- Further studies on chronic pudendal nerve stimulation must be carried out to identify the best

stimulation parameters and to verify the long term results (D)

- The thalamus may be a promising target for the development of new therapies for lower urinary tract dysfunction. Further investigation on this matter is needed before its potential role can be elaborated.

5.3. Electrical stimulation of the pelvic floor musculature

The aim of electrical stimulation in patients with neurogenic urinary stress incontinence is to improve key functions, namely the strength and/or timing of the pelvic floor muscle contraction. Electrical stimulation is provided nowadays mostly by portable battery powered stimulation, offering a wide combination of wave forms, frequencies, intensities, electrode placements etc.

In patients with incomplete denervation of the pelvic floor muscle and of the striated sphincter, electrical stimulation via anal or vaginal plugs performed over months, may improve pelvic floor function, and may thus improve incontinence. The incompleteness of the lesion should be as such that the patient is able to contract voluntarily the pelvic floor to some extent, even if such contraction is weak.

Conclusions

- There is no study published which deals with electrical stimulation via anal or vaginal plugs could be able to improve the strength of pelvic floor musculature (LOE 4)

Recommendations

- In patients with incomplete denervation and some voluntary contraction of the pelvic floor muscle and the striated sphincter, electrical stimulation may be an option to improve pelvic floor function, thus improve incontinence (C/D)

5.4. Intravesical electrical stimulation (IVES)

The technique involves a catheter with a stimulation electrode, introduced into the bladder and connected to the stimulator. Saline (0.9 %) is used as the current leading medium within the bladder. The neutral electrode is attached to the skin in an area with preserved sensation, usually in the lower upper abdomen. The afferent stimuli induced by IVES travel along afferent pathways from the LUT to the corresponding CNS structures. This “vegetative afferention” results in sensation of bladder filling/urge to void, with subsequent enhancement of active contractions, and possibly also in voluntary control over the detrusor. Feedback training is mediated by enabling the patient to observe the change of the detrusor pressure on a water manometer, which enables the patient to notice when a detrusor contraction takes place. This also facilitates voluntary control.

Intravesical electrical stimulation of the bladder (IVES) is still not established as a therapy for patients with neurogenic detrusor dysfunction. IVES may help to verify function of afferent pathways, proper indication is crucial and this type of therapy should only be applied in those with afferent fibers between the bladder and the cortex, proved by the evaluation of viscerosensory cortical evoked potentials. Intravesical electrotherapy may be able to improve neurogenic bladder dysfunction. Studies about IVES were reviewed in previous consultations [129].

Conclusions

- Basic research during the last decade supports the underlying working concept of IVES (LOE 3)
- The results reported in the literature are controversial, mainly because of varied inclusion and exclusion criteria (LOE 3).
- In the only sham-controlled study the treatment period was short and the inclusion and exclusion criteria were not fully defined (LOE 3).

Recommendations

- Intravesical electrotherapy may improve neurogenic bladder dysfunction, inducing bladder sensation and the urge to void (B/C)
- IVES is the only available option to induce/improve bladder sensation and to enhance the micturition reflex in patients with incomplete central or peripheral nerve damage, but corroborating controlled evidence is needed (B)
- Selection of patients is crucial and IVES should be applied only if afferent fibers between the bladder and the cortex are still intact and if the detrusor muscle is still able to contract (B)
- The ideal indication is the neurogenic hyposensitive and hypocontractile detrusor (C)

5.5. Sacral neuromodulation

Two indications for neuromodulation are clearly valid in urology: overactivity/ urgency urinary incontinence and chronic urinary retention (aside from vesicosphincteric dyssynergia) [130], as discussed elsewhere in the consultation. This section focuses on the possible application of sacral neuromodulation in patients with neurological bladder dysfunction. The literature survey was undertaken with the key words: neurogenic bladder; spinal cord injury; spina bifida; meningomyelocoele; multiple sclerosis, sacral neuromodulation

Hypotheses on the modes of action of neuromodulation

The first effects of electricity on the bladder were reported during electro stimulation treatment of pelvic floor muscles (with the aid of electrodes situated in the anus, the vagina, on the penis...) during urinary

incontinence reeducation [131-134]. Inhibition of bladder contractions by electrostimulation was seen. Tanagho and Schmidt, the pioneers of neuromodulation, attributed the benefits of neuromodulation in urinary incontinence to a hypertrophy of the pelvic muscles, allowing better control [135]. Voluntary contractions of the pelvic floor muscles can cause reflex relaxation of the bladder. However, the most widely held hypothesis currently is that neuromodulation allows a restoration of normal vesical reflexes [136-138] (LOE4). This hypothesis explains that the stimulation can inhibit the guarding reflex pathway and restore normal urination or turn off supraspinally mediated overactivity by blocking ascending sensory pathways. The role of cortico-subcortical structures was recently emphasized in studies of patients with incontinence [139, 140] (LOE4) or retention [141] (LOE4). Somatic afferents as the vectors for neuromodulation mechanism of action is supported by the observation that visceral nerve fibers are not activated by the parameters normally used [142] (LOE4). Despite data obtained in animals [143] (LOE4), it seems that neuromodulation cannot be effective in patients with a non functional peripheral nerve circuit.

Treatment of neurogenic detrusor overactivity incontinence

Prior to 2010 the literature examining the use of sacral neuromodulation (SNM) in the neurogenic population was scarce and limited by heterogeneous patient populations including multiple neurologic diagnoses, lack of randomized controlled trials, small sample sizes, and short-term follow-up. Many studies even recorded results for incontinence and for retention at the same time, without always separating the results. Since the technique's first stages, Vodusek [134, 135] (LOE4) reported that non-muscular electrical stimulation of the sacral somatic afferents can induce bladder inhibition in patients who present with DO secondary to a medullary lesion, be it due to trauma or to multiple sclerosis (MS). The data on SNM in the neurogenic population is more or less limited to patients with stroke, Parkinson's disease, MS and incomplete spinal cord injury. In recent years, however, the literature has shifted somewhat to separate studies based on individual neurologic diagnoses, moreover, one randomized trial to this effect is underway (Knüpfer at al. 2014, [144]) (LOE3). With these limitations in mind, the current literature is generally positive and indicates that SNM demonstrates similar efficacy among the neurogenic and the non-neurogenic populations in terms of successful test phase, device implantation, clinical outcomes and urodynamic outcomes.

Two points must be kept in mind when treating patients with neurological bladder:

- The disappearance of wettings between catheterizations can be considered a success by itself in patients using IC. In contrast, in able-bodied patients, treating retention with IC is most often considered a failure
- On the other hand (contrasting, for example with botulinum toxin injections), neuromodulation does not systematically require the use of IC. Furthermore, reversibility of neuromodulation is a strong point that must be considered when devising a therapeutic plan.

The main published series are summarized in **Table 4**. Author definitions for neurological pathology differed widely: some authors considered a history of pelvic surgery as a possible etiology while others included only patients with medullary neurological lesions. Despite this, several points considering the neurological etiology of the bladder dysfunction can be discussed;

- MS is not a contra-indication for neuromodulation [139, 145, 146] (LOE3-4). However, it seems important to propose this treatment only in patients who present with a stabilized form of multiple sclerosis. In addition, patients must be clearly informed that the results of neuromodulation may be altered by the evolution of their underlying illness.
- Patients with incomplete medullary lesions, whether of traumatic or other origins, may benefit from neuromodulation [139, 147-152] (LOE3-4). On the other hand, all authors agree on excluding patients with complete medullary lesions. Clinical data, especially from the Hohenfellner series [149] (LOE3), support among others those reported by Schurch et al. in 2003 [153] (LOE4). These authors published a study in which they recorded external anal sphincter (EAS) electromyographic activity caused by stimulation of the S3 sacral root during a percutaneous needle evaluation (PNE) test in three patients who presented with neurogenic DO and DSD secondary to a complete traumatic medullary lesion. They describe a reflex response with early and late latency in the three patients. They also demonstrated that the EAS contraction observed during the PNE represented an indirect motor response mediated by the afferent nerves towards the spinal cord. Despite the recording of an EAS motor response in the three patients, they did not obtain any urodynamic or clinical benefit. This suggests the participation of supraspinal neuronal centers— presumptively a spino-bulbar spinal pathway—in the SNM mode of action. However, these data are contradicted by an experimental study using bilateral neuromodulation in the cat [154] (LOE4).
    - Guys et al. [155] demonstrated significant but limited urodynamic differences in children (LOE3). However, the clinical translation of these modifications has not been reported. It must be emphasized that, in the absence of electrodes adapted to paediatric sizes, the study was carried out without the usual percutaneous evaluation phase.

- Encouraging short term results in neurological bladder dysfunction do not necessarily translate into long-term efficacy [149] (LOE2). Despite a positive test in about half of the patients tested, long term (54 months) results were poor in almost all patients (1/12 had neuromodulation efficacy).

- Sievert et al. [156] performed acute bilateral sacral S3 nerve stimulation in 10 patients with complete spinal cord lesions (SCLs) during the spinal shock phase, with six patients as controls. After a mean follow-up of 26 months, the cystometric capacity increased and IDC were abolished in the stimulation group. Further studies should look into this technique and question the ideas about the working mechanism in sacral nerve stimulation since afferent stimulation effects are unlikely in complete SCI.

- One of the largest and latest series is from Chaabane et al. [157]. They looked at the results of PNE testing and SNM implants with a mean follow-up of 4.3 years in 62 patients (34 with DO, 28 with chronic urinary retention). DSD was present in nine cases. 41 patients (66.1%) had more than 50% improvement on urodynamic evaluation and bladder diary with PNE, and 37 were implanted. At follow-up results remained similar to the evaluation phase in 28 cases (75.7%). In six cases (16.2%), clinical response had been lost; in these six cases, neuromodulation failed on average 12.0 months after implantation.

Particular attention has been given to the outcomes of SNM in the MS population. These patients present unique challenges given the heterogeneity of neurologic lesions and the ability of the disease to progress over time. Engeler et al. (2015) performed a single center prospective series for the treatment of neurogenic lower urinary tract dysfunction (NLUTD) caused by Multiple Sclerosis. Out of seventeen patients (13 women, 4 men) treated with SNM for refractory NLUTD, enrolled 2007–2011, 94 % had a positive test phase with a >70 % improvement. After implantation of the pulse generator the improvement in voiding variables persisted. At 3 years, the median voided volume had improved from 125 to 265 ml, the post void residual from 170 to 25 ml, micturition frequency from 12 to 7, and number of incontinence episodes from 3 to 0. Only two patients developed lack of benefit. No major complications are reported. These results are based on a careful patient selection, patients had to have stable disease and confirmed neurogenic lower urinary tract dysfunction [158]. (LOE2). These results correlate with those reported in a review article which was carried out up to December 2014 by Puccini et al. (2016). Based on two prospective studies the authors conclude “SNM seems to be a safe and effective treatment for LUTS in MS patients. Further and larger studies as well as randomized controlled trials are needed to confirm its clinical role in patients with MS.” [159] (LOE3)

In a prospective neuromodulation database study, Peters et al. (2013) enrolled patients with mixed etiology [160]: stroke (n=17), multiple sclerosis (n=13), Parkinson’s disease (n=10), incomplete spinal cord injury (n=4), cerebral palsy (n=1) and some others. 63 of 71 (88,7%) had a positive test phase and received the implantable pulse generator. This group of patients was compared with the group of patients with non-neurogenic bladders. Most patients (> 50 %) in both groups reported moderate and marked improvement in overall bladder symptoms of two years, and the patients with neurogenic bladder dysfunction experienced benefits after neuromodulation similar to the benefits experienced by those without coexisting neurologic condition. These results are encouraging, however, there are still some issues which need to be solved, e.g. unilateral vs. bilateral implantation especially in patients with a neurogenic underactive detrusor. Life time of the implanted generator (battery) of course depends very much on how much electricity is necessary. Moreover, also the issue of performing MRI needs to be discussed with the patient and his neurologist as MRI might damage the implant (according to the producing company). (LOE3)

Scheepens et al. [150] reported two prognostic factors for poor response (the study population was six incomplete medullary injuries, five patients with cauda equina syndrome, six with multiple sclerosis, and one with myelomeningocele) (LOE3): duration of the symptoms (more than seven months in this study) and the existence of a neurological cause for bladder dysfunction. Neurological patients with a very localized and incomplete nervous condition were the most successful. Patients with herniated disc surgery had a greater chance of good response. Patients with complete medullary or large sacral lesions were poor neuromodulation candidates.

Clinical results of neuromodulation do not necessarily correlate to urodynamic results. Bosch indicated in his series [147] that almost half of the patients considered to have had a good outcome clinically in reality retained some overactivity. One publication reported correspondence between urodynamic test data and clinical data [139] (LOE4). In 2001 Chartier-Kastler [161] et al. published the results of a prospective study concerning the evolution of urodynamic parameters during the acute phase of the PNE test in 14 patients with neurogenic DO. The authors concluded that the acute phase of PNE was accompanied by a significant change in urodynamic parameters in more than 2/3 of the patients, and that this should be a possible means for selecting patients.

Sacral neuromodulation for urinary retention in neurological bladder dysfunction

Only two studies reported specific results for neurogenic urinary retention.The first is by Hohenfellner et al. [149] (LOE3), reporting on 11 patients. Of these

patients, three were implanted with temporarily satisfactory results in only two.

Lombardi et al. in 2014 evaluated 95 incomplete SCI patients suffering from chronic, neurogenic non-obstructive urinary retention. Only 41 % were suitable for implant after the test phase. The implant was done unilaterally. After three years 25 of all patients (29%) were considered to be successful, 11 (19%) were failures. The majority of them with the unilateral implant had success when the contralateral L3 sacral root was stimulated. The authors conclude that SCI patients with neurogenic, non-obstructive urinary retention are good candidates for SNM in the medium follow-up. [162] (LOE2)

Due to the limited available data and the rather low success rate, SNM currently holds a marginal place in neurogenic retention patients. Patients need to be clearly informed of the high risk of failure. In this respect the bladder contractility test could be helpful in order to predict a successful outcome of sacral nerve stimulation in acontractile neurogenic bladders [163]. It is also necessary to be especially prudent in patients with cauda equina problems, who may have the illusion of recovering urination, but actually may be enhancing abdominal straining to evacuate their bladder. In reflex incontinence, patients with complete spinal cord or cauda equina lesions are poor candidates (LOE4). While a few studies have reported on SNM in specific contexts [164-167], patients should be informed that IC is the first-line therapeutic option for neurogenic urinary retention.

Recommendations

- Sacral neuromodulation can have an inhibitory effect on neurogenic DO (C)
- While sacral neuromodulation has a place in the care of neurological urinary incontinence or neurological urinary retention, the proportion of patients whose condition is improved is much less than in non-neurological pathologies (B).
- Indications for sacral neuromodulation in the care of DSD in neurological urinary dysfunction are still not established (D).

6. SURGICAL TREATMENT OF URINARY INCONTINENCE

6.1. Denervation procedures for treating reflex urinary incontinence due to detrusor overactivity

Peripheral bladder denervation

The best known bladder denervation technique was developed by Ingelman-Sundberg [1,2]. The technique comprises resection of the inferior hypogastric plexus in contact with the bladder through an inverted U-shaped vaginal incision, dissecting the bladder laterally and posteriorly, as widely as possible. In the most recent paper [2], the authors report up to 54% recovery over a mean follow-up of about three years. Each published series is from the same group, is retrospective and reports only a small sample size (LOE4). It has only occasionally been used in neurogenic DO.

Isolated rhizotomy of ventral and/or dorsal sacral roots

Historically, attempts at sacral root surgery first focused on cutting the motor (ventral) sacral roots in order to abolish detrusor reflex contractions. It was soon clear that this method failed within six months. With a different objective, Brindley [3] developed a technique involving stimulation of ventral sacral roots to obtain controlled and complete bladder voiding in cases of SCI. He realised that patients only acquired continence if the stimuli causing reflex bladder contraction could be blocked [4]. Early techniques consisted in selective destruction of the dorsal sacral roots that evoke detrusor contractions. These selective rhizotomies did not, however, give the best results. Only after complete de-afferentation of the sacral micturition centre by intradural rhizotomy were better results obtained [5-8] (LOE2-3).

The technique of "selective" dorsal sacral rhizotomy has been studied more extensively but since 1988 no publications can be found anymore. It involves making an extra-dural approach to the sacral roots (S2-5), isolating and stimulating the dorsal (sensory) contingent whilst monitoring changes in urodynamic pressure within the bladder in order to cut only those fibres responsible that do not show evoked overactivity. This implies that only the senory nerves are cut and the motor nerves are preserved. To retain reflex erection, S2 must be preserved, at least on one side. This treatment may be proposed for patients with neurogenic DO, and also those with urgency incontinence. The most recent article from 1988 by Lucas *et al.* [9] is about 22 patients (LOE3). At the mean follow-up of 4 years, 39% of patients retained a urodynamically stable bladder with satisfactory clinical response. The authors ascribe these improved results to a more extensive rhizotomy. However, it should be noted that there was a marked heterogeneity of patients in this series, three out of the eight, considered to be "successes", were IDC patients with leakage due to DO.

Mertens *et al.* [10] applied a technique previously used for limb spasticity, namely microsurgical DREZotomy, the aim of which is to destroy the dorsal root entry zone (DREZ). This zone, first defined in 1972 by Sindou [11], is a functional anatomical entity that groups together the proximal portion of the dorsal root, the medial portion of the dorso-lateral tract and the superficial layers of the dorsal horn. The technique involves making a micro-surgical lesion (by micro-coagulation) on the ventro-lateral portion of the entry zone, near the apex of the dorsal zone. The effect of DREZotomy is to selectively block nociceptive afferents, and their relays, and myotatic afferents. The benefit of the limited lesion is to avoid complete abolition of tactile and proprioceptive sensitivity and to prevent the development of deafferentation phenomena. To treat neurogenic DO, the lesion must be made on both sides from S2 to S3, or even S4. The results from the first series concerned 38 patients treated for incapacitating lower limb spasticity, treated by extended DREZotomy from L2 to S1. 58% of these patients were permanently catheterized. At six months, DO had disappeared in 82%, with 63% having significantly improved bladder capacity. At 18 months post-surgery, leakage had disappeared in 89% of cases. Since 2003, no publications on DREZotomy for neurogenic LUT disorders were found, although the technique is still applied to alleviate pain.

Percutaneous sacral root block

Sacral root block is an old technique, since Dogliotti [12] proposed it as early as 1931 to relieve vertebral cancer pain by chemically sectioning several dorsal roots. An injection of alcohol causes denervation due to the fragmentation of myelin in the endoneurium. In the 1950s, Bors [13] applied the technique to the bladder, standardized the procedure and described preliminary results. Later authors reported on a few series (LOE3) [14, 15], but always with the same result; the benefit disappeared after a few months. Phenol, considered to be "selective" for C fibers was then tried but the results were no better [16-18]. Chemical destruction of the sacral nerve roots has proved ineffective and is accompanied by a high rate of minor complications (pain), resulting in significant discomfort and prolonged hospitalization (LOE3) [14, 15]. Mulcahy *et al.* [19] proposed sacral rhizotomy by percutaneous radiofrequency for neurogenic bladder (LOE4). A recent study was published by Ferreire et al. [20]. In 8 SCI patients they performed a bilateral block of S3 with bupivacaine. These 8 responders had an increased bladder capacity and for 3 out of 4 patients autonomic dysreflexia (AD) improved.

Rhizotomy of posterior sacral roots and stimulation of the anterior sacral roots

Electrostimulation to improve micturition in patients with spinal cord injury has been extensively re-

searched since 1954. Direct stimulation of the detrusor, the spinal cone, the splanchnic and sacral nerves have not produced reliable results. Since 1969, Giles Brindley developed a set of electrodes for stimulating the spinal roots in the *cauda equina*. The technique, first tested in baboons, led to the development of an implanted stimulator to induce micturition in paraplegic patients. Sacral rhizotomy performed during implant surgery makes it possible to control bladder hyperactivity and ensure continence. The energy source and the electronics for adjusting the stimulation parameters are not implanted. The transmitter transforms the electric current from the energy source into electromagnetic waves, which are picked up by the implanted receptor and re-transformed into an electric current that circulates to the electrodes in contact with the nerve. Depending on the surgeon's decision, the implant is placed within the membranes (intradurally) of the dura mater or outside them (extradurally), so as to stimulate the sacral roots from S2 to S4. At the same time, it is essential to perform posterior rhizotomy from S2 to S4 to remove any detrusor overactivity, though this is difficult to perform, especially extradurally [21] (LOE4). This technique can only be performed in those with spinal damage who are para- or tetraplegic. The sacral reflex arc must be preserved.

Micturition is not continuous: the detrusor cannot be stimulated without also stimulating the sphincter. The parasympathetic fibers and the fibers destined for striated muscles are stimulated together. The response of detrusor smooth muscle fibers causes a gradual increase in pressure, which continues after stimulation has ceased. The "on-off" response to stimulation of striated muscle fibers is different. When stimulation stops, the striated sphincter immediately relaxes, whilst the detrusor continues to contract. A new wave of stimulation increases and maintains sufficient detrusor pressure to cause micturition after stimulation stops. The careful selection of stimulation and stopping times results in a discontinuous, but satisfactory, micturition. Sphincter fatigue due to electrical stimulations, blocking of pudendal nerve motor fibers [22] (LOE4) or use of specific detrusor stimulation by performing an anodal block [23] (LOE 4) have been reported, together with poor efficacy.

Stimulation can also help defecation and erection and it resolves to some extent autonomic dysreflexia and also spasm of the lower part of the body, but it should be remembered that the principal object of sacral nerve stimulation combined with posterior rhizotomy is to achieve urine continence and bladder voiding. Induced erection is a secondary benefit but not an indication for the procedure, and men should be warned that they would lose reflex erection after posterior rhizotomy.

The results of the intervention are summarized in Table 5. Briefly, the outcome with regard to continence and bladder voiding are good (LOE 2-3). Failures result from incomplete rhizotomy, where bladder hyperactivity persists, or from sphincter insufficiency which may be treated by additional placement of an artificial sphincter [7, 8] (LOE3). Incomplete rhizotomy can be surgically completed [7, 8, 24] (LOE 2-3). In all reported series, mean bladder capacity increased significantly (LOE 2-3). Micturition was obtained by electrostimulation with a post-voiding residue (PVR) of $\leq$ 50 ml in 69 to 100% of patients. All series reported decreased incidence of urinary infection, but the defining criteria were too varied to allow conclusions to be drawn. Posterior sacral rhizotomy probably protects the upper urinary tract from detrusor overactivity. It can resolve the problem of pre-operative reflux [24, 25] (LOE4). However, posterior sacral rhizotomy should be complete. Indeed, in a series of 500 patients, Brindley [24] (LOE3) reported twelve cases of upper urinary tract impairment, ranging from grade I reflux to upper urinary tract dilation.

Martens et al. looked at patients in the Netherlands who underwent a Finetech-Brindley procedure [26]. They investigated the effects on quality of life in a group of 46 patients that still used the implant. They also looked at the presumed beneficial effects of the rhizotomy only, comparing with a group of 70 matched controlled patients that had optimised standard care. The patients had a significant better Specific Impact of Urinary Problems score, general QoL index (Qualiveen), and continence rate, and less urinary tract infections compared to the Control Group. If the stimulator was not used anymore, patients still benefited from the rhizotomy with regard to QoL and continence rate. The subscales of the SF-36 had better scores for the patients who used their stimulator as compared to those who did not use the stimulator and compared to the Control Group. The conclusion was that the active group had a better QoL than the rhizotomy group, and both groups had advantages over optimized standard care. Schurch [27] focused on the specific problem of dysreflexia and recorded its persistence during stimulation in all patients who had suffered prior to surgery, but with marked improvement in symptoms.

Krasmik reported on the outcome of 137 retrospective analysed patients. After a mean follow-up time of 14.8 years elevated detrusor pressure was reduced from 65/137 to 2/137 patients, wheras low detrusor compliance changed from 62/137 to 13/137 patients. Mean bladder capacity significantly ($P<0.001$) improved from 272.4 ± 143.0 to 475.0 ± 82.7ml. The mean number of symptomatic UTI also decreased significantly ($P<0.001$) from 6.2±4.5 to 2.5±2.6 per year. The number of patients suffering from incontinence had significantly ($P<0.001$) decreased from 70/137 to 44/137. At the last follow-up visit, 107 (78.1%) patients were still using the stimulator. A total of 84 complications requiring surgical revision were observed. Defects of the stimulator cables or the receiver plate were the most common events (n=38) [28].

Castano-Botero et al reported on a retrospective analysis of 104 SCI patients who underwent an extradural implant procedure. Incontinence resolved in

86% of caseswhereas UTI's went down from 91% to 16% [29].

Moreover the effect on bowel emptying can also be very rewarding as was published by Rasmussen et al. They reported that 73% of the 586 respnding patients used the device for defecation and were very happy with it [30].

Conclusion

- Bladder denervation is mainly reserved for those suffering complete spinal cord injuries.

Recommendations

- No peripheral bladder denervation technique has passed the test of time (D)
- Injections of neurolytic products to treat detrusor overactivity should be abandoned, since they are ineffective in the medium and long term and expose patients to morbidity (A)
- Sacral dorsal rhizotomies need to be quite extensive to treat successfully neurogenic DO. So they may be performed only in patients with lower limb neurological impairment (B)
- In certain situations, dorsal rhizotomies can be undertaken in association with ventral root stimulators (Brindley's technique) or even with continent cystostomy (B)
- Electrostimulation of the anterior sacral roots is a valid option for managing neurogenic bladder in patients with spinal lesion, with long-term follow-up (B)
- It must be combined with destruction of all or part of the posterior sacral nerves, and cannot therefore be performed in patients with conserved lower limb motility(B)
- The reflex arc must be intact(B)
- Posterior rhizotomy exposes men to loss of reflex erection and women to a loss in reflex vaginal lubrication(B)
- It is vital to assess the patient carefully before implantation so as to determine whether he/she will be able to mount a toilet or grasp a urinal handrail (B)

6.2. Surgery for Incontinence associated with poor bladder emptying

Incontinence in neurological patients can be aggravated by deficient bladder emptying and retention. Two mechanisms can be involved: detrusor sphincter dyssynergia (DSD) or detrusor underactivity.

6.3. Surgical treatment of detrusor external sphincter dyssynergia (DSD)

DSD is a characteristic feature of suprasacral and infrapontine lesions and can be treated with sphincterotomy. The aim of sphincterotomy is to produce reflex micturition into a condom catheter which acts as a pressure relieve valve, thus protecting the upper urinary tract. For the last thirty years, endoscopic sphincterotomy has been the technique of choice for patients who cannot or do not want to do IC. It is invasive, irreversible and the patient has no adaptation period [35, 36] (LOE3). Prosthetic sphincterotomy using a urethral endoprosthesis (or stent) is an alternative.

Sphincterotomy recommendation supposes a diagnosis of a neurological cause of DSD that is complicated by hydronephrosis, vesicoureteral reflux, autonomic dysreflexia or repeated urinary infections secondary to poor bladder voiding. Patients should have failed or refused IC. Main contra-indications are [37, 38]:

- Impossibility to retain a condom catheter. All sphincterotomy techniques, including stenting, are contra-indicated for men who cannot retain a condom catheter (hence also for women). A semi-rigid penile prosthesis can be placed to help retain the condom catheter [39] (LOE3). However, patients must be informed that there is a 20% to 30% risk of erosion and infection of the penile prosthesis for those with SCI, as opposed to only 2.7% in the general population [40, 41] (LOE3).
- Detrusor acontractility or hypocontractility. Patients with spinal cord injury and no reflex detrusor contraction during urodynamic tests are poor candidates for the various techniques of sphincterotomy.
- Patients who wish to father children and are candidates for vibro/electro-ejaculation and an artificial insemination program.

Endoscopic sphincterotomy

Emmett [42] first described endoscopic sphincterotomy in 1948. He performed cervico-prostatic incisions in patients with SCI, but later realized that the problem lay in the striated sphincter. External sphincterotomy was performed in 1958 by Ross *et al.* [43]. They carried out cold-blade surgery and placed a catheter (Ch 22-26) for tamponade, since nearly all patients required transfusion (one of the ten patients in the series died after surgery). A few attempts at surgical sphincterotomy via the perineal and subpubic myotomy routes were tried later. Complexity and frequent serious complications explains why these approaches were abandoned [44, 45]. Sphincterotomy with electrocoagulation was finally found to be the best technique.

Endoscopic sphincterotomy morbidity includes hematuria, which can be abundant and sometimes difficult to control, requiring transfusion in 2-13% of patients (LOE2-3). Incision at the twelve o' clock position seems to offer the lowest risk of hemorrhage, with three and nine o' clock sphincterotomies entailing the highest risk [46] (LOE4).

Post-operative impotence is also a common complication. Rates of up to 56% were reported in early series [47-50] (LOE3). More recent series (Table 6, LOE 2-3), most using a median, or slightly deviated incision, have not affected sexual function. However, it should be noted that the population concerned may

have many other reasons (neurological, psychological, etc.) for suffering from erectile dysfunction. When sphincterotomy is accompanied by complete incontinence there are obvious reasons for psychological difficulties during intercourse. This issue must be discussed with the patient before surgery. The fear of this sequel sometimes causes the patient to decide against surgery; use of an incontinent prosthesis as first-line therapy can enable the patient to gain insight into this potential consequence of endoscopic sphincterotomy.

If striated sphincter section fails, the possibility of bladder neck stenosis should be investigated. This is seen in from 2 to 21% of patients (LOE 2-3). Section of the bladder neck may then improve voiding, but will result in permanent incontinence. Before surgery, the surgeon must make sure that the patient accepts this situation and can use a condom catheter.

Results of endoscopic sphincterotomy are summarized in 6 (LOE2-3). Any analysis is made difficult by the absence of unequivocal criteria of success. Some patients are improved by sphincterotomy, even with a 200 ml residue. Most authors use indirect urodynamic criteria to evaluate success (decrease in bladder pressure during micturition, decrease in PVR). The most obvious result is the improvement in autonomic dysreflexia observed in tetraplegic patients. It also appears that the intervention reduces the rate of symptomatic UTIs. However, chronic bacteriuria is not improved [51]. The reported results concerning resolution of hydronephrosis and vesicorenal reflux differ, and in each series, there are very few patients. Another essential point, well known in practice but rarely reported, is the recurrence of neurogenic DSD in many patients [36, 52, 53] (LOE3). Riccotone *et al.* (LOE3) [53] reported 82% recurrence of symptoms after ten years of follow-up. Juma *et al.* [36] (LOE3) report similar results after eleven years, with patients undergoing an average of 1.7 sphincterotomies. Pan *et al.* reported a mean duration of benefit of almost seven years, which could be sustained with a repeat procedure [54]. A single study has tried to address predictive factors for a successful sphincterotomy. In this retrospective study, although detrusor leak point pressure and retrograde perfusion pressure were found to be superior to residual urine volume in predicting sphincterotomy success, results were not statistically significant [55]. 30-68% of patients eventually develop some impairment of the upper urinary tract [36, 54]. Patients who have undergone this surgery must therefore be regularly monitored to detect any distension of their upper urinary tract.

The group from Ginsberg published their long term data on 97 patients who underwent bladder neck incision with external sphincterotomy (BNI/ES) over a period of 40 years. During the period reviewed, a solitary redo BNI/ES was done in 46 patients, a second redo BNI/ES was done in 23 patients, and a third redo BNI/ES was done in 7 patients with success rates of 50%, 68.2%, and 85.7%, respectively. All patients had a normal serum creatinine level at the end of the follow-up. Mean elapsed follow-up after the last redo BNI/ES was 119 months (range, 6-408 months) for all patients evaluated. Mean durability of successful redo BNI/ES was 109.1 months. [56]

Table 6: Results of endoscopic sphincterotomy

	Number patients	LOE	Mean Follow-up (months)	Success criteria
Chancellor *et al.* 1999 [51]	26	2	24	- PVR decrease - Hydronephrosis, VR reflux decrease (100%, 100%) - Improved micturition comfort (80%) - Improved autonomous hyperreflexia (100%)
Catz *et al.* 1997 [90]	32	3	NP	- Significant decrease in PVR - Decrease in infections (74%) - Decrease in hydronephrosis, reflux (66%, 40%) - Improved autonomous hyperreflexia (100%)
Perkash *et al.* 1998 [95]	37	2	9	NK
Fontaine *et al.* 1996 [91]	92	2	20.6	- Decrease in hydronephrosis, reflux (100%, 90%) - Significant decrease in PVR, micturition pressure - Decrease in infections (74%) - Improved micturition comfort (73%) - Improved autonomous hyperreflexia (93%)
Noll *et al.* (1995) [35]	105	3	59	No statistical study, but: - Improved autonomous hyperreflexia (42 to 17%) - Decrease in mean PVR (180 to 70 ml) - Decrease in micturition pressure (from 97 to 37 cm H2O) - Decrease in frequency of symptomatic urinary infections (8.1 to 3.6 per year)
Rivas *et al.* 1995 [96]	22	2	12	- Improved autonomous hyperreflexia (44%) - Significant decrease in PVR, micturition pressure - Decrease in hydronephrosis (40%)
Juma *et al.* 1995 [77]	63	3	132	- Renal function (creatinine): normal in 97% of patients - on X-ray, 30% of patients showed upper urinary tract impairment. - 2/3 patients had more than one sphincterotomy
Vapnek *et al.* 1994 [52]	16	3	39	- 31% required repeated sphincterotomy - 50% failure rate (sub-pubic catheter placed)
Namiki 1984 [92]	9	4	3	- PVR < 50 (100%)
Ruutu *et al.* 1982 [93]	11	4	NS	- Subjective improvement in micturition comfort (56%) - Improved autonomous hyperreflexia (100%)
Carrion *et al.* 1979 [94]	60	3	12	- Reflux disappeared (86%) - Significant decrease in reflux: 75%

LOE: Level of evidence; NK: Not known; PVR: Post-Void Residue

Prosthetic sphincterotomy

In 1990, Shaw *et al.* proposed using a wire mesh stent (Urolume) to treat patients with spinal injury presenting with DSD [58] (LOE3). Since then, various stents have been used.

7 lists the types of stent used for DSD, according to classification criteria [59, 60]. They can be placed in various sections of the urinary tract: prostatic urethra, through the striated sphincter or more distal in the sub-sphincteric urethra. Our review is limited to placement through the striated sphincter.

Table 7: Urethral stents used in neurogenic DSD

Temporary stents					
Stent	Expansion method	Size		Material	Maximal duration (months)
		Caliber (F)	Length (mm)		
Not specific to the striated sphincter **First-generation**					
Urospiral [97]	Non expandable	21	40-80	Stainless steel	<12
IUC [98]	Non expandable	16-18	25-80	Polyurethane	<6
Second-generation					
Memokath [99]	Heat	22/34	30-70	Nitinol	<36
Specific to the striated sphincter					
Diabolo [61]	Self-expansion	18	38	Medical steel	>12

Permanent stents				
Stent	Expansion method	Size		Material
		Caliber (F)	Length (mm)	
Urolume Wallstent [100]	Self-expansion	42	20-40	Steel alloy
Titan [101]	Balloon	43	19-58	Titanium
Memotherm [102]	Heat	42	20-80	Nitinol
Ultraflex [103]	Self-expansion	42	20-50	Nitinol

Temporary prosthetic sphincterotomy

Temporary stents make it possible to carry out a therapeutic test to check the feasibility of condom catheter use, check that placing a foreign body in the urethra does not induce autonomic dysreflexia and ensure the patient accepts the mode of micturition. Moreover, during this trial period, it is possible to study how the bladder empties in the seated position, and assess the necessity of additional treatment for smooth muscle sphincter dyssynergia at the level of the bladder neck. As this treatment is simple and reversible, it is possible to propose it very early to the patients, rendering the patient autonomous with regard to carer-assisted catheterization, if this were the prior mode of micturition and leaving the possibility to discuss any fertility and sexual issues, and considering the possibilities of preserving sperm. For patients with SCI, early temporary stent placement (within six months of trauma) theoretically has the added advantage of waiting for recovery of upper limb motility to enable IC After using a temporary stent, the patient may choose his mode of micturition; i.e. return to his former state, change to another temporary stent, replace it by a permanent stent, or choose surgical sphincterotomy.

By definition, temporary stents should be self-retaining, easy to remove and must not epithelialize. Only the temporary stent Diabolo [61] is specific for the external urethral sphincter. The results of two types of temporary stenting (test) for incontinence have been published in the same series [62] (LOE3). In a retrospective study of 147 patients, the authors demonstrated a significant effect on incontinence throughout the mean ten month test period, with very low morbidity (15%). The temporary stents were removed easily from all patients without sequelae. After this period, 62.6% of patients chose permanent sphincterotomy, usually by means of a permanent stent. Memokath is another device that has been studied in neurological patients [63-68] (LOE3-4). Several authors report complications (32-100%) using this stent, which seems to induce a lot of bladder stones and to be quite difficult to remove, especially if it is left longer than 18 months. When used as second-line treatment following failed sphincterotomy, Memokath success-

fully reduced post-void residuals, but failed to improve urodynamic parameters including bladder capacity, detrusor leak point pressure, bladder compliance, and maximum detrusor pressure [63].

Permanent prosthetic sphincterotomy

Permanent stents are designed to integrate with the urethral wall [69]. They resist the striated sphincter and prevent its closing during reflex contraction. They can be removed if necessary, or at the patient's request, with recovery of striated sphincter contraction [70, 71]. Permanent stents are made of biocompatible materials such as nitinol (a nickel and titanium alloy) and titanium. They usually consist of a mesh comprising a single thread (e.g. Urolume) or several threads (e.g. Ultraflex). None of the stents are specifically adapted for the urethral striated sphincter. Three have been reported for treating neurological patients with DSD: Urolume, Memotherm and Ultraflex. All can be placed under local anesthesia. Table 8 summarizes the principal series published on these devices. Only Urolume was studied according to strict prospective criteria [51] (LOE1-2). Using stringent clinical and statistical methods, they classified the stent as LOE 1 for effectiveness and morbidity in DSD with a 5-year follow-up. 160 patients with SCI (mean age 36.3 years) in 15 North American centres, were treated prospectively with Urolume for DSD. Urodynamic parameters for micturition pressure, PVR and functional bladder capacity were measured before treatment and then annually up to 5 years afterwards. Mean micturition pressure, the primary criterion, was significantly lower 5 years after stenting. PVR decreased significantly and was maintained after 5 years. Mean bladder capacity remained constant. Hydronephrosis, suffered by 28 patients before surgery, disappeared in 22 (78.6%) and was improved in the others. Autonomic dysreflexia resolved in 70% of cases. The indwelling catheters of 63 of the 86 (84.9%) patients catheterized before surgery could be removed. The percentage of positive urine cultures remained unchanged after stenting. No cases of peri- or post-operative bleeding, soft tissue erosion or bladder lithiasis were observed during the study. One case of prosthetic encrustation occurred during the first year; three during the second year; three during the third year; two during the fourth year and five in the fifth year. Urothelial reaction was reported in 44.4% of cases, but 93.3% of these were mild and none required treatment. No erectile dysfunction was reported. Stents had to be removed from 24 patients (15%), four of whom received new implants. 80% of the patients considered their situation improved by stenting, and 84% of physicians considered the treatment effective. 47 patients required supplementary treatment on the bladder neck (endoscopic section in 20 cases). In the mid-term, prosthetic sphincterotomy using a Urolume stent appears to be satisfactory. However, the situation is not so clear over the longer-term. It is not always easy to remove the stent, especially from patients who have not been monitored regularly. Some teams report highly complex surgery for stent removal, especially in the event of associated urethral stenosis [72-75] (LOE3). A small study (n=12) following patients up to twenty years after insertion, suggests a high rate of complications, as 5/6 patients who completed the 20-year follow-up developed bladder neck dyssynergia requiring incision, 2 patients developed obstructive encrustations within the first year of insertion and another patient developed bladder cancer [76]. However, in those patients who completed the 20-year follow-up, sustained significant improvements in maximum detrusor pressure and duration of detrusor contraction were recorded.

Table 8: Results of the main series on sphincterotomy using urethral stents

	Stent	Year	LOE	n	Efficacy (%)	Mean follow-up (Months)	Migration (%)	Complications
Pannek et al. 2011 [63]	Memokath	2011	3	22	78	10	18	32

Whether patients should be offered prosthetic or endoscopic sphincterotomy is not yet agreed. Endoscopic sphincterotomy is the preferred standard treatment for DSD, where IC cannot be performed. Two prospective studies carried out in the US in 1994 indicated that prosthetic sphincterotomy was at least as effective as standard sphincterotomy in patients with SCI, and offered advantages in terms of morbidity, duration of hospitalization and cost [77. 78]. The two studies were not randomized. Follow-up was short (mean 15 months), with a potential risk of bias, since the conclusion that external sphincter balloon dilatation is as effective as endoscopic and prosthetic sphincterotomy is not borne out by long-term outcomes [79].

A prospective, multicenter, randomized study comparing endoscopic sphincterotomy with prosthetic sphincterotomy was published in 1999 by Chancellor and Rivas, using the Urolume stent [80]. Fifty-seven patients in three specialist spinal cord injury centers were included. The study concluded that prosthetic sphincterotomy was as effective as endoscopic sphincterotomy and required shorter hospitalization. Polguer et al published their experience with the Ultraflex (n=11) and Memotherm (n=11) during 56 months in patients with DSD. Complementary procedures after stenting included: five stent prolongation or displacement (mean interval 7.6 months), six bladder neck incisions (12.2 months), three urethrotomy (42 months), ten obstruction treated by laser (47.3 months). Eight patients had a change of their urinary pattern: four underwent ileal conduit diversion, one had a continent urinary diversion, one chose self intermittent catheterization, two were under indwelling catheterization waiting for another treatment. Stent retrieval was either harmful or impossible for four of them. Three patients were free of complementary procedures. They conclude that nitinol urethral stent was an effective treatment initially. However after years urethral stenosis and hypertrophic growth of the urethral mucosa usually require extra endoscopic procedures (0.31 per patient per year). They recommend yearly endoscopic follow-up. [81]

6.4. Bladder neck incision (BNI) for detrusor-bladder neck dyssynergia (DBND)

The rationale to use BNI was that sympathetic overactivity might inhibit detrusor contraction and transurethral incision of bladder neck might interrupt the inhibitory reflex arc and result in restoration of detrusor contractility. In a single retrospective study BNI was performed in 22 patients with high-level SCI and DBND demonstrated upon video-urodynamics, who were previously managed by either IC or indwelling catheter [82]. Voiding symptoms were complicated by autonomic dysreflexia in 17/22 patients. Deep incisions were carried out at the 5 and 7 o'clock positions, sparing the external urethral sphincter. A satisfactory surgical outcome was recorded in 86.4% of the patients 3 months post-op (LOE3). While all patients additionally suffered from DSD preoperatively, an open urethral sphincter during voiding was reported in 86.4% of them following BNI, and autonomic dysreflexia became less severe or resolved in 88.2% of sufferers. The authors hypothesized the presence of a urethra-to-bladder neck reflex pathway to explain additional improvements in DSD

Recommendations

- Where clean intermittent catheterization is not possible, the use of a urethral stent is possible (B).
- Whatever type of sphincterotomy is chosen (surgical or prosthetic):
- Patients must think carefully about the different modes of micturition possible for them (A).
- The few studies reporting long-term results of sphincterotomy demonstrate the vital importance of regular patient monitoring for the recurrence of DSD or blockage (B).
- This mode of micturition is contraindicated in women, and in men with difficulty in maintaining a condom catheter (B).
- Men who wish to have children should be warned of the risk of ejaculatory duct obstruction (B).
- For patients who have chosen surgical sphincterotomy:
- The reference technique involves an elective 11, 12 or 1 o'clock incision of the urethral sphincter (B).
- Although surgical sphincterotomy is the accepted reference treatment for neurogenic DSD, analysis of the literature highlights the lack of reliable efficacy and reproducibility criteria for the technique (B).
- For patients who have chosen prosthetic sphincterotomy:
- Different types of stent are used, depending on whether sphincterotomy is temporary or permanent. Stents are complementary, and different designs can be used for different situations (B).
- Surgical complications depend as much on the surgeon's competence as on the material and may be reduced by experience (C).
- Clinical studies have demonstrated that neurogenic patients prefer prosthetic sphincterotomy because it is reversible, even when permanent stents are placed (C).
- Careful follow-up, using yearly cystourethroscopy is mandatory when leaving a permanent urethral stent (B).
- Published data is inadequate to support a recommendation on the use of bladder neck incision in patients with inadequate bladder emptying due

to detrusor-bladder neck dyssynergia, either as a first-line procedure or as a complementary approach to DBND recognised following permanent urethral stenting. Further studies are needed.

6.5. Surgery to increase detrusor strength

For some patients, the cause of detrusor underactivity lies in the bladder wall. In this case, the control circuit functions but the bladder muscle is too weak. At present there is no medical treatment for this situation. The general objective is to reduce peripheral resistances as much as possible and where this fails, to propose IC. However, some teams have suggested placing rolled strips of muscle around the bladder. Some authors have also suggested a strip of *rectus abdominis* muscle. This is easier to perform and may be used essentially for reconstructive surgery, such as in bladder exstrophy [83-85] (LOE4). The only team to have published results on detrusor underactivity in man is that of Ninkovic *et al.* [86] (LOE2). They reported interesting results from 20 patients suffering from neurogenic detrusor underactivity and requiring self-catheterization. They reported a technique that they had designed in animal experiments [87,88] (LOE4) and which consisted of transferring a free strip of latissimus dorsi muscle, which was anastomosed to the epigastric vessels and the lowest branch of the intercostal nerve. Out of 20 patients, with a mean follow-up of 44 months, 60% no longer required IC, with PVR below 100 ml. After complementary surgery on the bladder neck, there was a 90% success rate that was stable over time. The authors reported no heavy morbidity, particularly with regard to the donor site. These promising results were largely confirmed in a multicentre trial involving 24 patients with a median follow-up time of 46 months [89]. Complete spontaneous voiding (mean PVR 25ml) was restored in 71% of the patients, while frequency of CIC was reduced in another 13%. Recurrent UTIs ceased in 91% of patients. A critical increase in bladder contractility index may be required to achieve complete bladder emptying, but the number of patients was too small for safe conclusions. Future development could use tissue-engineering techniques to construct vascularized and contractile strips implanted around the bladder with the same procedure.

Recommendations:

- Latissimus dorsi myoplasty on the bladder is a promising technique that needs to be validated further (C).

6.6. Stress urinary incontinence (SUI) due to sphincteric incompetence

Some patients with neurogenic lower urinary tract dysfunction will suffer from incontinence due to sphincter weakness. In general, patients with lesions affecting the brain or suprasacral spinal cord will not suffer from this problem, as the sacral sphincter guarding reflexes will be intact. However, patients with lesions of the conus medullaris, the cauda equina or peripheral sacral nerves are at risk of developing neurogenic stress incontinence. Patients with neurological disease may also suffer from stress incontinence due to direct sphincter injury from urethral catheter trauma or as a result of previous interventions such as sphincterotomy or dorsal rhizotomy. In women, SUI may be present for non-neurogenic reasons such as urethral hypermobility due to previous pregnancy and childbirth.

People with neurogenic lower urinary tract dysfunction and SUI may also have impaired bladder storage function. If this is the case, a surgical procedure that treats the stress incontinence in isolation might put the patient at risk of upper urinary tract deterioration (as the upper tracts become exposed to the full force of the bladder dysfunction, having lost the “safety valve” effect of a weak sphincter) or of persisting incontinence. Pre-operative urodynamic evaluation of bladder function is therefore mandatory before undertaking surgery for neurogenic SUI.

The question as to when it is safe to treat neurogenic SUI while leaving bladder dysfunction uncorrected has been studied most intensively in the paediatric age group. Most series relate to children with spinal dysraphism/myelomeningocoele and, typically, authors report the necessity to proceed to bladder augmentation in at least a third of patients. Even with a thorough urodynamic and radiologic preoperative evaluation, some patients will have late bladder compliance deterioration [106-123]. However, the issue continues to generate debate and studies have not reached total consensus; for example, Snodgrass et al. [124] (LOE3) published a retrospective analysis of 30 children (mean age: 8.6 years) who had a bladder neck sling procedure and appendico-vesicostomy without augmentation. At 22 month of mean follow-up, only one patient had had to undergo a bladder augmentation. In a subset of 16 patients who had urodynamics at 24 months, 13/16 had an increase of their maximum bladder capacity. However, 67% of the patients required anticholinergic therapy. In contrast, Dave et al. [125] (LOE3) strongly advocate the case for simultaneous bladder augmentation. The authors report a series of 15 children followed for at least five years after an isolated bladder outlet procedure (5 Pippi-Salle, 5 slings and 5 artificial urinary sphincter). At a mean follow-up of 11.25 years, all the patients underwent surgery to increase bladder capacity, either for recurrent incontinence or for upper urinary tract deterioration. At present, no definitive conclusions can be drawn as to advisability of routine prophylactic bladder augmentation, but many authors recommend a concomitant bladder augmentation when performing a bladder outlet procedure [126] (LOE4). The option of using detrusor injections of botulinum toxin in children offers a further therapeutic approach in circumstances where there is uncertainty.

A further important consideration when contemplating neurogenic SUI surgery is the means of bladder emptying following treatment of the sphincter weakness. In particular, patients who are emptying their bladders using an element of straining will not be able to empty in this way post-operatively. Patients will therefore need to consider how they will empty their bladder once continence is achieved. The options available to patients will include: IC (either via the urethra or a continent catheterisable abdominal conduit) or the use of a suprapubic catheter (either on free drainage or with a catheter valve). There will be some patients, who have only limited neurological damage, who will continue to be able to empty their bladder using voluntary voiding post-operatively but, even in this group, it is necessary to warn patients of the possible need for post-operative IC and to make sure that they are capable of using the technique before embarking on treatment.

Farag et al performed a systematic review on the treatment of stress urinary incontinence in neurogenic patients published from 1992 to 2013. Thirty studies were identified with Level 3 evidence. The quality of reporting was 43-81%, with significantly higher quality noted in studies published after 2002. None of the studies followed a randomized controlled trial (RCT) design. Three primary surgical procedures were used in 29 of 30 studies: artificial urinary sphincter (AUS), urethral slings, and urethral bulking agents. One study used a ProACT device. AUS was considered more successful than urethral bulking agents ($77 \pm 15\%$ vs. $27 \pm 20\%$, $P = 0.002$). Urethral bulking agents reported higher failures than urethral sling procedures ($49 \pm 16\%$ vs. $21 \pm 19\%$, $P = 0.016$) and AUS ($21 \pm 19\%$ vs. $10 \pm 11\%$, $P < 0.002$).They concluded that the quality of evidence obtained from non-RCTs is modest. Surgeries for NSUI have relatively high success rates but also high complication rates. [127]

6.7. Bulking agents

There have been some studies reporting on the use of bulking agents in neuropathic patients (**Table 9**). Most of the published series relate to the use of periurethral injections in children. Various agents have been used. Polytetrafluoroethylen (TEFLON) was one of the first [128, 129]. It was once popular for treating vesico-ureteric reflux, but it has been abandoned after several authors reported possible particle migration and granulomatous reaction to this product [130, 131] (LOE2). Collagen has also been used, but is no longer available. Collagen lysis was found to lead to the loss of the bulking effect over time [129, 132-139]. Other synthetic products that have been used include polymethylsiloxane (MACROPLASTIQUE) and dextranomer hyaluronic acid copolymer (ZUIDEX) [128, 140-146]. Henly et al. [188] demonstrated that distant migration of particulate silicone was observed in animals after periurethral injection with polymethylsiloxane (LOE4). One of the main advantages of periurethral injections of bulking agents is that they are minimally invasive and can even be carried out as an outpatient procedure. The product is usually injected in the region of the bladder neck using a retrograde endoscopic approach. The bulking agent is injected at up to four sites with the aim of achieving urethral coaptation. Dean et al. [146] have suggested using an antegrade approach whereby the bladder neck is accessed using a percutaneous puncture into the bladder.

The results of periurethral injection surgery are summarized in Table 9. There are difficulties in comparing results from different series, because patient populations and definitions of treatment success differ. In particular, the criteria for defining “improvement” and “social continence” vary. Therefore, it seems appropriate to consider the proportion of “dry patients” as defining clear-cut success (even if some authors add to this result a notion of “dryness for some hours” between voiding or catheterization). Using this definition, 0 to 36% of the patients are considered to be cured using bulking agents (LOE2-3).

Most results are observed after a mean follow up that rarely exceeds 2 years (LOE2-3), although one series has reported long-term improvement up to 7 years after the last injection [148].

There are other important considerations to be made when interpreting the results of periurethral bulking agents. The first is that the studies in children generally contain patients with two types of problems: congenital urinary tract malformations (epispadias, bladder exstrophy) and neurogenic lower urinary tract dysfunction (mainly myelomeningocoele). This is of importance because there is some indication that, in children, bulking agents work slightly better in patients with malformations than in those with neurological problems [128, 135, 143, 148]. The global results of the series are therefore probably more optimistic than the results that might be observed in a population of only neurological patients. A second point is that these children have frequently already undergone various surgical procedures, which could modify the results of the injection procedure. Although a high proportion of the patients in these studies use IC, some have satisfactory outcomes while continuing to void spontaneously.

Although the use of bulking agents does not appear to cause any severe complications, there is the suggestion that the presence of deposits of inert material might lead to greater difficulty in performing future bladder neck surgery [143, 148]. It is also important to acknowledge that the failure to correct incontinence is in itself a complication of the operation [126]. Gender and previous bladder/sphincter surgery do not seem to be reliable prognostic factors regarding the success of the injections

6.8. Autologous Sling Procedures

In women with neurogenic lower urinary tract dysfunction, the use of an autologous fascial sling to support the urethra (usually close to the bladder neck) has been widely used to treat stress incontinence. A sling can either be used in isolation or in conjunction with other procedures such as bladder augmentation. **Table 10** summarises the results of published case series. Complete continence is observed in 83 to 89% of the patients (LOE3). Once again it should be emphasised that many patients will be dependent on bladder emptying using IC or an SPC, because the patient's neurological dysfunction may preclude voluntary voiding and because the sling may have to be inserted under tension in order to provide sufficient outflow resistance in the face of neurogenic intrinsic sphincter deficiency. All of the series report a low morbidity rate from the procedure. In particular, the risk of urethral erosion is very low when fascial slings are used. Synthetic sling materials have generally not been advocated when significant sling tension is required because of the risk of secondary urethral erosion [129,] (LOE3). However, there is a lack of studies that compare the use of autologous tissue and synthetic material. Bladder neck slings appear to be capable of providing good results in children. Some series suggest that girls have better outcomes [124,149-151].

The group from McGuire published retrospectively about 33 women with neurogenic SUI treated with an autologous fascial sling. The mean follow-up time was 52 months, while the mean age of the patients was 37 years. Causes of neuropathic bladder were myelomeningocele in 21 and spinal cord injury in 12 patients. A total of 30 patients were successfully treated and satisfied with the outcome of the operation (91%). Twenty-five patients (76%) were totally dry, while 5 patients (15%) had markedly improved but still required one pad per day. The complication rate was 15 %. [152]

6.9. Suburethral tapes

Midurethral tape operations, such as the tension-free vaginal tape procedure, have taken a major role in the management of stress incontinence in the non-neuropathic population but have not been adopted for the treatment of neurogenic stress incontinence; concerns about the risk of urethral erosion have been discussed already. Furthermore, intrinsic sphincter deficiency represents the usual pathophysiology in neurogenic SUI, contrasting with urethral hypermobility in non-neuropathic women.

There is very little published data available on the efficacy of midurethral tension-free tape operations in adult women with neurogenic LUTD. In a retrospective series of 12 women treated by TVT [153] with a mean follow up of 10 years, 9 patients were available for assessment of which 7 were dry and 2 were improved. The authors did not report any urethral erosions on follow up.

For male patients with post-prostatectomy incontinence, the use of synthetic tapes is increasing but, there is very little data for patients with a neurological cause to their incontinence, other than case reports. The use of this type of device in patients with underlying neurological illness should clearly be very cautious until further data emerges from clinical trials (LOE4).

6.10. Artificial urinary sphincter (AUS)

The AUS is recognized as one of the most effective treatments for urinary incontinence. It has the inherent advantage that it provides an adequate urethral closure pressure during the urine storage phase of the micturition cycle but then allows voiding to take place in the face of a low bladder outlet resistance. In patients with SUI, it is able to deliver either complete or "social" continence in 75 to 87% with satisfaction rates ranging between 85 and 95%. These rates are provided by published case series that contain a majority of patients with post-prostatectomy stress incontinence (PPI), along with some neuropathic patients. However, outcomes are probably similar for patients with neuropathic stress incontinence and a low-pressure bladder reservoir (LOE4) [154]. It should be noted that most of the published data on the use of the AUS in neurogenic SUI relates to men, although the device is also used in female patients with neurological disease as was published by Phe et al [155].

Before using the AUS in neurogenic SUI, several factors must be considered:

- Firstly, the risk of implant infection and erosion is probably higher than in the PPI population. It is generally recommended that patients undergo pre-operative urine culture and sterilisation of the urine before surgery [156] (LOE4).
- Manual dexterity must be sufficient to allow the patient to use the AUS pump- either to open the cuff to urinate, or to allow IC [154]. They must also accept the need for IC should the bladder have reduced contractility. However, some studies seem to indicate that the cycling activation of the pump could be avoided in patients performing IC (LOE3) [157, 158]. Bersch et al. [157] have described a modified technique.
- The cuff implantation site in adult patients with a neurologic bladder dysfunction is debated. The cuff can be implanted via a retropubic approach at the level of the bladder neck or around the prostatic apex. Alternatively the cuff can be implanted around the bulbar urethra using a perineal incision. Proponents of the retropubic approach argue that perineal incisions may cause cicatrisation problems for patients in wheelchairs. Moreover, traumatic catheterization is a well-known risk factor of urethral erosion in the non-neurological population undergoing an AUS [118] (1 to 5.5% in contemporary series) and, although it is recognized that IC is possible in AUS implanted patients [159], the risk of traumatic catheterization and subsequent cuff erosion might be higher when the bulbar urethral site is used. On the other hand, inserting an AUS cuff around the bladder neck is technically more difficult in adults in comparison with peri-bulbar implantation (LOE4). Some investigators are now exploring the possibility of using a laparoscopic technique for sphincter implantation [160].
- It is necessary to know the ejaculatory status of males in order to discuss the possible impact of the device on ejaculatory function. Cuff implantation around the bladder neck may allow patients to achieve antegrade ejaculation [161] (LOE4).

As previously stated, a thorough urodynamic evaluation of the bladder is mandatory in order to evaluate the potential impact of bladder compliance following AUS implantation. This has been reported in several retrospective series (LOE3) [108-123]. The reasons for this change in bladder behaviour are not known, and it has been observed particularly in populations of patients with myelomeningocoele [115, 117, 119, 120, 122]. In the event of any doubt about the quality of the bladder reservoir, bladder augmentation should be performed. The main results of published series are summarized in **table 11**. The continence rate is high, especially when a bladder augmentation has been performed (59 to 100% of the patients). The older series include some patients with the previous version of the AMS 800 (AMS 792). Therefore, it is possible that the long-term outcomes for patients being implanted today may be better than those seen in the past as a result of technical modifications of the device. Device infection, cuff erosion into the urethra and loss of fluid from the implant are the main causes of loss of an AUS. Infection and erosion typically occur in the early months after implant but late erosions are seen [114] (LOE3). The majority of the authors consider AUS to be the "gold standard" procedure to treat neurogenic sphincter deficiency in men.

**** AUS modified**AUS modified and two groups of patients depending of their age at AUS implantation***

6.11. Surgery of the bladder neck

Three main procedures have been described. Historically, the technique of Young [162], later modified by Dees [163] and Leadbetter [164] came into use, essentially for reconstruction in cases of exstrophy and epispadias. The principle was to mobilise the trigone (after ureteric reimplantation) in order to resect bladder neck tissue, so as to reconstruct the trigone around a small catheter. Although some authors [165, 166] described its use in neurogenic patients, the procedure has rarely been used in this patient group. The Kropp procedure [167] involves the use of a tubularised flap of the anterior bladder wall, which is used to extend the bladder neck and create an intravesical conduit. The tube is secured to the posterior bladder wall between the ureteric orifices. In the initial technique, the tube was tunnelled submucosally, but this manoeuvre was thought to increase the risk of tube stenosis [168, 169] (LOE3).

A third technique is that described by Pippi-Salle [170]. It is considered to be a variant of the Kropp procedure (also called a Kropp-onlay), with an anterior bladder wall flap that is not tubularised. Initial descriptions involved routine ureteric reimplantation but this was abandoned in later patients as long as there was an absence of reflux [171, 172] (LOE3). In a systematic review, Kryger et al. [126] (LOE4) stated that only data on 83 patients for the Kropp technique and 25 with the Pippi-Salle procedure have been published. Since that review there has been a lack of further significant data concerning the outcomes of these procedures. The continence results are good (50-69% for the Pippi-Salle procedure, 78-81% for the Kropp procedure) [168, 169]. However, several problems exist with the two techniques. Firstly, the techniques do not allow easy endoscopic access to the bladder. This is a major problem because it prevents or limits future endoscopic procedures (especially ureteroscopy, botulinum toxin injections and litholopaxy). Secondly, 28-45% of patients (especially male) report catheterisation difficulties following a Kropp procedure. For the Pippi-Salle procedure, continence rates are lower than for the Kropp procedure, but fewer cases of catheterisation difficulty have been reported [126]. However, a revision procedure is necessary in significant numbers, and it has rarely been used in male patients.

6.12. Complete bladder neck or urethral closure

Closure of the bladder outlet may be required if alternative approaches to managing stress incontinence are inappropriate or have failed. In women, closure can be achieved either via a vaginal or an abdominal approach while in men, either the bladder neck or the bulbar urethra can be the site of closure. Bladder drainage is maintained using a continent catheterisable abdominal conduit (e.g. using the Mitrofanoff principle), an SPC or (rarely) an ileo-vesicostomy.

Colli published a single surgeon experience in 35 patients with 4-13 years follow-up. BNC was paired with suprapubic catheter diversion. Indications for BNC included severe urethral erosion in 80%, decubitus ulcer exacerbated by urinaryincontinence in 34%, urethrocutaneous fistula in 11%, and other indications in 9%. The overall complication rate was 17%. All but two patients were continent at follow-up. [173]

Bladder neck or urethral closure can be technically difficult and a secondary operation to close a persistent fistula may be needed in some cases [174]. Interposing vascularised tissue between the bladder neck suture line and the urethral or vaginal closure is a well-described aid to the avoidance of closure failure; a flap of rectus abdominis can be used for this purpose. Bladder neck closure has also been used in children where other means of correcting SUI have failed or are felt to have a limited chance of success. The published series of cases provided some reassurance that children with closed bladder necks do not suffer from excessive complications in the form of renal deterioration, bladder rupture or stone formation.

As a general principle, urethral closure should not be undertaken in cases where it is possible to maintain urethral patency using alternative approaches to treat SUI. For example, patients with neurogenic lower urinary tract dysfunction are at high risk of stone formation in the bladder or upper tracts and it is desirable to maintain easy endoscopic access to the bladder in order to allow potential endoscopic treatment. Finally, preserving the natural urethra may constitute a safety measure if high bladder storage pressures are present or in the event of any complication with bladder access via a continent catheterisable abdominal conduit or suprapubic catheter [175].

Recommendations:

- Patients with stress incontinence in association with neurogenic lower urinary tract dysfunction require careful assessment in order to plan appropriate management. Video-urodynamic study must be used to evaluate both bladder and sphincter function (C).
- The clinical assessment must also evaluate the degree of patient handicap in order to determine whether they can perform self-catheterization, or whether an alternative means of emptying the bladder will be required. (D).
- Patients require careful preoperative counselling with respect to the benefits and risks of different operative approaches
- Autologous slings can be used to treat neurogenic stress incontinence. (B).
- Due to the limited evidence base, possible sphincter deficiency, perceived risk of complications and potential consequences on future management options, the Committee is unable to recommend routine use of synthetic slings and

tapes to treat stress urinary incontinence in neurogenic patients (D). Synthetic tapes could be recommended in older women with stable neurological conditions and SUI due to urethral hypermobility (C) as opposed to younger patients (e.g. meylomeningocele) with neurogenic ISD (negative recommendation).

- Artificial urinary sphincter can be used to treat neurogenic stress incontinence (A).
- Bladder neck reconstruction can be used to treat neurogenic stress incontinence (D).
- Bulking agents can be used to treat neurogenic stress incontinence when there is a demand for a minimally invasive treatment (D). The patient should be aware that the technique has a low success rate.
- Bladder neck closure should be offered to patients who have persistent neurogenic stress incontinence where alternative treatments have either failed or are likely to fail (B).

6.13. Surgical alternatives excluding denervation procedures to treat reflex incontinence due to neurogenic detrusor overactivity

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; bladder augmentation; enterocystoplasty; gastrocystoplasty; sigmoidocystoplasty; colocystoplasty; ureterocystoplasty; autoaugmentation; detrusorectomy

6.14. Bladder augmentation using intestinal segments

The aim of bladder augmentation is to provide long-term protection to the upper urinary tract by reducing the risk of impairment due to high bladder pressure, as well as to improve storage function [181]. First performed in man by Von Mickulicz [182] who used a segment of small intestine, the technique has regained popularity since the 1970s after the introduction of IC [183]. Unlike complete bladder replacement, enterocystoplasty preserves the integrity of the trigone of the bladder with the urethra and ureters, and reimplantation is not necessary. A segment of the gastrointestinal tract is taken out of continuity from the rest of the gut, and sutured onto the bladder. Various augmentation techniques using different segments of the gastrointestinal tract (caecum, colon, and ileum) have been described. Bladder augmentation is indicated wherever bladder capacity and compliance is reduced, or in the event of detrusor overactivity, when all conservative treatments (medical treatments, detrusor injections of botulinum toxin and/or neuromodulation of the posterior sacral roots) have failed [181, 184].

Before performing bladder augmentation, it is essential to ensure that:

- There is no malignant disease or lithiasis in the bladder.
- Renal function is normal and the upper urinary tract is unimpaired (screen particularly for lithiasis).
- There is no gastrointestinal tract disease (Crohn's disease, hemorrhagic rectocolitis, short gut syndrome, etc.).
- The patient is willing and capable of self-catheterization. This can be combined with continent cystostomy.

Technical principles:

There are two stages to the surgical procedure: first bladder preparation and then augmentation. Usually open surgery is performed, but recently laparoscopy has been reported [185, 186] (LOE3). At present, except for technical articles on laparoscopy, there are no publications comparing this technique with open surgery.

The bladder can be prepared either by clam cystoplasty or by supratrigonal cystectomy. The preferred preparation depends on the quality of the detrusor, and more particularly on whether the bladder has retained its visco-elastic properties. Where the detrusor is very fibrous and thick, supratrigonal cystectomy should be envisaged, since otherwise exclusion of the ileal patch may occur.

Clam cystoplasty

Clam cystoplasty involves freeing the anterior/ posterior surfaces and dome of the bladder. The bladder can be opened either in the transverse plane or sagittal plane, the incision starting and ending about 2 cm above the bladder neck. If the lateral surfaces are not mobilised, the vesical arteries can be preserved to maintain vascularization of the bladder dome. Robot-assisted laparoscopic augmentation cystoplasty has been recently introduced. Preliminary results have been reported in children with spina bifida [187].

Supratrigonal cystectomy

Supratrigonal cystectomy involves resection of the body of the bladder, but retaining the trigone. The bladder is freed under the peritoneum and the superior vesical arteries ligated and sectioned. The bladder pedicles are ligated and sectioned laterally up to the trigone, which is preserved. The body of the bladder is excised 1-2 above the trigone. During the bladder dissection, care must be taken to spare the ureteric vascularization.

Ureteric reimplantation

Ureteric reimplantation must be carefully discussed in the event of vesicoureteric reflux (VUR). Several authors have reported that improved bladder compliance precludes the need for reimplantation (LOE 3)

[188-191]. They have reported a resolution rate of about 85% for VUR, classified below grade IV. For grade V reflux, improvement was observed in 2/3 of patients. Except for the work of Simforoosh [188], these results were obtained in small heterogeneous series of children (neurogenic bladders and congenital anomalies), and after relatively short mean follow-up times (1 to 5 years).

Hayashi et al. [192] reported on 22 patients treated by ureteric reimplantation during bladder augmentation (LOE 3). Their work was original in that it gave detailed account of renal function after long-term follow-up (mean 12 years). Ureteric reimplantation during bladder augmentation did not result in greater morbidity and 97% of patients recovered. Renal function was preserved and satisfactory. The case for ureteric reimplantation during augmentation cystoplasty was supported by a small non-randomised study (LOE2-3), where Wang *et al.* demonstrated that lack of ureteric reimplantation during cystoplasty in children with neurogenic bladder was a risk factor for residual high-grade reflux, which, in turn, was a risk factor for febrile UTIs [193]. A larger non-comparative non-randomised study (LOE3-4) reported equal success rates for the two methods, but ureteric reimplantation had been mostly reserved for the higher grade reflux cases [194]. These results were presented as part of a literature review which was inconclusive as to the superiority of the results of either method [194]. Accordingly, the need for ureteral reimplantation during bladder augmentation should still be considered, especially for cases of grade V reflux. However, improved bladder compliance will reduce some VUR.

Intestinal segments

The choice of intestinal segment depends on patient's history and the local conditions. All segments of the gastrointestinal tract may be used, except the jejunum because of the risk of water-electrolyte disorders. The most frequently used segment in adults is the ileum, because it is easy to remove, is close to the bladder and may be shaped easily into a reservoir. Colon segments are used more often in children. The removed intestinal segment must always be detubularized to reduce peristalsis to a minimum and to obtain a reservoir with low pressure. The segment is then placed and sutured onto the bladder in the form of a patch. For supratrigonal cystectomy, the intestinal segment needs to be longer and fashioned into a neo-bladder [184].

Technical variations aim to reduce mucus secretion and reduce the reabsorption of urine by the intestinal mucosa that leads to metabolic acidosis. A number of variant techniques have been proposed but not developed extensively. Seromuscular colocystoplasty lined with urothelium involves removing the detrusor, leaving the bladder mucosa intact, and then covering it with a demucosalized sigmoid patch [195]. Seromuscular enterocystoplasty necessitates removing the mucosal membrane of the intestinal segment surgically, or destroying it by argon beam [196], before placing it onto the prepared bladder [197].

A third technique uses an appendicular-based cecal flap, aiming for a less invasive form of augmentation cystoplasty [198]. The technique involves isolation of a 10-12 x 3 to 5-cm cecal flap on the base of the appendicular pedicle, by which the bladder was augmented and the appendix was brought out through the abdominal wall for catheterization. Without any bowel anastomosis, the cecal anterior wall was repaired.

An experimental technique tested only pre-clinically is the reversed seromuscular ileocystoplasty, where the seromuscular layer of the ileal loop from its antimesenteric aspect was sutured to the bladder mucosa of the previously bivalved bladder. Complete epithelialization of the ileum's serosal surface with transitional epithelium was confirmed 4 weeks post-operatively [199].

Results of enterocystoplasty

The main published series for patients undergoing surgery for neurogenic bladder are summarized in **Table 12**. Peri-operative mortality is estimated between 0 and 3.2% (LOE 2-3). The most frequently reported early morbidity (LOE 2-3) is prolonged post-operative ileus in up to 11.7% [200-203]. A nasogastric catheter is no more justified in neurological patients than in the general population (LOE3) [204]. Other common complications include episodes of febrile UTI (4.8-9%), urinary fistula (0.4-4%), that usually resolve, and thrombo-embolic complications (1-3%). When the pelvis has been irradiated, the patient must be warned of the increased risk of entero- or colovesical fistula. Stoma revisions (up to 50% in a small series) and wound infections have also been reported [203].

Chronic bacteriuria always occurs with IC and should not be considered a complication [203] (LOE4). Cases of late urosepsis have, however, been reported [255]. The risk of calculus in the enlarged reservoir ranges from 10-50% [205-209] (LOE 2-3). There may be a higher risk of developing upper urinary tract lithiasis than in the general population [210-212] (LOE3).

After bladder augmentation, intestinal transit disorders are frequent and probably underestimated (0-30% [213-215]). Several explanations have been proposed (ileocecal valve not preserved, biliary salt malabsorption, etc.). Somani et al. conducted a cohort study (LOE2) focusing on this particular problem [266]. They report a high rate of intestinal transit disorders, affecting almost 50% of patients treated for neurogenic bladder. These complications distressed patients and nearly 10% regretted having undergone surgery. Although transit disorders cannot be attributed to surgery alone (patients with neurogenic

bladder may have intestinal transit disorders unrelated to surgery), patients should be informed of this risk.

Since the gastrointestinal tract mucosa resorbs urine, water-electrolyte disorders may occur. Hyperchloremic acidosis is reported in up to 15% of cases (LOE 2-3). These water-electrolyte disorders may be accompanied by anomalies of calcium metabolism that do not appear to have any significant long-term effect, for example on growth in childhood, but the subject is still under debate (LOE 3) [217-220]. However, care must be taken when treating patients with a marked decrease in creatinine clearance, since metabolic acidosis is no longer compensated [184] (LOE4).

In theory, diversions performed using the ileocaecal junction and the end segment of the ileum would expose patients to a risk of vitamin B12 deficiency (with possible onset of megaloblastic anemia). The fact that the intestinal segments measure less than 50 cm would explain why few patients suffer clinically overt vitamin B12 deficiency.

The risk of cancer development of the newly formed reservoir is particularly important, since neuro-urological surgery is often indicated in patients with long life expectancy, many being children. The general consensus today is that patients with a bladder reservoir are at higher risk of developing a tumour than are the general population, but this risk has not as yet been clearly defined. The rates for the risk of tumour development range from 1 to 4.6% [221-224] (LOE 3-4). Most of the published cases concern adenocarcinoma at the junction of the intestinal mucosa with the urothelium. These usually developed long after the initial surgery (over 10 years in most cases). Some patients developed urothelial tumours with the typical risk factors. Two facts should be emphasised with regard to neurogenic bladder (augmented or not):

- The sensitivity and specificity of the routine bladder tumour diagnostic and monitoring tools (urinary cytology, BTA test, simple cystoscopy, etc.) may be reduced. Patient monitoring can only be envisaged by regular cystoscopy with biopsy of suspect areas.
- Monitoring is essential, since many patients develop tumours without symptoms and may not be diagnosed until late.

Monitoring frequency needs further investigation. A review of a series of cystoplasties performed in patients with congenital abnormalities including neurogenic bladder found comparable risk of bladder cancer, compared to control patients managed only by IC (4.6% vs 2.6%, p=0.54) [224]. In addition, a projected cost-analysis based on post-augmentation malignancy and cost estimates from published reports or US government sources concludes that annual screening with cytology and cystoscopy of children with spina bifida subjected to augmentation cystoplasty is unlikely to be cost effective at commonly accepted willingness-to-pay thresholds, but would be justified if the annual rate of cancer development were more than 0.26% (12.8% lifetime risk) or there were a greater than 50% increase in screening effectiveness and cancer risk after augmentation [225].

The most serious and possibly life-threatening complication is cystoplasty perforation (LOE3). This can happen whichever gastrointestinal segment is used, but occurs more often after ileocystoplasty [226] (LOE3). It is estimated to occur in 5-13% of cases [230] (LOE3). Perforation usually occurs on the graft or at the junction of the bladder with the enterocystoplasty, and often results from high pressure within the enterocystoplasty, or more rarely from traumatic catheterization or urodynamic investigations [227] (LOE4).

Functional outcome

The functional outcome of bladder augmentation by enterocystoplasty is given in Table 12. Only series of patients undergoing bladder augmentation for neurogenic bladder were retained in our analysis. Given the wide range of indications, surgical techniques and enteric segments used, and retrospective nature of studies, it is difficult to draw any clear conclusions. Nonetheless, all authors reported an improvement in bladder capacity and compliance (LOE2-3). More than 90% of patients achieved nocturnal continence, and 91-100% achieved diurnal continence (LOE2-3).

Two quality-of-life studies (LOE2) reported improvement rates exceeding 90% [202, 231]. A 92% satisfaction rate was reported by a long-term follow-up study (mean 14.7 years) and patients would recommend the treatment to a friend [205]. However, a potential bias might arise due to the heterogeneous population analysed in some of these studies, including a mixture of patients with neurogenic and idiopathic DO.

If the bladder compliance defect persists, exclusion or ischemia of the intestinal patch must be investigated [222, 230]. Sometimes urinary leakage is related to sphincter deficiency and may be treated by an AUS [233] or other means of urethral pressure reinforcement [222, 232]. However, most authors consider that this type of adjunctive treatment should not be performed routinely since most patients have a good functional outcome after bladder augmentation, and only those with marked sphincter deficiency prior to surgery require these measures.

Possible alternatives to enterocystoplasty

Gastrocystoplasty and ureterocystoplasty

The use of a pedicled segment of stomach (gastrocystoplasty) or ureter (ureterocystoplasty) as an alternative to enterocystoplasty has been reported mainly for children with a neurogenic bladder. In theory, its advantage lies in the absence of metabolic acidosis, but in adults this is very theoretical. Moreover, both these intestinal segments secrete less mucus than the small and large intestines [234-238]. Abdel-Azim *et al.* [236] reported gastrocystoplasty in adults

(LOE3). In the light of their experience with children, they decided to use this technique in a set of young adults (mean age: 23 years, range: 4-32 years). Their paper records that the short-term results (3 years mean follow-up) of gastrocystoplasty were satisfactory, with increased functional bladder capacity and no impairment of the upper urinary tract (LOE3). However, two disadvantages are reported. First, a hematuria-dysuria syndrome requiring occasional use of antacids sometimes accompanied gastrocystoplasty. Second, the maximum bladder capacity was lower than that observed with enterocystoplasty. This may have a benefit for easier bladder voiding, but if the bladder were to lose some capacity, further surgery would potentially be required. The outcome in the very long-term for patients who have undergone this procedure remains unknown.

(Max BC: Maximal Bladder capacity, DP: Detrusor pressure at the maximal bladder capacity)

Kidney transplantation and augmentation cystoplasty

The general notion is that augmentation cystoplasty should be beneficial in patients with chronic renal failure and performed prior to transplantation, as a low-pressure reservoir might delay the native kidney's death and optimize graft survival rates. However, published studies suggest otherwise. In a small series (n=11) of neurogenic bladder patients, augmentation cystoplasty did not affect progression to end-stage renal disease (LOE2-3) [239]. More strikingly, prior cystoplasty was found to be associated with higher risk of graft rejection compared to non-cystoplasty transplants, up to 7 years post-operatively (LOE2-3). Although the authors suggest this may be due to higher rates of febrile UTIs and chronic rejection, it might also be due to a more severe underlying pathophysiology which resulted in the necessity of a cystoplasty in those children [240]. The same group of authors conclude that the timing of augmentation cystoplasty in relation to the transplant surgery (before or after) has no significant effect on the outcome of the transplantation, with respect to graft acute rejection, graft survival (up to 7 years) and incidence of febrile UTIs (LOE2-3) [241]. In terms of serious complications, patients with augmented bladders and a history of renal transplant on chronic immunosuppression were found to have a significantly higher incidence of bladder cancer compared to patients who were not immunosuppressed (15% vs 2.8%) [224] (LOE3).

Autoaugmentation by detrusor myotomy

Bladder autoaugmentation without any associated gastrointestinal tract surgery as an alternative to enterocystoplasty was proposed as early as 1972 by Mahony and Laferte [242] who performed detrusorotomies (detrusor incision without resection) to increase bladder capacity and reduce incontinence. With Cartwright and Snow [243], the technique then evolved to detrusorectomy (myectomy). This involves excising a thick segment of muscle from the dome of the bladder, leaving only the mucosal membrane in place. Bladder pressure gradually dilates the "demuscularized" area resulting in bladder augmentation. The intervention, initially described by extra-peritoneal laparotomy, can be performed by video-assisted surgery [244, 245] or by robot-assisted surgery [246] (LOE4). The detrusor can be dissected by laser [247] (LOE3). The area around the detrusorectomy can be protected using the omentum [248] or a striated muscle [249] (rectus abdominis muscle) to prevent perforation and retraction (LOE4).

Techniques using free-graft or pedicled de-epithelialized gastric patches [250, 251] require gastrointestinal tract surgery and were therefore not included in the present work. Furthermore, most of the previously published studies concerned children. All the studies are retrospective and with few patients. For children, most authors [248, 253-256] report poor results after surgery, both symptomatic and urodynamic, together with a risk of upper urinary tract impairment (LOE4). Two authors recently reported better results with certain technical adjustments, namely an extensive detrusorectomy [257] (LOE4) and rectus muscle hitch and backing [249] (LOE4). The last technique supposes a large dissection of the rectus muscle. Urothelium is then sutured to this muscle in the theoretical objective to prevent its retraction and shrinkage.

Only three retrospective series are available for adults. The first, published by Stöhrer et al. in 1997 [205] (LOE3), reports interesting results for efficacy, with increased functional bladder capacity. However, the authors did not report mean follow-up and described a mixed population with 39 patients with neurogenic bladder and 11 patients without. The two other published series concerning adults [252, 253] did not confirm these findings but did confirm the marked superiority of enterocystoplasty with respect to both urinary symptoms and upper urinary tract impairment (LOE3). Detrusor myectomy achieves better results for idiopathic DO; nearly all patients (5 of 6) with neurogenic DO were not improved, with a mean follow-up of 79 months [252] (LOE3).

There is little information on specific complications, but detrusorectomy is simpler and seems to present less risk than enterocystoplasty. A comparative retrospective study (LOE4) reported 20% complications for enterocystoplasty (infectious, digestive and parietal complications) against only 3% for detrusorectomy [253]. The rate of secondary rupture and/or perforation is poorly documented. An experimental animal study concluded that the bladder rupture pressure was slightly lower after detrusorectomy than after enterocystoplasty, thus potentially exposing the patient to an increased risk of rupture [259] (LOE4).

Bladder augmentation using biomaterials

Research interest in the role of tissue engineering in bladder reconstruction is growing. This research appears to evolve along three axes [260]:

a. use of acellular natural or synthetic biomaterials: an acellular biomaterial graft is used as a tissue implant which becomes incorporated through the ingrowth of cells of the native host bladder

b. use of biomaterial scaffolds which have been pre-incubated with autologous cultured human urothelial and smooth muscle cells

c. composite cystoplasty, which combines the use of autologous cultured urothelial cells with a host pedicled and de-epitheliased smooth muscle segment.

Most publications concern preclinical studies [261-265] (LOE4). Several biomaterials have been used which can be grouped in 3 categories: (a) decellularized natural matrices produced from a variety of tissues; (b) matrices produced from natural extracted polymers (e.g., collagen, alginate, chitosan and hyaluronan); and (c) synthetic polymers including polyglycolic acid (PGA) and poly-caprolactone (PCL) (see

reviews [260, 266]). These biomaterials can only be used after performing clam cystotomy since the area to be colonized should not be too large. It also appears that the use of biomaterials is associated with higher incidence of bladder lithiasis. The best studied natural materials are porcine intestinal submucosa (SIS, Cook) and bladder-derived acellular matrix [267, 277-282].

Results from only two pilot human studies have been fully published to-date [280, 281].The former reported on neurological patients, the latter on non-neurogenic OAB patients. In a small prospective study of 7 young myelomeningocele patients (LOE 2-3), Atala [281] describes his technique, which consists of seeding patient's urothelial and muscle cells on a biodegradable scaffold. After 7 weeks, this engineered artificial bladder could be implanted in patients. Although the small number of patients doesn't allow definitive conclusions, a trend towards an improved bladder capacity and compliance was observed. It was also implied that patients who received cell-seeded collagen-coated PGA scaffolds wrapped in omentum as a vascular bed had the best outcomes. Encouraging results were also reported in 12 women with intractable non-neurogenic OAB who were submitted to bladder augmentation using an acellular matrix of porcine dermal collagen and elastin fibres (Pelvicol, Bard) [280] (LOE4). Significantly improved or cured incontinence was achieved in 67% of them at a 12-month follow-up. Finally, a recent review article [276] claims results in short report form from two small Phase II trials on patients with neurogenic bladders due to either spina bifida (paediatric patients) or SCI (adults). Success rates of 60% and 67% are reported for up to 2-year follow-ups, depicting patients with preoperative 'normal bladder cycles' as the best candidates for bladder augmentation with a tissue-engineered scaffold. Further studies, including larger trials are necessary to evaluate routine use of biomaterials.

Recommendations

- Any segment of the gastrointestinal tract may be used for bladder augmentation, but the ileum seems to give the best results in terms of ease of use, risk of complications and efficacy (B). Few data are available concerning gastrocystoplasty and ureterocystoplasty in adults (D)
- When the bladder suffers a significant compliance defect, supratrigonal cystectomy and reconstruction is preferable to clam cystoplasty (B).
- Bladder augmentation may solve low-grade vesicoureteric reflux. In the event of grade IV or V reflux, ureteric reimplantation may be necessary (C).
- Patients should be informed that the most frequent and serious complications are bladder calculi and perforation at the bladder/bowel junction, usually caused by over-pressure (B).
- Bladder augmentation may have sequelae such as intestinal transit disorder, and patients should be informed of this before surgery (C).
- The body of evidence concerning detrusor myomectomy in neurological patients is controversial. Therefore, detrusor myomectomy should not be recommended in these patients with impaired bladder function (D)
- Bladder augmentation using biomaterials or tissue engineering is promising, but the preliminary results need to be confirmed by larger studies (D)
- Due to risk of complications, regular follow up is needed (B)

Cutaneous continent urinary diversion

Keywords; Continent urinary diversion; vesicostomy; cystostomy; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis

For certain patients, urethral catheterization can be or become, unacceptable or even impossible. The following list is not exhaustive, but describes the more frequent reasons:

- Functional limitations of the upper limbs (tetraplegia [295] unilateral or bilateral plexus problems, musculoskeletal trauma problems)
- Cognitive disorders (forgetfulness, lack of comprehension, refusal)
- Difficulties in terms of mobility and/or undressing (spasticity, upper SCI resulting in difficulty in maintaining the equilibrium of the trunk and or limited control of the upper limbs, obesity).
- Failure to reach the urethra independently (more common in women, compounded by the tilted pelvis and all other factors that cause mobility difficulties.)
- Urethral injuries (stenosis, fistulas, hyperesthesia), urethral pain.

In these situations, management requires careful consideration; in some, a continent cystostomy may be an option. The general principle is to permit the emptying of a full bladder, independently and easily, by IC through an efferent tube attached to the wall of the lower half of the abdomen. The absence of any leakage from the cystostomy is controlled by its own watertight system, associated with the return process of a capacitive and compliant reservoir. This will require careful selection of patient candidates, especially when there is any function impairment of the upper limbs (trauma to the spinal cord) [296-298] (LOE3).

Assessment is essential, and must include the motivation of the patient, capabilities for dressing and undressing, capability of catheterization in the planned stomal area, and tolerance for the time and potential

discomfort involved. In the case of cognitive difficulties that are too significant, if a severe upper limb dysfunction exists [295], or if compliance of the patient remains an impossible obstacle, continent diversion is not indicated. Impaired renal function can also be a contraindication [299].

In neuro-urology, techniques for heterotopic continent neo-reservoir (e.g. Koch pouch, Benchekroun, Mainz, Miami pouches) are seldom used initially. They can be offered to patients with VUR, with incontinence through the native urethra despite bladder enlargement, or when closure of the bladder neck will be needed (e.g. uretero-vaginal fistula).

Results of the different types of cystostomy:

The series are mainly retrospective (LOE 3) and frequently combine several techniques. This makes the analysis of the results difficult, but some major facts can be gleaned from them. The catheterizable tube must be able to penetrate the intact or enlarged bladder and it must be able to reach the abdominal wall through a direct pathway with easy access for the patient that has already been predetermined by pre-operative research. The pathway of the tube must be direct in order to facilitate self-catheterization. Techniques can be grouped in two major categories: simple tubes implanted with an anti-reflux system and intestinal loop invaginations.

a) Simple tubes: virtually any anatomical structure that is tubular or that can be tubularized and that is vascularized can be used to make a continent catheterizable tube [299] (LOE4). The two structures that are the simplest to use are:

- The appendix: Trans-appendicular cystostomy according to Mitrofanoff's procedure [300] has long been the most used technique (LOE3). Different modifications have been proposed, especially to gain more length by removing a cecal cuff.
- A short, remodeled intestinal segment (small intestine, less frequently the sigmoid or right colon). Yang and Monti simple [301] (LOE3) or double technique and the Yang-Monti technique modified according to Casale in order to gain length by avoiding a double tube [302] (LOE3).

Other structures have been used in a more anecdotal manner, primarily in children: cecum and appendix monobloc [303] (LOE4), bladder [304] (LOE4), stomach [305] (LOE4), distal ureter [306] (LOE4), Meckel's diverticulum [296, 307] (LOE4), or the preputial or clitoral skin [308] (LOE4).

For most authors, continence of the tube was achieved by implantation in the native bladder or in the augmentation via a submucosal path similar to that used in ureteral reimplantation for VUR. (LOE4). The submucosal path length must be at least 2cm, and is adapted to the bore of the tube (two to three times the diameter) [298] (LOE4). A posterior or posterolateral bladder flap (kept in case of a supratrigonal cystectomy) should allow a more solid implantation of the tube in the bladder [309] (LOE2). Direct implantation into the cystoplasty has also been reported. The cutaneous anastomosis is made in the lower half of the abdomen, at the umbilicus, or in the right or left iliac fossa. It seems essential that the site of the stoma would be determined preoperatively in patients with functional limitations of the upper limbs. The site is chosen based on the patient's capabilities and the position during self-catheterization (seated in a chair, supine, other). The surgical technique used in this particular case must allow access to any point on the lower half of the abdominal wall [310-312]. Most authors recommend the interposition of a skin flap in the distal end of the tube in order to minimise stenosis of the circular orifice scars. Several techniques have been proposed: flap in V, VQZ [313] (LOE3), and VR [314] (LOE3). However, at present, the results published do not confirm that the risk of stenosis is avoided by any of the techniques.

Table 13 summarizes the results in terms of stoma continence and complications, specifically pertaining to the continent stoma. The necessity of reservoir augmentation (80% of published cases) and techniques allowing reinforcement of ureteral continence are addressed elsewhere. Continent stomas are obtained overall in 75 to 100% of cases (LOE3). Seven studies indicate significant improvement in quality of life after the procedure related to improved autonomy in bladder evacuation, to continence, and to improved sex life [297, 309, 311, 312, 315-317] (LOE2-3).

The rate of stoma complications (16-60%) is dominated by the risk of stenosis, which is most often treatable by a simple dilation [318] (LOE3). Many authors emphasize the fact that this complication occurs most often in the year following surgery. However, Liard et al. [319] (LOE3) reported an elevated (65%) intervention rate at 20 years of monitoring. For most authors the rate of complications related to the tube continence was lower when the segment used was the appendix or intestines remodeled according to Yang-Monti (LOE3). However, these two plasties seem to have equivalent complication rates. Only Narayanaswamy et al. [320] (LOE3) reported higher rates for catheterization difficulty and reintervention with the Yang-Monti tube in comparison to the appendix. The Monti tubes in this study were double tubes in 68% (17/25) of cases, and the majority of the complications were related to the junction area for the two hemi-tubes and not to stoma stenosis. Therefore it seems that this lengthening method should be used with caution. If there is a problem with tube length, the method proposed by Casale [302] (LOE4) has the theoretical advantage of avoiding an anastomosis on the tube or a bent pathway at the junction of the two tubes.

The umbilical anastomosis site for the stoma may be related to an increased frequency of stoma stenosis [304, 321] (LOE3). The poorer vascularization of the umbilicus has been proposed as an explanation [321]. However, results on this point are contradictory with more recent studies [309].

b) Other types of continent urinary stoma:

Techniques are extremely varied. Two technical approaches can be broadly outlined here:

- Invaginated valves (Koch pocket, Benchekroun, Mainz), in which the continence mechanism is tied to the flattening of the invaginated valve by urine accumulated in the neo-reservoir;
- Ileal-caecal reservoirs, in which a portion of the ileum and the ileal-caecal valve are used as a continence mechanism (Indiana pouch, Charleston pouch, Miami pouch).
- A new technique using a pedicled cutaneous flap which is surgically elevated from a hairless area on the abdomen, tubularized and passed through the anterior abdominal wall directly into the bladder (The Daoud technique) [322].

Data in the literature do not allow a determination to be made as to the superiority of one type of stoma over the others. However, the catheterization difficulties seem to be lower with stomas that use the appendix, and the risk of lithiasis seems to be higher with the stomas constructed using metal staples [323] (LOE4). Several authors have also specifically reported results in neurological patients [312, 322, 324-329] (LOE3). Continence rates for the stoma vary between 63 and 100%. Complication rates for the stoma are between 10 and 23%.

Bladder outlet management; although prospective studies are missing, evidence from retrospective analyses (LOE2-3) suggest that continent diversion combined with bladder neck closure is superior in terms of functional outcomes to continent diversion with an open bladder neck, whilst having similar morbidity [330]. Another series reports primary continence rate following bladder neck closure and continent vesicostomy of 82% [331]. Both series report however on a mixed patient population.

Recommendations:

- Indication for cystostomy presumes a multidisciplinary evaluation involving the urologist and a neurologist or a reeducation doctor, as well as stomatherapy nurses or occupational therapists for estimating patient catheterization capabilities (A)
- Use of the appendix to carry out continent cystostomy is the standard method in children, but few long term data are available in adults (C). The appendix may have a short mesentery, so a reconfigured ileal segment is often needed.
- If the patient has undergone an appendicectomy, the use of a segment of the small intestine can be proposed, with slightly poorer short term results (C)
- Long term follow up of after continent cystostomy is needed to have a better idea of the long term results of the various procedures (C).

6.15. Non-continent cutaneous urinary diversion

Keywords; neurogenic bladder; spinal cord injury; spina bifida; myelomeningocele; multiple sclerosis; urinary diversion; ileovesicostomy; Bricker; ureterostomy; vesicostomy; ileal conduit

Non-continent cutaneous diversion refers to all methods used to divert urine, and where incontinence remains or where a system of extra-physiological continence is created, i.e. urine flow is continuous and requires a means of collecting urine attached to the skin. In the context of neurogenic bladder, these diversions make it possible to obtain low bladder pressure and to preserve the upper urinary tract. This type of surgery is a last resort for the many complications related to neurogenic bladder (and congenital anomalies of the lower urinary tract), in patients for whom other therapies have failed to help. Urinary diversion techniques, however, have been largely replaced by augmentation cystoplasty in the treatment of refractory neurogenic bladder, at least in some groups of neurological patients. The analysis of the US national database of patients with spina bifida between 1998-2005 demonstrated that 3,403 patients were submitted to augmentation cystoplasty as opposed to 772 treated with urinary diversion. Moreover, patients undergoing urinary diversion required more healthcare resources, with significantly longer hospital stays,

higher total charges and more use of home health care after discharge home [342].

Four techniques are described for non-continent urinary diversions for patients with neurological vesico-sphincter disorders. In order of frequency these are: ileal conduit urinary diversion, ileovesicostomy, cystostomy and cutaneous ureterostomy.

Ileal conduit urinary diversion

Ileal conduit urinary diversion is the type of diversion most frequently performed on neurological patients with bladder dysfunction. Pre-operative location of the intended stoma site is crucial and must be adapted to the patient's main position (wheelchair or bed); the stoma site must be easy to access for management. The ileal segment must be as short as possible to prevent stasis [343] (LOE3). There is a variant to this technique whereby a segment of jejunal loop is removed and a stoma made on the left hemi-abdomen. This technique can be proposed after irradiation of the pelvis minor, if the ileum has been impaired and a short loop must be used (about 10 cm) to avoid metabolic disorder (jejunal conduit syndrome: hyperkalaemia, hyponatraemia, hypochloraemia, acidosis) [344] (LOE3).

In neurological patients, ileal conduit urinary diversion by laparoscopy and by robot-assisted laparoscopy has been described [345-349] (LOE4). Patients seem to benefit from the procedure, though this remains to be confirmed in the medium and long-term [350] (LOE 2). Uretero-ureterostomy on conduit diversion has also been described in neurological transplant recipients in whom the donor ureter is too short to achieve a tension-free ureteroileal anastomosis [351]. Graft survival rates at mean 5.3 years follow-up was 83%.

Some series of neurological patients were evaluated to determine the onset of early and late complications [350, 352-357] (LOE2-3). The first study to use the recently introduced Clavien system reported on a series of multiple sclerosis patients (n-53), of whom 43% developed minor complications (Clavien grades I-II) and 11% major complications (Grades III-IV) [358]. Early series of children can be evaluated to determine the morphology of the upper urinary tract and renal function after urinary diversion over a long period (up to 20 years) [359-364] (LOE3). Despite complications, significant improvements in patients' quality of life were recorded, in both retrospective [359] and prospective studies [350]. The latter, however, noted that only aspects of QOL associated with the limitations and constraints induced by urinary problems were improved, not the overall QOL.

Mortality is estimated between 0 and 3.4% (LOE2-3). The commonest early complication is intestinal obstruction (4 to 12.6%), usually reversible after prolonged intestinal drainage [350, 352, 353, 355-357] (LOE2-3). The risk of gastrointestinal fistula should also be taken into account (0 to 3.3%). As for entero-cystoplasty, the current trend is to try to reduce nasogastric tube drainage time to a few hours [365] (LOE3). The most frequent medical complications encountered (3 to 8%) are febrile urinary infections and thrombo-embolism (2 to 3%; LOE2-3). Other major complications include: urinary fistula in 0.3 to 3.4% of patients which may be prevented by placing a ureteric catheter for about ten days (LOE3). This complication could be a risk factor for later uretero-ileal anastomosis stricture (LOE4).

The risk of long-term intestinal obstruction ranges between 5% and 7% (LOE3). Even when a short intestinal segment is used, some patients can experiment transient constipation or diarrhoea, which could adversely affect their quality of life [366] (LOE2).

Complications affecting the bladder left in situ. For the particular indication of neurological patients with bladder dysfunction, several authors have proposed not carrying out cystectomy so as to avoid potentially morbid surgery. At present, this is debatable for several reasons:

- There is a risk of pyocystis formation in the unused bladder (21-50%) [352, 353, 357, 367] (LOE3). Even where conservative treatments have been attempted (combining vesicular irrigation with antibiotherapy) [368] (LOE3), secondary cystectomy is then necessary in a high proportion [353, 359, 361]. For women, a surgical alternative is vaginovesicostomy, which appears to be effective [354, 361] (LOE4).
- The unused bladder frequently becomes infected and may become an "irritative thorn", especially in patients with spinal injury or multiple sclerosis (LOE 4) [353, 369].
- The risk of bladder neoplasia is higher in neurogenic patients, the principal risk factors being long-term indwelling catheterization (more than 8 years), bladder calculi and smoking [370-372] (LOE3). Moreover, screening by cystoscopy-biopsy is not effective [373, 374] (LOE3).
- Improvement of the cystectomy technique (noticeably laparoscopic cystectomy) has considerably reduced related morbidity [350, 375] (LOE2-3). Supratrigonal cystectomy can be performed in men, preserving the prostate and preventing any genital and sexual sequelae.

Upper urinary tract complications. Stenosis of the uretero-ileal anastomosis may occur in the medium and long term. This is very damaging to the upper urinary tract and requires regular monitoring. In contemporary series, it occurs in 2 to 7.8% of cases within 10 years [352-357] (LOE3). For cases followed for more than 10 years, the finding of 16.5 to 50% stenosis is essentially that of early paediatric series [359-364] (LOE3). Impairment of the upper urinary tract and renal function seems to be correlated mainly with stenosis of the uretero-ileal anastomosis, but also

with a long ileal graft and stomal stenosis leading to poor voiding and pyelonephritis [360] (LOE4). In the event of poor functioning of the uretero-ileal anastomosis, some authors suggest endoscopic dilation before further surgical repair of the anastomosis (LOE3) [356, 376-378]. Surgery however remains the reference treatment [378] (LOE3).

The risk of upper urinary tract lithiasis (3 to 31%) is always present in these patients (even without stenosis of the uretero-ileal anastomosis) [352, 353, 356, 357] (LOE3). Patient monitoring should include regular screening of the upper urinary tract to detect any lithiasis and to implement timely treatment (LOE 4). Chronic bacteriuria is frequent but should not be treated if asymptomatic. Both patients and attending physicians must be informed so as to avoid the administration of unnecessary antibiotics. However, the risk of febrile infection persists over the long term and may be predisposed by uretero-ileal stenosis (12 to 34%) [352, 353, 356, 357].

Stoma complications. These are relatively frequent (18.6 to 30%) and varied [353, 356, 357]. The risk of peristomal herniation is the most frequently reported (between 7.7 and 10%). Stomal stenosis may also occur. Stoma complications appear to occur more often in obese patients (LOE3) [379].

Some patients, usually adults who underwent surgery as children and who subsequently to recover a continent system, or who have had complications with their non-continent urinary diversion could ask for undiversion [380-384] (LOE3-4).

Ileovesicostomy

This technique was first described by Cordonnier in 1957 for treatment of three children suffering from myelomeningocele [385, 386](LOE4). Its theoretical advantages are relative simplicity, the absence of dissection and suture of the ureter, thus preventing ureteral complications and the potential of restoring the integrity of the bladder (only one case described) [387] (LOE4). The surgery consists in removing a 10 cm ileal segment from about 15 to 20 cm above the ileocecal valve. One side of the segment is anastomosed to the dome of the bladder and the other to the skin halfway between the iliac spine and the umbilicus. A partial cystectomy is performed to reduce reservoir volume and possible urine stagnation. Surgical variants have been described with simple partial detubularization of the ileum before vesico-ileal suture [388], or the creation of a modified Boari flap on the bladder associated with partial detubularization of the ileum [387, 390-393] (LOE3). These improve drainage by reducing the ileal segment. Laparoscopic ileovesicostomy seems to be feasible [389, 394] (LOE4), and robotic ileovesicostomy has been described. A small, retrospective comparative study (LOE3) reported similar results in terms of continence and complications with the open surgery group, although a trend for less blood loss and shorter hospital stays was noted in the robotic group [395, 396].

One of the problems with ileovesicostomy, particularly in women, is the need for further surgery to prevent residual urinary leakage. All authors agree that this significantly prolongs surgery time. This further surgery may consist in closing the bladder neck or placing a suburethral tape [436, 438,443, 448, 449] (LOE3). Some authors propose performing this surgery later, where necessary [388] (LOE3).

Early complications are related to the underlying condition of these patients, which is often poor. No case of post-operative mortality has been reported in the published series [385, 387, 388, 390-393, 395-400] (LOE3). Other early complications were related to poor results of the surgery performed to render patients continent (4). Patients with this type of problem are the most likely to resort to cystectomy with ileal diversion (3 to 6%) [387, 397] (LOE3).

Late complications are summarized in Table 14

Only one series to date has more than five years of follow-up [400]. It should be noted that, despite reduction in complication rates, particularly those related to chronic upper tract infections and stone formation, none of the patients in this series remained complication-free [399]. The largest series to-date also report high complication rates (up to 74%), albeit reduced in comparison with preoperative rates [397].The most frequent new adverse events appear to be poor emptying related to stenosis of the stoma or the ileovesical anastomosis. Only one group of authors specifically mention problems related to stoma equipment that occur in about 38% of patients [397] (LOE3). The incidence of renal or vesicular lithiasis can be as high as 25% in some series, and several authors report that affected patients had a history of lithiasis [399].

Renal function appears to be preserved with this procedure at least with a mean follow-up of five years (LOE 3) [387, 388, 390-393, 397, 398, 401]. No case of impaired renal function, or even post-operative uretero-hydronephrosis was reported. Two patients in a series with long-term follow-up developed a bladder tumour [393] (LOE4).

Vesicostomy

Vesicostomy was described by Blocksom in 1957 [402] and detailed subsequently by Lapides [403, 404]. The technique consists in constructing a bladder tube anastomosed to the skin by making a transverse suprapubic incision to reach the space of Retzius. The stoma is located half way between the umbilicus and the incision. The principal benefits simplicity and reversibility, particularly in children [405-411], making it possible to envisage temporary surgery to treat an acute urological problem. In pediatric series, an improvement in the symptoms of infection was reported, with 6 to 20% of patients suffering bladder calculi and 6 to 18% stomal stenosis. Hydronephrosis improved or stabilized in most cases. The rate of end-stage renal failure varied between 6 and 18% for mean follow-ups of 6-7 years.

Nowadays, it is rare to conserve a vesicostomy long term. The long-term results of Lapides [404] (LOE3) are therefore all the more interesting. At two years of follow-up, there was no urinary infection, 16% poor drainage, 12% calculi, and renal function was preserved. At 10 years, however, end-stage renal failure, mainly due to calculi and repeated infection of the upper urinary tract, and mortality were reported [404, 412] (LOE3). Follow up at intervals ranging up to 20 years, showed the rate of chronic renal failure is around 16.6% [402-413] (LOE3).

Recently, percutaneous button vesicostomy placement under endoscopic control was proposed as a temporary continent alternative to Mitrofanoff in a series of 10 children with neurogenic bladders. The authors only discuss the feasibility of the procedure, not its efficacy [414].

Cutaneous ureterostomy

Cutaneous ureterostomy was first performed in the 1960s, to treat children with spina bifida and severe upper urinary tract impairment [415, 416]. The technique was also developed to treat malformative uropathies (exstrophy of the bladder and the posterior urethral valves) [416-419]. During this procedure, the ureters are anastomosed direct to the skin without using intervening gastrointestinal tract tissue. It is only feasible in the context of significant ureteric dilatation, and even then chronic stenting is often needed. The absence of gastrointestinal resection/ anastomosis avoids a major source of morbidity and mortality, but successfully achieving urine containment with appliances can cause considerable problems. In the absence of cystectomy, two short lateral incisions are made in the iliac fossa, at approximately 3-4 cm from the anterosuperior iliac spine. Direct retroperitoneal access is made and the two ureters located on the internal border of the psoas muscle or above the iliac vessels. It is important that the peri-ureteral region be spared and the ureter sectioned as low as possible. The ureter is then catheterized and raised to the skin. The stoma is formed by attaching the ureter to the skin, or by spatulating the sutured ureter on a V-shaped cutaneous incision (separate sutures with fine resorbable thread). Variants are described so as to obtain only one stoma: Y-transuretero-ureterostomy, implantation of both ureters in a single stoma, and implantation of a single ureter (ureter of the less functional kidney ligated, or even nephrectomy). The use of cutaneous plasties may remove the need for ureteral catheterization [420].

The main inconveniences are: cutaneous stenosis if the stoma is left unstented, upper urinary tract infections, and calcification around catheters. Moreover, it is frequently necessary to construct a double stoma. It is used in adults, usually in the context of palliative urinary diversion for those with obstructive pelvic cancer (bladder, uterus, rectum), and rarely in neurological patients [416-421]. Long-term results with a mean follow-up of 8 years are given hereafter: rates of stenosis between 8.7 to 11%, infections from 6.6 to 10% and calculi from 10 to 15.5%) [419, 421] (LOE3). Renal function was preserved for short follow-up times, but fatal end-stage renal failure occurred in up to 26.6% of children during long-term follow-up [418] (LOE3).

This technique is almost never used for neurological patients with bladder dysfunction anymore because conservative treatments (intermittent catheterization, urological endoscopy) have improved and the number of children suffering from spina bifida or presenting with complex malformation of the lower urinary tract has gradually lowered. Moreover, new urinary diversion techniques have been developed.

Recommendations:

- Non-continent urinary diversion is the last resort for patients with neurogenic bladder (A).
- Bladder should be removed during the procedure because of the risk of later complications at this site (B)
- It may be indicated for urological dysfunction or in the event of a motor handicap that prevents other modes of micturition (C).
- Ileal conduit urinary diversion has the best long-term results for non-continent diversion, if the following pre- and peri-operative precautions are taken (B):
- Pre-operative identification of optimal location for the stoma site, with wheelchair test, if necessary.
- Utilization of a short intestinal segment (10 cm maximum).
- Minimal dissection of the ureters.
- There are several reports of good results for ileovesicostomy, but the medium-term results need to be confirmed in the long term. Quality-of-life studies should also be performed (C)
- Vesicostomy may be a useful temporary solution, particularly for children (D)

- Cutaneous ureterostomy shouldn't be used for non continent urinary diversion in adult patients because of the rate of long term complications (B).

IV. NEUROLOGICAL FAECAL INCONTINENCE

1. EPIDEMIOLOGY

Central nervous system (CNS) disorders are common, and patients with these disorders frequently experience bowel symptoms.[1][2] In those individuals, bowel symptoms are associated with significant impairment of quality of life. [2][3] Chronic constipation is the commonest symptom of bowel dysfunction seen in the majority of individuals in spinal cord injury, and over one-third of patients with Parkinson's disease (PD) and multiple sclerosis (MS).

2. PATHOPHYSIOLOGY

The digestive and excretory functions of the gastrointestinal tract are dependent on the interrelated physiological phenomena of gut transit and rectal evacuation. [4] Transit is under the complex regulatory interplay of the enteric nervous system and extrinsic autonomic innervation, whilst rectal evacuation depends on an interplay between conscious perception of rectal sensori-motor function and the internal and external anal sphincters. Excessively rapid transit and/or failure of the anorectal control mechanism can result in faecal incontinence, and it is easy to see how CNS disorders can result in bowel symptoms.

The level and extent of injury are the most important factors in determining bowel symptoms in both SCI and MS. Supraconal lesions (above the conus medullaris, where inhibitory input is lost) - slow whole gut transit and there is hypertonia (with consequent reduced rectal compliance) and hyperreflexia of the hindgut (i.e. distal to the splenic flexure).[5] The latter two abnormalities predispose to reflex defaecation and incontinence. By contrast, lesions within the conus or in the cauda equina (where excitatory sacral parasympathetic supply is lost) have rectal hypotonia and hyporeflexia predisposing to rectal impaction and overflow incontinence. [6]

In terms of extent of injury, since the striated external anal sphincter is under voluntary control from Onuf´s nucleus in the ventral horn of the sacral spinal cord, complete SCI results in loss of voluntary control of the anal sphincter is lost. Complete SCI has been shown to result in the most severe degree of bowel dysfunction. [5]

The pathophysiology of bowel dysfunction in patients with Parkinson´s disease is quite different. Dystonia of the striated muscles of the pelvic floor and external anal sphincter explains the defecatory dysfunction [6] which is associated with delayed colonic transit time secondary to central and peripheral neurodegeneration. [7]

3. ASSESSMENT

Current bowel symptomatology is assessed, regarding bowel frequency, stool consistency, faecal incontinence and manoeuvres needed to achieve bowel management. This information is usually gathered from standard patient and carer history. Use of diaries is especially valuable to reflect the chronic burden of these symptoms. [8] This can be supplemented by questionnaires, whether generic (Cleveland Constipation score, St Mark's incontinence score or condition specific score has been developed for neurologic patients, the Neurogenic Bowel Dysfunction (NBD) Score.[9]

Digital rectal examination allows assessment of rectal filling, resting anal tone, ability to generate a voluntary contraction and also gives a crude assessment of anal sensitivity. The place of more interventional physiological or radiological transit investigations is not established, but may be appropriate if there is any co-morbidity (prior anal surgery, obstetric history, pelvic organ prolapse). Plainly, patients with alarm symptoms should have necessary colonic imaging performed. Alarm symptoms in this patient group are more difficult to recognise, but any worsening of established bowel dysfunction, weight or blood loss warrants investigation.

4. CONSERVATIVE TREATMENT

The primary aims of bowel care are twofold: firstly to achieve bowel evacuation without excessive toileting time and secondly to avoid fecal incontinence. The first step requires optimizing stool consistency with adequate fluid and fibre intake, and stimulating evacuation of stool on a regularly scheduled basis with digital rectal stimulation. A range of other non-invasive interventions may supplement this: Valsalva or manually-generated external pressure, oral medications – stool softeners, stimulant laxatives and prokinetic agents; diet modification; biofeedback – a re-education strategy to inform change in bowel function; electrical stimulation and functional magnetic stimulations. The key to successful bowel management is intensive patient education and training. If conservative bowel management fails, surgical management may be necessary.

4.1. Bowel program/bowel care [9]

Initial management for all subjects is medication review (especially bladder drugs such as antimusca-

rinics, baclofen, ditropan, codeine analgesia, non-steroidal anti-inflammatory drugs (NSAIDs) and antibiotics) and addressing any unusual dietary habits. In general, scheduled defecation should be attempted once a day or on alternate days. However, knowledge of bowel frequency prior to injury is important in deciding on the bowel program.

4.2. Specific techniques

Establishing a regular diet to optimize bowel motility is important and in general reducing fibre intake is helpful in improving the bloating and flatulence caused by slow whole-gut transit. Conversely, a higher fibre diet helps improve stool consistency and therefore prevent fecal soiling. Excessive quantities of caffeine, alcohol and foodstuffs containing the sweetener sorbitol can cause the stools to become looser and hence more difficult to manage.

Promoting a sense of privacy and comfort while exploiting gravity to achieve a successful bowel regime, is advised. Digital rectal stimulation (DRS) can be used to invoke a reflex contraction of the colon and rectum, and hence a bowel action, although caution is advised as it may cause local trauma and induce autonomic dysreflexia (AD) in SCI individuals. Finally, manual extraction of stool can be used and combined with a Valsalva maneuver to improve effectiveness. [8]

Chemical stimulants such as suppositories and enemas may supplement the above by causing a reflex contraction of the rectum. Implicitly, there is little point in using these agents when the rectum is empty on digital checking. Stimulants range in potency, from glycerine suppositories, through micro-enemas, to larger volume stimulant enemas.

4.3. Assistive techniques for defecation [10]

Abdominal massage with the heel of the palm, in a circular motion from right to left may help increase bowel transit and movement of content towards the rectum. In small controlled trials, positive effects were seen in patients with multiple sclerosis and with spinal cord injury. Anal stimulation with pulsed water irrigation to break up stool impactions and to stimulate peristalsis is a safe and effective method for individuals with SCI who develop impactions, or do not have an effective bowel routine.

Several studies have been published on transanal irrigation (TAI), with efficacy demonstrated in a variety of neurological diseases. [11] Long-term efficacy has been demonstrated, with associated health economic benefit. [12] Amongst factors correlating with positive outcome were neurogenic bowel, low rectal volume at urge to defecate, low maximal rectal capacity, and low anal squeeze pressure increment. A perforation rate of 1 in 500,000 has been suggested in long-term safety studies.[13]

4.4. Appliance/assistive techniques for faecal incontinence

Anal plugs are one option although previous studies have yielded conflicting results. Whilst anal plugs may provide a benefit to the majority of patients, it does not suit all eligible patients, with *in situ* plug retention being a problem for some.

Neuromodulation, electrostimulation or magnetic stimulation are techniques that offer an alternative intervention option for neurogenic bowel dysfunction in children and adults.

5. SURGICAL TREATMENT

The mainstay of current treatment in neurogenic faecal incontinence is adopting a conservative approach towards reversing the systemic effects and optimizing the mechanics of defecation through the use of laxatives and irrigation approaches. Surgery should be normally reserved for patients who have failed conservative therapy. This section focuses on specific aspects of faecal incontinence surgery in neurogenic patients. Options for surgical treatment of neurogenic bowel dysfunction are limited consisting of; 1) sacral nerve stimulation, 2) antegrade continent enema procedure, 3) dynamic graciloplasty, 4) artificial anal sphincter, 5) elective colostomy, 6) postanal repair.

Outcomes with these techniques are limited to uncontrolled studies. [14] Sacral nerve stimulation has been reported to restore continence in patients with intact muscle structure. The overview of the studies shows that electrical nerve stimulation is effective in *partial* spinal cord injury, however,there are no reports for complete spinal cord lesions. A 17-year experience with sacral deafferentation (SDAF) and implantation of sacral anterior root stimulator (SARS) showed improved continence in over 80% of individuals. [15]

The original antegrade continent enema procedure was developed by Malone et al. who reported successful results in five children with intractable faecal incontinence. [16] This procedure has been applied mainly to the paediatric population with neuropathic bowel dysfunction and anorectal anomaly, and successful outcome was achieved in 70-100 %. Modifications have been reported including application among adult neurogenic patients with faecal incontinence, and similar success rates (83-100 %) were reported. [17]

There are other more intrusive surgical procedures that have been applied to small numbers of patients with neurogenic faecal incontinence – defunct ones (such as dynamic graciloplasty) or extant ones like artificial anal sphincter. Definitive studies are not available in this population, and given the nature of referral practice are unlikely to ever be performed.

Retrospectively reported series on the effect of colostomy or ileostomy formation in SCI patients have shown significant improvements in average time

spent on bowel care per week and quality of life. [18]The early and long-term complication rates are seen in the minority of patients, most frequently related to mucus discharge per rectum and diversion colitis, respectively. The decision about type of surgery depends on a multitude of factors related to manual dexterity, co-morbidity, carer availability and toilet set-up: as such careful patient counselling in individuals who have failed conservative therapies is the key to success. [17]

Conclusions

- In reflex bowel, digital rectal stimulation relaxes the external anal sphincter and increases peristaltic contractions by facilitating an excitatory anorectal (ano-colonic) reflex, and enhances bowel movement and evacuation
- Abdominal massage has beneficial effects on neurogenic bowel dysfunction, including defecation function and fecal incontinence
- Transanal irrigation is a safe method to improve constipation and faecal incontinence in individuals with neurogenic bowel dysfunction
- An anal plug can help control fecal incontinence in selected neurological patients
- Different forms of electrical stimulation seem promising for fecal incontinence and defecation management in neurologic patients
- To increase adherence rate with bowel care program/clinical practice guideline, implementation strategies should be addressed to care providers
- SNS is a minimally invasive procedure, and seems to be an option for faecal incontinence and constipation due to functional deficit of the anal sphincter without structural defect in incomplete neurogenic lesions
- Antegrade continence enema stomas are effective for controlling faecal incontinence and constipation associated with neurogenic bowel dysfunction especially in neuropathic children
- Elective stoma formation is an option for some SCI patients with medically refractory symptoms.

Recommendations

- Multi-faceted programs are the first approach to neurogenic bowel management and are supported by lower levels of evidence. They may consist of toileting, rectal stimulation (digital or with water stream), manual feces extraction, transanal irrigation and other assistive techniques
- Diet can help but multi fibre is not necessarily indicated in patients with upper motor neuron lesion
- Autonomic dysreflexia when using mechanical stimulation and assistive techniques can occur in neurologic patients with a high spinal cord lesion
- Studies on larger series with long term follow-up are needed to determine the role of SNS in the treatment of faecal incontinence associated with neurological lesions and identify those patients most likely to benefit

V. SPECIFIC NEUROLOGICAL DISEASES

1. DEMENTIAS

Methods. Using MEDLINE we identified English-language journal articles and reviews up to the date of the current Consultation, which were added to literature obtained for previous Consultations, looking for the keywords Alzheimer's disease, vascular dementia, dementia with Lewy bodies, frontotemporal dementia, urinary incontinence, bladder dysfunction, management.

The dementias can be categorized according to clinical presentation, neuropathology and/or aetiology into four major dementia groupings, (I) the Alzheimer's group (Alzheimer's disease, AD); (II) the vascular group (including large and small vessel disease, particularly white matter disease); (III) the Parkinson's group (including Parkinson's disease dementia complex (PDD, being regarded as identical to DLB), and dementia with Lewy bodies (DLB), both being connoted as Lewy Body diseases); (IV) the frontotemporal group (including Pick's disease and Semantic dementia) [1]. Normal pressure hydrocephalus (NPH) is a less common pathology, but nonetheless important.

1.1. Alzheimer's disease

Epidemiology and prevalence

Alzheimer's disease (AD) is the most common type of dementia in clinical and autopsy surveys. AD affects mostly elderly people. The symptoms include worsening of the memory, impairment of language and other cognitive functions (analytical thinking, abstract reasoning). Ultimately, there is loss of self-hygiene, eating, dressing and ambulatory abilities, incontinence and motor dysfunction. The onset of incontinence usually correlates with the disease progression (LOE 3) [2]. In other words, urinary incontinence inevitably occurs in the advanced stage of disease, while urinary incontinence is not common in the early stage of AD. This is in contrast with early occurrence of urinary urgency and incontinence in vascular dementia and dementia with Lewy bodies. The prevalence of incontinence in AD is between 23 % and 48 % (LOE 3) [3, 4]. However, most previous studies did

not mention the type of dementia concerning 'frequency of urinary incontinence in dementia'. The prevalence of incontinence in dementia ranges from 10% (of out-patients) to more than 90% (of advanced, institutionalized individuals) (LOE 3) [5].

Pathology and disease-specific urinary tract problems

AD at the outset was identified by its unique pathology, the amyloid plaques and neurofibrillary tangles containing phosphorylated tau that Alzheimer referred to as "a clotting of fibrils…. in addition an extraordinary number of peculiar patches disseminated throughout the entire cortex." Amyloid and tau can now be measured *in vivo* by positron emission tomography and/or examination of the cerebrospinal fluid (CSF). There is a familial occurrence of AD [3]. In such cases, mutations in the genes encoding amyloid precursor protein (APP); presenilin 1 (PSEN1), or presenilin 2 (PSEN2) are reported.

The clinical hallmark of AD is memory impairment. A sense of memory failure, detected by the patient or a close relative, is usually the presenting symptom. Motor and sensory symptoms are absent until late in the course of the disease. However, other cognitive domains, such as language, praxis and recognition skills, are affected even early in the presentation. AD has a gradual and progressive course, and duration is typically 10 years from diagnosis to death. The advent of central cholinesterase inhibitors and glutamate receptor antagonists has had a positive effect on the memory symptoms of AD [6-8].

In early stages of AD the prevalence of urgency incontinence is lower than in dementia with Lewy bodies [9, 10]. During stage III (advanced) AD, urinary and faecal incontinence occur due to loss of sphincter control [10]. In a study by Del Ser et al. (LOE 3) urinary incontinence was associated with severe cognitive decline in pure AD but usually preceded severe mental failure in patients with dementia due to diffuse Lewy body disease [10]. Nobili et al. (LOE 3) performed quantitative EEG in AD patients, finding that incontinence was predicted by alpha power in the right side [11]. In another study by Nobili et al. (LOE 3) the value of regional cerebral blood flow from a posterior temporal-inferior parietal area in each hemisphere predicted development of incontinence [12]. A brain computer tomography study done by Sugiyama et al. (LOE 3) in AD patients showed that the degree of brain atrophy was more severe in those with detrusor overactivity (DO) than those without it [13]. DO was found in 40-61 % of their patients [13] (LOE 3). The incidence of DO in AD patients is low as compared with vascular dementia and dementia with Lewy bodies [9]. Haddad et al. (LOE 3) described two patients with vesicoureteral reflux, one of them showing buccosalivary, gastroesophageal, vesicoureteral, urethroprostatic and urethrovesical reflux as a consequence of the neurologic dysfunction [14]. In a study of 144 patients with AD reporting urinary incontinence, the most common type of urinary incontinence was urgency urinary incontinence. Clinical Dementia Rating and Barthel's Activities of Daily Living predicted the severity of detrusor overactivity in urodynamics [15].

Diagnosis and treatment

Franssen et al. (LOE 2) examined the occurrence of the following developmental reflexes: the tactile suck reflex, the palmar and plantar grasp reflexes, and the plantar extensor reflex in healthy elderly, cognitively and functionally mildly impaired patients, and patients with AD [16]. Prevalence of all five reflexes was more than 6 times higher for those categories that comprised doubly incontinent patients compared to continent individuals. The frequency of developmental reflexes rose sharply with the onset of progressive incontinence, suggesting its cortical origin. As demonstrated above, the development of incontinence in AD patients is associated with cognitive impairment and brain degeneration, suggesting its CNS origin. Therefore behavioural therapy, toilet training and prompted voiding would be appropriate treatment modalities for this type of incontinence.

Hutchinson et al. (LOE 3) suggested that caregivers of patients with AD should study the toileting behaviours. This would permit them to provide physical and cognitive assistance while attempting to avoid accidents and "catastrophic events" [6]. Tariot (LOE 4) stressed the necessity for taking into account different factors (like mobility, cognitive functions, general medical conditions), when planning treatment (also for incontinence) in AD patients [7]. Lancioni et al. reported three AD patients who could learn to use urine alarms [17] (LOE 4). Again the general guidelines should apply for choosing the best management of incontinence in AD patients. The treatment should be tailored to individual patient needs and disease status. There is insufficient evidence to support non-pharmacological and non-surgical conservative interventions, for the prevention or management of incontinence in community dwelling people with dementia [18] (LOE 1).

There is still some controversy that the central acethylcholinesterase (AChE)- inhibitors given by the neurologist might exacerbate urinary incontinence in those patients. Donepezil hydrochloride is a selective central AChE inhibitor, which decreases degradation of acetylcholine in the brain, then increasing the concentration of acetylcholine in the synaptic cleft [19]. This drug is widely used to ameliorate cognitive decline in patients with AD [20, 21] which is thought to be due to a decrease in cholinergic innervation of the cerebral cortex and the basal forebrain [22]. Since the bladder is innervated by the parasympathetic cholinergic nerves, neurogenic lower urinary tract (LUT) dysfunction occurs in a subset of patients with AD [5, 13].

Although donepezil may facilitate cholinergic neurotransmission in the CNS, common adverse effects of donepezil, such as nausea and abdominal discomfort, have been attributed to effects on the peripheral

nervous system (PNS) [20]. This peripheral influence may contribute to altered bladder function. However, according to Sakakibara et al. (2005) the patients with AD showed a slight increase in the bladder capacity, which cannot be explained by the PNS effects alone [23] (LOE 3). Although it is unknown to what extent central cholinergic circuits may participate in the regulation of micturition, recent experimental studies showed that lesions in the nucleus basalis Meynert in the basal forebrain (central cholinergic nucleus projecting fibres to the frontoparietal cortex) give rise to decreased bladder capacity) [24]. In addition, improved cognitive status and alertness may well lead to proper initiative to hold urine. Central AChE inhibitors including donepezil hydrochloride, therefore, may have complex effects on the LUT function. It seems possible that donepezil could ameliorate cognitive function without serious adverse effects on the LUT function in patients with AD. This should be true also for other selective central AChE inhibitors. A large crossover cohort study used the Dutch PHARMO Record Linkage System, with 10 years of data on drug dispensing for over two million people. It suggested no firm association between AChE inhibitor treatment and risk of UI could be shown, except possibly during the first month of treatment [25] (LOE2].

Many elderly patients and their caregivers seek medical care for dementia and overactive bladder (OAB) together. In order to answer this, recent clinical trials of a combination therapy of central AChE inhibitors and peripheral anti-cholinergics for ameliorating both cognition and incontinence are available. In 26 older individuals who had both cognitive problems and overactive bladder (AD in 8, vascular dementia in 5, a combination of AD and multiple cerebral infarction in 8, and others), Sakakibara et al. reported that addition of 20 mg/day propiverine, an anticholinergic agent, to 5 mg/day donepezil improved OAB without any cognitive change [26] (LOE 3). Sink and colleagues retrospectively studied 3536 nursing home residents who were taking central AChE inhibitors, in whom 10.6% were prescribed anticholinergics together [27]. They found no differences in cognitive function between groups of AChE inhibitors alone and AChE inhibitors with anticholinergics (LOE 3). Isik et al. demonstrated that patients with advanced Alzheimer's Disease tolerated Trospium chloride without significant changes in MMSE (Mini-Mental Status Examination) scores [28] (LOE 3). The combined use of a 'central' AChE inhibitor and a 'peripheral' muscarinic receptor antagonist remains a matter of controversy and the Dementia Working group of the International Continence Society has put forward a recommendation that antimuscarinics that do not easily cross the blood brain barrier or are more selective for the M2/M3 receptors should only be used in patients with dementia reporting incontinence [29] (LOE 3). There is a study indicating that this combination would be pharmacologically sound as a site-directed therapy [30].

Guidance for further research

There is still no cure for AD, which is progressive and a type of dementia-associated disease. We are still lacking studies evaluating LUT disorders in AD. No systematic review has been performed regarding the possibilities of medical management (both pharmacological and behavioural) of incontinence. An open issue also remains the question of aggressive surgery for LUT problems in these patients. Whether we should offer surgical therapy for incontinence in patients with stress incontinence and progressive AD is so far unanswered.

Conclusions

- Detrusor overactivity seems to be the most common cause of incontinence in Alzheimer's disease (AD) patients (LOE 3), while the incidence is low as compared with vascular dementia and dementia with Lewy bodies
- The degree of functional incontinence is associated with cognitive impairment and brain degeneration (LOE 3)
- EEG studies, occurrence of developmental reflexes and regional blood flow studies can predict the development of incontinence in AD patients (LOE 3)
- Selective central AChE inhibitors ameliorate cognitive function without serious adverse effects on LUT functions in patients with AD (LOE 3)
- A combination therapy of central AChE inhibitors and peripheral anticholinergics for ameliorating both cognition and incontinence awaits further studies (LOE 3)

Recommendations

- The extensive and aggressive therapy of incontinence in AD patients should be reserved for those with good general status and ambulation (C)
- In the case of ambulatory patients, prompted voiding, behavioural therapy and oral anticholinergics seem to be the treatment of choice (C)

1.2. Vascular dementia

Epidemiology and prevalence

Vascular dementia is the second most common form of dementia after Alzheimer's disease (AD) among the elderly. Pooled prevalence from eight European countries was 1.6% for vascular dementia in subjects older than 65, compared to a prevalence of 4.4% for AD (LOE 3) [31]. A meta-analysis of the European studies on the incidence of dementia showed vascular dementia constituted 17.6% of all incident dementia (LOE 3) [32].

Population-based MRI studies suggest that moderate white matter disease (WMD, a major cause of vascular dementia) affects around 10% (7.6–24%) of the general population of persons over 55 years of age [33], comparable to type 2 diabetes. WMD develops into three different geriatric syndromes; 1) vascular dementia (usually mild in the Mini-Mental State Examination and other general cognitive function), 2) vascular parkinsonism, and 3) so-called vascular incontinence, i.e. urinary frequency/ urgency with or without incontinence [34]. Among these three syndromes, urinary and gait disorders are more prominent than dementia, and usually precede dementia. Comorbidity of Alzheimer's disease (a degenerative disease) and WMD (a vascular disease) is not uncommon.

Vascular dementia may be the result of a single strategic infarct, particularly involving the thalamus and left angular gyrus, or multiple cortical or subcortical infarcts that produce WMD. There is an elevated risk for subsequent dementia in patients who have had a stroke in comparison to controls without any evidence of a stroke (LOE 2) [35]. Diabetes and hypertension are stronger risk factors for vascular dementia than for Alzheimer's disease (LOE 3) [36]. The apolipoprotein e4 genotype is a risk factor for vascular dementia as well as AD (LOE 3) [37].

Pathology and disease-specific urinary tract problems

In patients with WMD, diffuse abnormalities are seen in the small deep perforating vessels of the hemispheric white matter, basal ganglia and brain stem. Pathological changes range from lipohyalinosis to fibrinoid necrosis and disintegration of small vessels. Disruption of the blood brain barrier is likely to precipitate or worsen progression of WMD [38] (LOE 3). Positron emission tomography imaging with 18F-fluoromisonidazole showed higher susceptibility to ischemia of white matter than gray matter in stroke cases [39]. Cortical WMD in MRI looks diffuse. However, within the brain, detailed pathology studies confirmed that the frontal lobe is most severely affected [40]. This is in line with documented frontal lobe atrophy on MRI volumetry, where glucose metabolism was also most severely reduced [41] (LOE 3). Corresponding to this, brain perfusion is most reduced in the frontal lobe of subjects with WMD [42] (LOE 3), a finding that remains to be fully explained. In patients with WMD reporting incontinence ("vascular incontinence"), performance on the frontal assessment battery suggests that performance on an inhibitory control task is decreased in patients with detrusor overactivity [43] (LOE 3).

The frontal cortex is an important higher center for micturition: damage to the prefrontal cortex, medial superior/middle frontal gyri, anterior cingulate cortex, supplemental motor area and insula result in marked lower urinary tract dysfunction in humans [44] (LOE 3), corroborated by functional neuroimaging [45, 46] (LOE 3). Altered spinobulbospinal micturition reflex control may contribute to DO emergence in brain lesions [47] (LOE 3). Functional neuroimaging studies showed that the prefrontal cortex was deactivated in elderly subjects with urinary frequency/ urgency [48] (LOE 3). Jirovec et al. (LOE 3) found that cognitive ability and mobility differ significantly between continent and incontinent patients [49]. When the variables were examined together, mobility emerged as the best predictor of the patient's urine control, followed by cognitive impairment.

The prevalence of DO in WMD cases is reported as 70-91% of patients. In Sakakibara's study, urodynamic studies in 33 subjects found DO more commonly in grade 1-4 white-matter lesions (82%) than grade 0 white-matter lesions (9%). Yoshimura et al. (LOE 3) found a 47% prevalence of DO which correlated with the presence of dementia [50].

Disease specific diagnosis and treatment

No specific diagnostic tests to evaluate dementia-related incontinence have been described. Since patients with dementia and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow standard principles, bearing in mind that this is a population of frail elderly people. The treatment should start with modification of behaviour, and general rehabilitation targeted at making the patient more ambulatory. No other specific treatment in dementia has been described, however certain issues like prompted voiding, anticholinergic drugs and intermittent catheterization have been studied.

In a review of trials where prompted voiding was implemented, Eustice et al. (LOE 1) found that prompting increased self-initiated voiding and decreased incontinence episodes in the short-term [51]. A single small trial suggested that adding oxybutinin, reduced the number of incontinent episodes in the short-term. Suzuki et al. (LOE 3) found best results with the use of a portable chamber pot and induced urination in ambulatory patients; no improvement was seen in bedridden patients treated with anticholinergics [52]. Sugiyama et al. (LOE 3) studied the effects of anticholinergic therapy in patients aged 65 years or older, with and without dementia [53]. Urodynamic studies demonstrated significant increase of maximum bladder capacity in the dementia group and the non-dementia group. There was no significant difference in rate of objective improvement between both groups. On the other hand, rate of subjective improvement was significantly higher in the non-dementia group (40%) than in the dementia group (15%). Improvement of functional bladder parameters was not associated with better subjective symptoms in the dementia patients.

In voiding failure, intermittent catheterization (IC) is often feasible. Lieu et al. (LOE 3) found that carer-assisted clean IC is an effective and safe treatment option for persistent urinary retention in elderly female patients with cognitive impairment and other disabilities [31]. 54% of the patients were able to void

spontaneously and were continent after a median period of 6 weeks with a range of 1 to 40 weeks. 27% had significant improvement in the symptoms of urinary incontinence and the residual urine volumes became progressively smaller. 19% failed this treatment modality. The recovery of spontaneous voiding was influenced by the age of the patient, the carer performing the IC and the development of catheter-related UTI. 25% developed symptomatic UTI, leading to delay in the recovery of spontaneous voiding. UTI development was associated with the presence of pre-existing diabetes mellitus and predisposing common medical conditions, the person doing the catheterization, and the presence of dementia.

Ayonou et al. (LOE 3) studied a group of 13 patients with dementia who underwent transurethral resection of the prostate (TURP) [54]. Six patients reported good urination, 3 reported some improvement in urination but requiring IC, and 1 developed incontinence. No specific study addressing the issue of incontinence surgery in woman with dementia has been reported. However, it seems that incontinence surgery in patients with dementia should be reserved only for the cases with good ambulation and without concomitant functional disorders of micturition (overactive bladder, hypocontractile detrusor).

Recommendations for further research

Since dementia is not a homogeneous disease, a population study specifically reviewing disorders of lower urinary tract function is needed. A study evaluating different treatment modalities in patients with dementia (especially anticholinergic treatment for overactive bladder and surgical treatment for stress incontinence) is lacking.

Conclusions

- Incontinence occurs in 30-100 % of patients with dementia (LOE 3).
- The degree of incontinence is strongly associated with the patient's general status and ambulation (LOE 3)
- There is no one major cause for incontinence in these patients; however overactive bladder is responsible for a significant proportion of incontinence (LOE 3)

Recommendations

- Interventional therapy of incontinence in dementia should be reserved for patients with good general status and ambulation (C)
- In case of ambulatory patients, prompted voiding, rehabilitation and oral anticholinergics can be employed (C)
- Where there is a significant post-void residual, intermittent catheterization is the treatment of choice (B)

1.3. Dementia with Lewy bodies

Epidemiology and prevalence

Dementia with Lewy bodies (DLB) is thought to be the third most common type of dementia in the elderly, accounting for 10 – 15% of cases at autopsy. In population-based studies of subjects aged 65 and older, the prevalence of DLB was found to be 0.7% [55]. The epidemiology of DLB is sparse; age and gender distribution, and potential risk factors have yet to be defined.

Pathology and disease-specific urinary tract problems

DLB primarily affects the basal ganglia (as in Parkinson's disease) and the cerebral cortex. Lewy bodies and Lewy neuritis are pathologic aggregations of alpha-synuclein (SNCA), a ubiquitously-expressed synaptic protein that has been implicated in vesicle production [56]. Lewy bodies also contain chaperone proteins and elements of the ubiquitin-proteasome system. Immunohistochemical staining for alpha-synuclein is the most sensitive and specific method for detecting Lewy bodies and can be used in a semiquantitative grading of severity of Lewy-related pathology [57]. Alpha-synuclein can now be measured *in vivo* by positron emission tomography and/or in the cerebrospinal fluid.

Many patients with DLB also have Alzheimer's disease pathology, which alters the clinical presentation. DLB patients who also have numerous neurofibrillary tangles display more core clinical features of AD [58]. Conversely, Lewy bodies also occur in more than half of patients with sporadic and early-onset AD [59]. The essential feature for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Fluctuations (waxing and waning of cognition, functional abilities and arousal, from almost normal to markedly confused or hypersomnolent) are a core feature of dementia with Lewy bodies. In DLB, autonomic dysfunctions occur and are included as a supportive feature for clinical diagnosis [60].

Horimoto et al. (LOE 3) found 97% incidence of urinary incontinence amongst patients with DLB. From the urological point of view, patients with DLB tend to develop urgency and urgency incontinence more often than do patients with Parkinson's disease (PD) or AD. Similar bladder capacity, detrusor pressure at maximum voiding, maximum urine flow, mean voided volume and post-void residual volume were found in each disease; DO was more prevalent in DLB than in PD and in AD [9]. Urinary symptoms were recorded in 35 % of patients with DLB, compared to 70 % in MSA and 25 % in PD patients. No detrusor-sphincter-dyssynergia was observed. DLB patients with DO had significantly higher Hoehn and Yahr scores than did those without. Since the prevalence of frequency, urgency, urge incontinence and DO is markedly lower in AD than in DLB, LUTS may contribute to the differential diagnosis of these two entities.

Disease specific diagnosis and treatment

Since patients with Lewy Body disease and incontinence usually have one or more concomitant diseases, the evaluation of the LUT functions should follow the general rules, bearing in mind that this is most often a population of frail elderly people.

1.4. Frontotemporal dementia (FTD)

Epidemiology and prevalence

Prevalence studies of FTD give ranges of 3.6-15.0 per 100,000 [61]. There is a high familial occurrence of FTD [62]. In such cases, a combination with parkinsonism, and rarely amyotrophic lateral sclerosis, also occurs. The distribution of FTD is equal between men and women. The mean duration of illness from onset to death is 4-6 years, with a range of 2-20 years.

Pathology and disease-specific urinary tract problems

Frontotemporal dementia (FTD), also known as Pick's disease, encompasses a diverse group of clinical and pathological disorders. There are several distinct clinical presentations, most commonly behavioral changes, but a language disorder, usually in the form of a progressive non-fluent aphasia, can be the main presenting sign. The most common clinical presentation of FTD is characterized by profound changes in personality and social conduct, including a decline in manners and social skills that are incongruent with the patient's premorbid behaviour. Affected patients lack emotional warmth, empathy and sympathy and are indifferent to others.

MRI of patients with FTD often shows atrophy in the frontal and temporal lobes (LOE 2), which may be asymmetric [63]. At autopsy, markedly gross atrophy of the frontal and temporal lobes is seen in FTD. On histologic examination the salient features include neuronal loss, micro-vacuolization and astrocytes gliosis centred on cortical layer II. Molecular pathology of FTD has identified four subtypes:

- classical Pick's disease (Pick body with accumulation of 3-repeat tau);
- mutations in the MAPT (microtubule-associated protein tau) gene;
- accumulation of TDP-43 (TAR DNA binding protein-43) with mutations in the PGRN (progranulin) gene; and,
- accumulation of FUS (fused in sarcoma) protein

There are no published data on LUTS in patients with FTD, but due to the cognitive state these patients have incontinence, either because they forget to take down clothes when they go into the toilet, or they have difficulty finding the toilet, or they may urinate in inappropriate places. Moreover, they may be affected by constipation, diarrhoea or faecal incontinence.

Diagnosis and treatment

There are no studies which show the significance of LUTS in fronto-temporal dementia. The importance of cortical regulation for social control of urinary habits needs evaluation.

Conclusions

- There are no studies available which show the significance of LUTS in patients with fronto-temporal dementia
- Since the underlying pathology is gross atrophy of frontal and temporal lobes, autonomic dysfunction including LUTS can be anticipated, but further research is needed

Recommendations

- The recommendations do not differ from those for other types of dementia

2. CONSTIPATION AND FAECAL INCONTINENCE IN DEMENTIA

Only one paper was retrieved related to the influence of dementia on the prevalence of faecal incontinence [64]. This evaluated a random sample (n= 485) of the population of 85-year-olds from Gothenburg, Sweden. Prevalence of urinary and faecal incontinence and dementia were 38%, 17% and 29% respectively. Dementia-affected men (50%) and women (60%) were more often incontinent than non-affected men (18%) and women (36%). Faecal incontinence was more prevalent in dementia (34/ 8% versus 6/ 7%): both urinary and faecal incontinence were more prevalent in demented women (43% and 20% respectively) than in men (27% and 11%). The prevalence of urinary and faecal incontinence and dementia were higher in residents of a nursing home or hospital (74%, 51% and 92% respectively) than subjects living at home (32%, 9% and 18%): of the dementia residents in an institution, 78% were incontinent compared with 37% living at home.

No specific paper was found on the management of faecal incontinence in people with dementia. Patients may benefit from a bowel habit training programme, which also includes management of constipation with non-pharmacologic (such as exercise and fibre) and pharmacologic measures.

Conclusions

- Although faecal incontinence is prevalent in people with dementia, no paper was found dealing with the disease-specific management of faecal incontinence (LOE3).

Recommendations

- Studies should be undertaken to ascertain management strategies for constipation and faecal incontinence in dementia

3. NORMAL PRESSURE HYDROCEPHALUS

Normal-pressure hydrocephalus (NPH) is characterized by a clinical presentation of gait disturbance, memory deficit, and urinary incontinence, combined with dilated cerebral ventricles and normal cerebrospinal fluid (CSF) pressure [65]. The clinical triad of this disorder is very much akin to those of vascular dementia or white matter disease (WMD), and should be considered before performing brain imaging in relevant patients. The syndrome was first described by Hakim and Adams in 1965 [66]. The effectiveness of the diversion of CSF flow by shunt operation in treating this syndrome is well documented [65] (LOE 2). Population-based MRI studies suggest that the incidence of NPH, or asymptomatic ventriculomegaly with features of idiopathic normal pressure hydrocephalus on MRI (AVIM), is around 1% (0.51-2.9%) in the general population of persons over 65 years of age [67], being estimated as one-tenth of WMD (LOE 3).

3.1. Pathology and disease-specific urinary tract problems

LUTS in NPH include urinary urgency and frequency (OAB). Sakakibara et al. found urinary symptoms in 93% of 42 idiopathic NPH patients [68] (LOE 3). These symptoms included storage symptoms in 93% of patients (Nocturia 64%; urinary urgency, 64%; urgency urinary incontinence, 57%; increased daytime frequency, 36%) and voiding/ post micturition symptoms in 71% (hesitancy 50%; prolongation /poor flow, 50%; sensation of post-void residual, 29%; straining, 21%; intermittency, 14%). In some patients urinary urgency /frequency preceded urinary incontinence. Among the clinical triad of NPH, urinary incontinence was regarded a late symptom, but gait disturbance and OAB can be the early manifestation of NPH.

Urodynamic findings of 42 NPH patients included low Q_{max} (<10 cm/s) in 40%; increased post-void residual (>30 ml) in 43% (average PVR volume 42.1 ml); low volume at first sensation (< 100 ml) in 33%; decreased bladder capacity (< 200 ml) in 57%; and DO in 95% of patients [68] (LOE 3). Although case series are often small (4-12 cases), DO is common (63-100%) [69] [70] (LOE 4). The high prevalence of DO suggests altered brain autonomic control in NPH [71].

3.2. Diagnosis

Diagnosis of NPH may comprise:

- Possible features; gait, cognitive and urinary disorders with typical ventricular dilatation in brain imaging
- Probable features; improved clinical symptoms by 30 ml withdrawal of the cerebrospinal fluid by a lumbar tap (the Tap test)
- Definite; improved clinical symptoms by ventriculoperitoneal shunt surgery, etc.

Functional neuroimaging in normal volunteers has shown that the anterior cingulate, prefrontal cortex and insula are activated in response to bladder filling as compared to an empty bladder [47]. Although NPH is a diffuse brain disease with dilated ventricles, hypoperfusion in the frontal lobe has been documented in NPH patients using PET [72], single-photon emission computed tomography (SPECT) [73] , and perfusion-weighted MRI [74] (LOE 3). Therefore, the frontal lobe is thought to be the anatomical substrate for urinary urgency and incontinence in NPH. According to the study by Sakakibara et al, using 97 NPH patients and [123I]-iodoamphetamine (IMP)-SPECT statistical mapping, there was a significant decrease in tracer activity in the right-side-dominant bilateral frontal cortex and the left inferior temporal gyrus in the severe urinary dysfunction group ($p<0.05$) [75]. The findings indicate that there is a link between right frontal hypoperfusion and urinary dysfunction in NPH. Importantly, bladder dysfunction and frontal lobe hypoperfusion in NPH can improve after shunt surgery. Recovery rate of OAB and urinary incontinence in NPH ranges from 20-80% [65] (LOE 4). After shunt surgery, bladder recovery is related to an increase in mid-cingulate perfusion [76] (LOE 3).

Since there is a surgical shunt therapy for NPH, early diagnosis of NPH in patients with OAB is important. In addition to OAB with/without urinary incontinence, patients with NPH commonly have gait disorder (parkinsonian and wide-based gait) and dementia that is milder than Alzheimer's disease. Differential diagnosis should include vascular dementia or white matter disease. If the shunt surgery failed, or was not applied to individuals with particular reasons (such as dementia), medical management (pharmacological and behavioural) of incontinence is put in place. However, no systematic review has been performed regarding the medical management of urinary incontinence in NPH.

Conclusions

- Clinical manifestations in NPH mimic those of vascular dementia or white matter disease (LOE 3)
- Urinary urgency and increased urinary frequency may precede urinary incontinence in NPH (LOE 3).
- Detrusor overactivity seems to be the most common cause of incontinence in NPH patients (LOE 3).

- Shunt surgery ameliorates urinary incontinence in NPH but the degree of improvement varies significantly (20-80%) (LOE 4).

Recommendations

- Typical gait, cognitive and urinary disorders with ventricular dilatation in brain imaging favours the diagnosis of NPH; a Tap test and shunt surgery may then be indicated (B).
- A systematic literature review is needed regarding the medical management of urinary incontinence in NPH, if shunt surgery is not successful or not undertaken (C).

4. MULTIPLE SYSTEM ATROPHY

Multiple system atrophy (MSA) is an uncommon but well-recognized disease entity that both neurologists and urologists may encounter. The term MSA was introduced by Graham and Oppenheimer in 1969 to describe a disorder of unknown cause affecting extrapyramidal, cerebellar, and autonomic pathways [77]. MSA includes the disorders previously called striatonigral degeneration (SND), sporadic olivopontocerebellar atrophy (OPCA), and Shy–Drager syndrome. The discovery in 1989 of glial cytoplasmic inclusions in the brains of patients with MSA provided a pathological marker for the disorder (akin to Lewy bodies in idiopathic Parkinson's disease (IPD)) and confirmed that SND, OPCA, and Shy–Drager syndrome are the same disease with differing clinical presentations. Immunocytochemistry showed that the glial cytoplasmic inclusions of MSA are ubiquitin-, tau-, and alpha- synuclein (SNCA)-positive, possibly representing a cytoskeletal alteration in glial cells that results in neuronal degeneration. SNCA is a presynaptic neuronal protein encoded by the *SNCA* gene located on chromosome 4. This protein appears to play a role in dopamine and other neurotransmitter metabolism, vesicle trafficking, modification of synaptic transmission, and regulation of membrane permeability. In contrast, pathologically increased expression and abnormal conformation of SNCA are reported to reduce neurotransmitter release by inhibiting synaptic vesicle reclustering after endocytosis. Familial occurrence is estimated to account for 1.6% of all cases, and data on such cases are being accumulated to identify candidate genes for this disorder, including *SNCA*, *MAPT* (microtubule-associated protein tau), etc.

Autonomic failure (postural hypotension and urinary dysfunction) is fundamental to the diagnosis of MSA: it is diagnosed when the criteria of either postural hypotension (systolic blood pressure fall > 30 mmHg or diastolic > 15 mmHg) or urinary dysfunction (persistent, involuntary urinary incontinence/incomplete bladder emptying) or both are fulfilled, along with poorly levodopa-responsive parkinsonism or cerebellar dysfunction [78]. Based on the major motor deficits, MSA can be classified as MSA-P (parkinsonism-predominant) or MSA-C (cerebellar-predominant) [77]. Clinical differential diagnosis between MSA-P, the most common clinical form, and IPD is difficult even for specialists. However, the lack of one-side dominance and resting tremor, poor response to levodopa, and rapid progression are all red flags indicating MSA. MSA-C can mostly be distinguished from hereditary spinocerebellar ataxias, although some individuals with such disorders do not have apparent heredity. Autonomic failure (AF) is almost invariably present and can be an initial manifestation (AF-MSA) [79]. Autonomic failure occurs in other neurodegenerative diseases, for example in a subset of patients with IPD (AF-PD), as well as in pure autonomic failure (PAF), both of which are considered Lewy body diseases.

This section reviews the current concepts of urinary dysfunction in MSA, with particular reference to urinary symptoms, (video-)urodynamic assessment and sphincter electromyography (EMG), and patient management.

4.1. Pathology and disease-specific LUT problems

Both overactive bladder and large post-void residuals occur in MSA. The second consensus statement on the diagnosis of MSA recognizes that the disease frequently begins with bladder dysfunction (although erectile dysfunction usually precedes that complaint). Patients may present with urinary incontinence, urinary retention, or a combination of incontinence and incomplete bladder emptying [78]. It is important that other common causes of poor bladder control are excluded by a urologist or uro-gynaecologist before the disorder is attributed to the neurological condition [80]. The prevalence of troublesome urinary symptoms in 256 patients with MSA compared with 158 aged matched control subjects [81] showed that MSA patients had significantly higher increased daytime frequency (45% of women, 43% of men), night time frequency (65%, 69%), urinary urgency (64% of men), and urgency incontinence (75%, 66%) than did the controls. They also had more hesitancy of micturition (62%, 73%), prolonged poor stream (71%, 81%), or intermittent stream (61%, 47%), or the need to strain to void (48%, 55%). Of particular importance is that the quality of life (QOL) index in the MSA group was significantly higher (i.e. worse) in MSA patients for bladder dysfunction (70%, 76%) than that in controls. Many of them show large post-void residual urine volume > 100 ml. Therefore both overactive bladder and large post-void residuals are common in MSA.

In MSA, urinary dysfunction precedes postural hypotension. Of various symptoms of autonomic failure (erectile dysfunction, urinary dysfunction, postural hypotension, respiratory stridor) in patients with MSA, urinary dysfunction has attracted less attention

than postural hypotension, although urinary dysfunction may result in recurrent urinary tract infection and cause morbidity. In addition, urinary incontinence results in impaired self-esteem, stress on the caregiver, and considerable financial cost. Postural hypotension was pointed out first in AF-MSA, which turned out to be a marker of autonomic involvement in this disorder. Both of the original two patients discussed by Shy and Drager had urinary frequency, incontinence, and urinary retention [82]. Other variants (MSA-P and MSA-C) rarely develop postural hypotension in their early stage. However, in the original reports, three of four patients with MSA-P showed voiding difficulty, retention, and urinary incontinence [83].

Thus, what are the most common and earliest autonomic features of MSA? In a study of 121 patients with MSA [84], urinary symptoms (96%) were more common than orthostatic symptoms (43%). The most frequent urinary symptom was difficulty voiding in 79% of the patients, followed by nocturnal urinary frequency in 74%. Other symptoms included urgency in 63%, urgency incontinence in 63%, diurnal urinary frequency in 45%, nocturnal enuresis in 19%, and urinary retention in 8%. The most frequent orthostatic symptom was postural faintness in 43%, followed by blurred vision in 38% and syncope in 19%. These figures are similar to findings reported by other centres [85, 86], and indicate that urinary dysfunction is a more common and often earlier manifestation than postural hypotension in MSA. Many factors might be involved in this phenomenon. Reports of focal lesions have shown that postural hypotension occurs in lesions below the medulla, whereas urinary dysfunction occurs in lesions at many sites in the neuraxis. MSA lesions involve the pons, the hypothalamus, and the basal ganglia, all of which might affect LUT function, as described below.

Urinary dysfunction also precedes motor disorder. Approximately 60% of patients with MSA develop urinary symptoms either prior to or at the time of presentation with the motor disorder [84]. This indicates that many of these patients seek urological advice early in the course of their disease. Since the severity of urinary symptoms is severe enough for surgical intervention, male patients with MSA may undergo urological surgery for prostatic outflow obstruction before the correct diagnosis has been made. The results of such surgery are often transient or unfavourable because of the progressive nature of this disease. Male erectile dysfunction is often the first presentation [84, 87], possibly preceding the occurrence of urinary dysfunction in MSA. The urologist confronted with a patient showing these features should be cautious about embarking on an operative approach. The neurologist encountering a patient with marked urinary symptoms might consider future investigation by brain magnetic resonance imaging (MRI) and sphincter EMG. Since motor disorders in MSA mostly mimic those in IPD, the urogenital distinction between these two diseases is worth considering, although a number of earlier studies on 'Parkinson's disease and the bladder' might inadvertently have included patients with MSA. The prevalence rate of urinary dysfunction and urgency incontinence in MSA is higher than that reported in IPD. In addition, urinary dysfunction is never the initial presentation in IPD.

4.2. Disease specific diagnosis

Since MSA is a neurodegenerative disease that affects multiple brain regions, patients may have a wide range of urodynamic abnormalities that change with progression of the illness. Videourodynamics and sphincter EMG enable assessment of lumbosacral cord functions, which help distinguish MSA from other parkinsonian disorders.

Filling phase abnormalities include overactivity in 33–100% and uninhibited external sphincter relaxation in 33% of MSA [88-90]. Detrusor overactivity seems to be the major cause of urgency incontinence in patients with MSA, and may be associated with uninhibited sphincter relaxation.

Cerebral diseases can lead to a loss of the brain's inhibitory influence on the spino-bulbo-spinal micturition reflex. The information that arises from the lower urinary tract reaches the periaqueductal gray matter (PAG), then goes down to the pontine micturition center (PMC), an area identical to, or just adjacent to, the locus ceruleus, which then activates the descending pathway to the sacral preganglionic neurons innervating the bladder. The basal ganglia are thought to be one of the higher centers for micturition, since lesions of this area lead to bladder overactivity. Positron emission tomography (PET) studies have shown that the hypothalamus, PAG, midline pons, and cingulate cortex are activated during urinary filling. The central pathology of MSA includes neuronal loss of neuromelanin-containing cells in the locus ceruleus [91] and the nigrostriatal dopaminergic system ('putaminal slit sign') [92] and cerebellum, and to a lesser extent in the ponto-medullary raphe ('pontine cross sign') [92, 93] and the frontal cortex [94, 95]. Experimental studies have suggested that the raphe modulates micturition function [96], and also that the cerebellum controls micturition function [97]. A single photon emission computed tomography (SPECT) study has shown that in the urinary storage and micturition phases, but not in the resting phase, activation of the cerebellar vermis was significantly lower in MSA patients than in control subjects [98]. These areas seem to be relevant for the occurrence of bladder overactivity and uninhibited sphincter relaxation in MSA patients.

Incomplete bladder emptying is a significant feature in MSA. In fact, 47% of patients with MSA had postvoid residuals (PVR) > 100 ml, whereas no patients with IPD had such levels [88]. The mean PVR volume was 71 ml in the first year, 129 ml in the second year (which exceeded the threshold volume for the start of clean intermittent catheterization (CIC)), and 170 ml in the fifth year from the onset of illness [99]. Pressure-flow analysis showed that bladder underactivity (a weak detrusor contraction) during voiding is more

common in MSA (71% in women and 63% in men) than in IPD (66% in women and 40% in men) [88]. The mean bladder outlet obstruction index (Abrams Griffiths number) are smaller in patients with MSA (12 in women and 28 in men) than in those with IPD (40 in women and 43) [88]. Detrusor-external sphincter dyssynergia is present in 47% of MSA patients [88]. A subset of patients with MSA has bladder overactivity during storage and underactivity during voiding (detrusor hyperactivity with impaired contractile function, DHIC) [100]. The exact mechanism of this phenomenon has yet to be ascertained. However, it has been recognized that the central mechanisms underlying bladder filling and voiding are distinct from each other; i.e. the area promoting micturition is located in the PMC and the frontal cortex, whereas that promoting urinary storage is in the pontine storage center, basal ganglia, raphe, and frontal cortex. Lesions in these areas may cause various combinations of urinary filling and voiding disorders, such as DHIC.

The role of the sympathetic nervous system may be important, and a key feature could be an open bladder neck, which can suggest sympathetic denervation. The bladder neck, also known as the internal (smooth) urethral sphincter, is a component in the maintenance of continence that is innervated by the sympathetic hypogastric nerve. Videourodynamic study is an established method for evaluating bladder neck function. In normal subjects, the bladder neck is closed throughout filling so as to avoid leaking. However, an open bladder neck is found in 46–100% of MSA patients and in 23–31% of PD patients, and an open bladder neck at the start of bladder filling, even without the accompaniment of bladder overactivity, was noted in no PD patients but in 53% of MSA patients ($p < 0.01$) [88]. Because open bladder neck is common in patients with myelodysplasia or a lower thoracic cord lesion at T12-L2 (where the sympathetic thoracolumbar intermediolateral [IML] nuclei are located) and is reproduced by systemic or intraurethral application of alpha1-adrenergic blockers [101], it is likely that an open bladder neck reflects the loss of sympathetic innervation.

Neurogenic changes in the sphincter EMG may suggest somatic denervation. A distinguishing pathology in MSA is neuronal cell loss in the Onuf nucleus, a group of anterior horn cells in the sacral spinal cord [92]. External anal sphincter (EAS)-electromyography (EMG) results for over 600 MSA patients have been reported, with abnormality rates of more than 70% in many studies [102, 103]. Abnormalities have also been recorded in the bulbocavernosus muscles in MSA [104]. A particular importance is not to miss the late components [105].

In a study of 84 probable MSA cases, 62% exhibited neurogenic change [106]. The prevalence was relatively low, presumably because up to 25% of patients had a disease duration of 1 year or less. In such early cases, the diagnosis of MSA should be made with extreme caution. In addition to the clinical diagnostic criteria, we usually add an imaging study and we perform gene analysis to the extent possible. The prevalence of neurogenic change was 52% in the first year after disease onset, which increased to 83% by the fifth year. Therefore, as expected, it is apparent that the involvement of Onuf's nucleus in MSA is time-dependent; and EAS-MUP abnormalities can distinguish MSA from idiopathic PD and other diseases in the first 5 years after disease onset. Receiver-operating characteristic analysis of sphincter EMG showed high diagnostic power in terms of the duration of motor unit potential (MUP) analysis [103].

In the early stages of illness, the prevalence of neurogenic change in MSA does not seem to be high. It is possible that some MSA patients never develop neurogenic change during the course of their illness. Wenning et al. (1994) reported 3 patients with normal EAS-EMG and a postmortem confirmation of MSA [85]. Therefore, a negative result does exclude a diagnosis of MSA. Paviour et al. (2005) reported that among 30 sets of clinical data and postmortem confirmation in MSA cases with a duration of more than 5 years, 24 (80%) had abnormal EAS-EMG, 5 (17%) had a borderline result, and only 1 had a normal EMG [107]. Neurogenic change does not correlate directly with a clinically obvious functional deficit, although urinary incontinence is more severe in the patients with neurogenic change than in those without it.

Prevalence of neurogenic change increases with the severity of gait disturbance (wheel chair bound) [106]. However, neurogenic change was not related to postural hypotension (reflecting adrenergic nerve dysfunction); erectile dysfunction in men (presumably reflecting cholinergic and nitrergic nerve dysfunction); detrusor overactivity (reflecting the central type of detrusor dysfunction); constipation (presumably reflecting both peripheral and central types of autonomic and somatic dysfunction); or gender [106]. The neurogenic change in EAS-MUP was slightly more common in those with detrusor-sphincter dyssynergia (DSD). It has also been suggested that not only suprasacral pathology, but also sacral/peripheral lesions can produce DSD [108]. Although denervation can be found in the other skeletal muscles in MSA, it occurs much earlier in the external sphincter muscles [109]. This is in contrast to amyotrophic lateral sclerosis, where denervation occurs in most advanced cases (respirator bound).

The neural sites responsible for cardiovascular autonomic failure in MSA are mostly central, in contrast to the peripheral lesions in PAF [80]. However, 31–45% of patients with MSA also have low-compliance detrusor, defined as a maximum bladder capacity/tonic detrusor pressure increase <20 ml/cmH_2O [84]. Low-compliance detrusor is known to occur in patients with spina bifida or in animals with experimental cauda equina lesions, most probably reflecting neuronal loss of bladder preganglionic neurons in the sacral IML nucleus and their fibers (pelvic nerve). Repeated urodynamic studies in MSA patients show

that the cystometrogram changes from bladder overactivity to low-compliance or atonic detrusor, and from negative to positive bethanechol supersensitivity [84]. Nineteen percent of MSA patients show denervation supersensitivity of the detrusor, indicating peripheral changes [84]. As the disease progresses, symptoms may change from urinary urgency and frequency to those due to incomplete bladder emptying. These findings suggest that the responsible sites of the bladder cholinergic disorder may change from the 'center' (supra-nuclear) to the 'periphery' (nuclear sacral IML and/or infra-nuclear) during the course of the illness. Since MSA primarily affects the preganglionic neurons in the autonomic nervous system [80], bladder findings that suggest postganglionic lesions might reflect trans-synaptic degeneration of the cholinergic fibers.

Besides bladder disorders, patients with MSA may have nocturnal polyuria, which results in nocturnal urinary frequency and morning hypotension. A post-mortem study revealed the degeneration of AVP neurons in the suprachiasmatic nucleus in MSA [104], leading to impairment of the circadian rhythm of the plasma AVP concentration in MSA [110, 111]. In addition, daytime postural hypotension may cause nocturnal polyuria in patients with MSA [112]. This is probably due to a combination of factors that include compensatory supine hypertension at night, leading to increased glomerular filtration.

4.3. Disease specific management

More than half of patients with MSA have urinary dysfunction either prior to or at the time of presentation with motor disorder. Since many of these patients develop incomplete bladder emptying, they may be misdiagnosed as having prostatic hypertrophy. In fact, the results of urological surgery are rarely favourable, since bladder underactivity contributes more to voiding difficulty than does outflow obstruction. Therefore, it is important to avoid inappropriate urological surgery in patients with MSA [80]. A conservative approach with medical measures to manage urinary problems can be effective.

Estimation of the PVR volume is a simple and useful test in patients with MSA; even if their urinary complaints are solely urinary urgency/frequency, they may be unaware that their bladders do not empty completely. If the patient has a significant PVR and is symptomatic, this aspect of the problem should be managed using CIC performed by either the patient or the caregiver. However, in patients with advanced disease and severe neurological disability, a permanent indwelling catheter, either transurethral or suprapubic, or urosheath drainage may be required.

If OAB/ DO is present, anticholinergic medication such as tolterodine, oxybutynin, propiverine, or propantheline may be indicated. However, anticholinergic side-effects, particularly dry mouth (probably mediated by M_3 receptors) and constipation ($M_2/_3$ receptors), may limit their use in a proportion of the patients. A subset of patients with MSA may develop mild cognitive decline at an advanced stage of the disease. Since the use of anticholinergic drugs carries a risk of cognitive impairment (M_1 receptors) [113], caution is needed. Anticholinergic drugs ameliorate urgency and frequency, but conceivably could reduce bladder contractility during voiding. Therefore, PVR should be measured and the medication should be withdrawn or CIC should be added if there is significant residual. If night-time urinary urgency/frequency is the problem, overnight bladder drainage may be considered [99].

Interactions can arise between drugs to treat bladder, postural hypotension, and motor disorders. Since incomplete bladder emptying in patients with MSA is due mostly to bladder underactivity, drugs acting on outflow obstruction are unlikely to benefit all patients. However, in some patients, alpha-adrenergic blockers may be effective in lessening PVR volumes, due probably to detrusor-sphincter dyssynergia [114]. Uro-selective blockers such as tamsulosin and naftopidil may be chosen, in the hope they have fewer side-effects such as postural hypotension. Importantly, the drugs most commonly used to treat postural hypotension in MSA are adrenergic agonists. Administration of amezinium, an adrenergic drug, may increase PVR volume and the risk of retention [115]. Amezinium most probably stimulates the alpha receptors, both in the vascular wall ($alpha_{1B}$ receptors, particularly in the elderly [116]) and the proximal urethra ($alpha_{1A/D}$-adrenergic receptors).

Pyridostigmine, an acetylcholinesterase inhibitor, can be effective in lessening PVR volumes [117]. Pyridostigmine also lessens postural hypotension, presumably by enhancing nicotinic acetylcholine receptor transmission in the sympathetic ganglia [118, 119].

Dopaminergic receptors: whether centrally acting drugs, such as pergolide (a dopaminergic $D_{1/2}$-receptor agonist) for parkinsonism, might ameliorate urinary dysfunction in MSA has not been fully studied. Early untreated IPD patients with mild urgency and frequency tend to benefit from levodopa ($D_{1/2}$) treatment. However, levodopa may augment bladder overactivity in IPD patients. Since D_1 selective stimulation inhibits the micturition reflex whereas D_2 selective stimulation facilitates it, the balance of these stimulations may explain the various effects of the drugs. Levodopa ($D_{1/2}$) and its metabolites, such as norepinephrine (noradrenaline), may also contract the bladder neck by stimulating alpha1 adrenergic receptors [115].

Desmopressin is a potent analogue of AVP used in the treatment of diabetes insipidus due to a loss of posterior pituitary AVP secretion. Mathias et al. [111] used 2–4μg of intramuscular desmopressin in patients with autonomic failure including MSA. 5μg of intranasal desmopressin once a night in MSA patients with impaired circadian rhythm of AVP and nocturnal polyuria also appears to be beneficial [120]. This small dose of desmopressin is unlikely to

cause adverse effects, but hyponatremia and signs of cardiac failure should be checked for regularly. Desmopressin could also ameliorate morning hypotension resulting from the abnormal loss of body fluid at night [111].

Micturition syncope: Well-known triggers for syncope in MSA include: 1) standing (postural syncope), 2) eating (post-prandial syncope), and 3) exercise (post-exertional syncope) [80]. In addition, syncope in patients with MSA may also be triggered by 4) voiding (micturition syncope) [121]. The detailed link between the bladder and the cardiovascular system is still uncertain in this condition. However, particularly in patients who use abdominal straining when voiding, CIC could lessen micturition syncope.

Recent studies suggest that bladder management may directly, or indirectly, affect survival of MSA [122, 123]. Coon et al. suggested that while the initial onset with autonomic symptoms was not associated with shortened overall survival, early autonomic symptoms in disease course, particularly bladder symptoms and severe urinary symptoms (requiring urinary catheterization), negatively affected survival [122]. Since MSA is a progressive disease that leads to urinary retention, early differential diagnosis from Parkinson's disease is necessary in terms of catheterization [124].

Conclusions:

- Urinary dysfunction is a prominent autonomic feature in patients with MSA, and it is more common (above 90%) and occurs earlier than postural hypotension in this disorder (LOE3).
- In contrast to idiopathic Parkinson's disease, MSA patients have more marked urinary dysfunction, which consists of both urgency incontinence and post-void residuals >100 ml (LOE1,2).
- Videourodynamic and sphincter EMG analyses are important tools for understanding the extent of these dysfunctions and for determining both the diagnosis and management of the disorders (LOE3).
- The common finding is detrusor overactivity, which accounts for urinary urgency and increased frequency (LOE3).
- Detrusor-sphincter dyssynergia, open bladder neck at the start of bladder filling (internal sphincter denervation), and neurogenic sphincter EMG (external sphincter denervation) are all characteristics of MSA (LOE2).
- These features may reflect pathological lesions in the basal ganglia, pontine tegmentum, raphe, intermediolateral cell column, and sacral Onuf's nuclei (LOE4).
- During the course of the disease, the pathophysiological balance shifts from central to peripheral, with bladder emptying disorder coming to predominate (LOE3).

Recommendations:

- Clinical features of MSA may mimic those of IPD, and the potential impact on treatment outcomes should be considered if there is any doubt about the underlying diagnosis (A).
- MSA is a progressive disorder and impaired detrusor contractility is common. Therefore it is important to avoid inappropriate urological surgery in patients with MSA (B/C).
- A conservative approach with medical measures in MSA patients includes anticholinergics for urinary urgency and frequency, desmopressin for nocturnal polyuria, uro-selective alpha-blockers and cholinergic stimulants for voiding difficulty, and CIC (clean, intermittent catheterization) for large PVR (post-void residual) (B).

4.4. Faecal incontinence

Lower gastrointestinal tract (LGIT) dysfunction is also common in patients with MSA. Sakakibara et al. [125] (LOE2) performed a bowel questionnaire in 15 patients with MSA and in 10 age-matched healthy control subjects. The MSA group showed decreased bowel frequency (< 3 times a week) in 9, difficulty in expulsion in 11, and faecal incontinence in 3; the control group showed decreased bowel frequency in only 2, mild difficulty in expulsion in 2, faecal incontinence in none. Therefore, constipation is the major bowel dysfunction in this disorder, although in advanced stages faecal incontinence is not uncommon.

Studies on the mechanism of bowel problems in this disorder are scarce. Stocchi et al. [126] (LOE2) performed anorectal manometry in 16 patients with MSA; 13 patients showed paradoxical anal sphincter contraction on fictive straining. Bardoux et al. [127] (LOE3-4) reported a case of a faecally incontinent patient due to MSA, who showed inability of anal squeezing. Sakakibara et al. [125] (LOE2) performed colonic transit time, sphincter electromyography (EMG) and rectoanal videomanometry in 15 patients with MSA and 10 age-matched healthy control subjects. Compared with the control subjects, MSA patients had significantly prolonged colonic transit time in the rectosigmoid segment and total colon. Sphincter EMG showed neurogenic motor unit potentials in none of control subjects but in 93% of MSA. In the resting state, MSA patients showed a lower anal squeeze pressure (external sphincter weakness) and a smaller increase in abdominal pressure on coughing. During rectal filling, MSA patients showed smaller amplitude in phasic rectal contraction, which was accompanied by an increase in anal pressure that normally decreased, together with leaking in 3 patients. During defecation, most MSA patients could not defecate completely, with larger post-defecation residuals. MSA patients had weak abdominal straining, smaller rectal contraction on defecation and larger anal contraction on defecation (paradoxical sphincter contraction on defecation, or anismus),

though these differences were not statistically significant.

Constipation in MSA most probably results from slow colonic transit, decreased phasic rectal contraction and weak abdominal straining, whereas faecal incontinence results from weak anal sphincter due to denervation. The responsible sites for these dysfunctions are still not known. However, as described in idiopathic Parkinson's disease, they most probably reflect lesions of both central and peripheral nervous systems that regulate the LGIT.

LGIT functional disturbance is often preceded by LUT dysfunction in MSA patients. Abnormalities in colonic transit time and rectoanal videomanometry in MSA were mostly similar to those in idiopathic Parkinson's disease, except for the sphincter denervation and resultant faecal incontinence in MSA.

When treatment of the bowel disorder in MSA is planned, use of objective parameters is recommended in order to clarify the action of drugs. A few such studies are available: Eichhorn and Oertel [128] (LOE3) gave polyethylene glycol 3350, an osmotic agent with high water binding capacity, in 2 patients with MSA, and found an improvement in stool frequency and difficult defecation in both patients. Similarly, Sakakibara et al. [129] (LOE2) measured colonic transit time in 4 patients with MSA. After administration of calcium polycarbophil, an osmotic and highly bulking agent, colonic transit time of total and the right segment shortened significantly. Liu et al. [130] (LOE2) performed colonic transit time and rectoanal videomanometry in 7 patients with MSA. After administration of mosapride citrate, a novel selective 5-HT4 receptor agonist, the patients showed a shortened total and rectosigmoid segment colonic transit time, lessened first sensation and an augmented amplitude in phasic rectal contraction. During defecation, mosapride augmented the amplitude in rectal contraction and lessened the volume of post-defecation residuals significantly. Similar results were obtained in a study by Sakakibara et al. [131] (LOE2), in which dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action), was prescribed.

MSA is a slowly progressive disease currently without cure. More research is needed to evaluate the pathophysiology of LGIT dysfunction, and to evaluate the effects of different drug treatment modalities.

Conclusions

- Patients with multiple system atrophy have often abnormal bowel function (LOE2).
- The most common bowel disturbances are slow colonic transit, decreased phasic rectal contraction and weak abdominal straining; faecal incontinence results from weak anal sphincter, due to denervation (LOE2).
- Bowel dysfunction, such as constipation, is common and has significant impact on quality of life of patients with multiple system atrophy (LOE3).

Recommendation

- More studies on neurologic bowel dysfunction and management in patients with multiple system atrophy are needed.

5. PARKINSON'S DISEASE

5.1. Urinary incontinence

Parkinson's disease (PD) is a movement disorder due to degeneration of dopaminergic neurons in the substantia nigra and a loss of dopamine-containing nerve terminals in the basal ganglia. Degeneration of the nigrostriatal pathway is accompanied by decreases in corresponding biochemical markers, including dopamine, tyrosine hydroxylase, dopamine metabolites, and dopamine transporter. These central nervous system changes also have influence on autonomic function; the most common problems are gastrointestinal (constipation), perspiratory (hypohidrosis) and urinary system.

LUT dysfunction in PD was estimated to occur in 37-71% in uncontrolled studies. Among these, in a study of Hattori et al. [132] (LOE3), 60% of PD patients had urinary symptoms, which could be divided in the following categories: storage LUTS in 28%, voiding in 11%, and both types in 21%. The prevalence of urinary symptoms correlated with severity of the disease, but not with the duration of illness. Gray et al. [133] (LOE3) reported that LUT functional disturbances in PD are not disease-specific and only correlated with age. In control-based studies [134-137] (LOE2) the prevalence of LUT symptoms (LUTS) was found to be 27-64%, and significantly higher than healthy controls. The majority of patients had onset of the bladder dysfunction after the appearance of motor disorder. Even patients with low disability may report LUTS, though this may not cause impairment of quality of life [138]. In one study, urinary incontinence in PD frequently occurred in conjunction with faecal incontinence, whereas no significant relation was observed between bladder and sexual dysfunction. Bladder dysfunction substantially affects the quality of life in patients with PD. Bladder dysfunction in PD correlates with neurological disability, and stage of disease, both suggesting a relationship between dopaminergic degeneration and LUTS. LUTS was more common in a group of PD patients with older age, as in healthy populations. Among LUTS, nocturia (nighttime urinary frequency) is the most prevalent symptom (>60%) [136, 137] (LOE2). Patients also complain of urinary urgency (33-54%), daytime frequency (16-36%), and urinary incontinence in 26% of males and 28% of females. These figures are almost the same in untreated, early PD patients [138]. Although

less common than storage symptoms, PD patients also report voiding symptoms. In the study by Sakakibara et al. [139] (LOE2), PD patients had significantly higher rates of delay in initiating urination (44% of men), prolongation/poor stream (70% of men), and straining (28% of women) compared with the control group. However, despite the voiding symptoms, PD patients have low post-void residuals. Impaired detrusor contractility is reported in urodynamic studies in PD and is related to the degree of motor impairment [140].

Pathology and disease-specific urinary tract problems

The net effect of the basal ganglia on micturition is thought to be inhibitory [141]; in PD, the bladder becomes overactive. Functional neuroimaging during bladder filling resulted in activation in the globus pallidus of normal volunteers and in the putamen in PD patients with detrusor overactivity. In contrast, dopamine transporter imaging (indicating brain dopamine neurons) was decreased in PD patients with urinary dysfunction than in those without it [142]. The micturition reflex is under the influences of nigrostriatal dopamine (both inhibitory in D1 and facilitatory in D2) and GABA (inhibitory). Deep brain stimulation in the subthalamic nucleus results in amelioration of motor disorder as well as increased bladder capacity and decreased post-void residuals [143] (LOE2). Therefore, urinary dysfunction in PD could reflect degeneration of the nigrostriatal dopaminergic cells associated with specific motor disorders. In addition to the nigrostriatal dopaminergic projection, the ventral tegmental area (VTA, the A10 cell group)-limbic cortex and the hypothalamic (the A11 cell group)-spinal cord dopaminergic projections are presumably involved in urinary dysfunction in PD.

In a study of PD and multiple system atrophy (MSA) patients, Sakakibara et al. [88] (LOE2) found urinary symptoms in 72% of PD patients. They were mostly attributed to DO (81%) and external sphincter relaxation problems (33%). During micturition, PD patients did not demonstrate DSD, but impaired detrusor contractility was observed in 66% of women and 40% of men. In addition, patients with PD had partial bladder outlet obstruction, e.g. mean bladder outlet obstruction index was 43 in men. Nevertheless, average volume of post-void residuals in PD was only 18 ml. Similar observations were reported by Defreitas et al. [144] (LOE2).

Specific diagnosis and treatment

In the differential diagnosis of PD and parkinsonian-type MSA, large post-void residuals, open bladder neck, and neurogenic change in sphincter motor unit potentials are common in MSA [80, 88] (LOE2), whereas they are rarely seen in clinically typical PD [145]. However, PD with dementia, or dementia with Lewy bodies, may have large post-void residuals and neurogenic change in the sphincter motor unit potentials [146], thereby mimicking MSA (LOE3). Bladder dysfunction in PD parallels other autonomic dysfunctions [147], cardiac denervation [148], and falls [149] (LOE3). Nocturnal polyuria is an important cause for nocturia and therefore patients reporting nocturia should fill in a bladder diary.

Guidelines now exist for the management of bladder dysfunction in PD [124]. Levodopa and other antiparkinson medication may affect bladder function in PD. To date the results are not consistent and the responses are not straightforward. Some reports have shown storage-facilitating effects of dopaminergic drugs. Kuno et al. [150] (LOE3) showed that change of bromocriptine to pergolide (D1<2 agonist) brought lessening of nocturia. Others have shown voiding-facilitating effects. In early PD [151] (LOE2) and advanced PD with the on-off phenomenon [152] (LOE2), a single-dose of levodopa exacerbates DO in the filling phase, but also improves bladder emptying through increased detrusor contractility. We still do not know the reasons for the discrepancy between different studies.

There are several factors underlying the complex bladder behaviour in PD. Post-synaptic dopamine D1 (excitatory) and D2 (inhibitory) receptors have a millimolar affinity to dopamine, whereas dendritic D2 (inhibitory) autoreceptors have a picomolar affinity to dopamine. Therefore, when levodopa is administered externally, it may first stimulate dendritic D2 autoreceptors, which might suppress the nigral cells and facilitate the micturition reflex. In cases of PD under long-term treatment with levodopa, dopamine receptors are down-regulated. Bladder overactivity might also involve an activation of D2 receptors in the spinal cord [153] (LOE2). In addition, in experimental animals, single doses of apomorphine showed a biphasic effect [154] (LOE2).

Deep brain stimulation (DBS) is a treatment option in advanced PD. The subthalamic nucleus (STN) is regarded as the key area in the indirect pathway, which is dominant in the parkinsonian state. DBS inhibits many cells within the STN, probably due to depolarization block and release of GABA from activation of inhibitory afferent terminals. In the STN, neuronal firings related to the micturition cycle have been observed in cats [155] (LOE2). DBS increased bladder capacity, facilitated bladder afferent pathways, and augmented activity of the prefrontal cortex in the brain of PD patients [156] (LOE2). In a cohort of 107 patients with advanced PD, patients treated with STN DBS reported the same degree of LUT symptoms compared to patients treated with either conventional oral medication therapy or an apomorphine pump, however had significantly less nocturia [157]. Acute urinary retention has been reported in two patients after subthalamic nucleus DBS [158] and detrusor overactivity has been reported following pedunculopontine nucleus DBS [159] (LOE3).

A double-blind, randomized, placebo-controlled study evaluated solifenacin 5-10 mg /day in 23 pa-

tients with PD and LUT symptoms. A significant improvement in the number of micturitions per 24 h period was observed in the solifenacin group compared to placebo at a mean dose of 6 mg/day. In the open label phase, the mean number of urinary incontinence episodes per 24 h period, as well as the number of nocturia episodes, decreased [160] (LOE2). A prospective evaluation of 33 men with PD reporting LUT symptoms taking doxazosin demonstrated a significant improvement in LUT symptoms, LUT-related quality of life and flow rates, though the response to treatment was dependent on the severity of neurological disability [161] (LOE 3).

A systematic review of anticholinergic use (centrally acting) to treat PD was done by Katzenschlager et al. [162] (LOE l). Cognitive adverse events of anticholinergics are a concern, particularly in elderly PD patients. This was first described in 1997 by Donnellan et al. in PD patients with overactive bladder [113] (LOE 3). They gave oxybutynin in four patients, who subsequently developed dementia, which reversed after discontinuation of oxybutynin. Factors underlying the cognitive effects of these medications include: 1) central muscarinic receptor affinity, e.g. high M1-receptor selectivity; and 2) easy penetration of the blood-brain barrier (BBB), e.g. high lipid solubility; a neutral charge or low degree of ionization; and a less bulky (number of rotatable bonds<5) and smaller molecular size (<450Da) [163] (LOE 2). Regarding BBB penetration, most anticholinergics have a molecular size between 300-400Da. Oxybutynin can readily penetrate the CNS, since it has high lipophilicity and neutrality, while anticholinergics have less marked lipophilicity or neutrality. Trospium, a quaternary amine, has a particularly high polarity.

Intradetrusor injections of onabotulinumtoxinA is a promising treatment for managing intractable DO in patients with PD and small case series have demonstrated improvement in clinical and urodynamic parameters [164-166] (LOE3). However the concern is urinary retention that may arise following treatment and the potential need to require catheterisation. This seems to be related to the dosage used and reports of incomplete bladder emptying and catheterisation is reported more when using 200 units compared to 100 units [164, 165].

Tibial nerve stimulation (TNS) has been shown to be effective in short term management of OAB symptoms in patients with PD. Acute percutaneous TNS (PTNS) has been reported to increase functional bladder capacity in PD, and following chronic stimulation urinary frequency and urgency urinary incontinence reduced [167]. However, long term outcomes in PD are lacking. Transcutaneous tibial nerve stimulation (TTNS) was found effective in the treatment of LUTS in 13 patients with PD, with benefits in urinary urgency and nocturia episodes, as well as urodynamic parameters [168]. The number of patients reported having Sacral nerve modulation is insufficient to draw any conclusions [169].

As in MSA, a very important issue in PD affected patients is the indication for pelvic surgery. Myers et al. [170] (LOE2) found that women with PD and LUT complaints have a lower maximum cystometric capacity and a higher rate of DO at lower bladder volumes in comparison with non-neurologic controls. Therefore surgery for stress incontinence in women with PD should be performed only when no significant DO is present, since this type of surgery can evoke or aggravate DO and subsequent urgency incontinence. Roth et al. reported outcomes of 23 patients with PD undergoing transurethral prostate resection for benign prostatic obstruction, emphasizing the importance of careful evaluation before any decision on intervention [171].

Conclusions

- In Parkinson's disease, LUT symptoms are associated with degeneration of dopaminergic neurotransmission (LOE2).
- The most common LUT disturbances are detrusor overactivity during storage, and impaired detrusor contractility during voiding (LOE2).
- The effect of levodopa on LUTS in PD patients remains to be fully elucidated (LOE3).

Recommendations

- Detrusor overactivity in PD patients can be treated with antimuscarinic drugs (B).
- For voiding failure with significant post void residual, the treatment of choice is intermittent catheterization (B).
- OnabotulinumtoxinA is a promising treatment for managing intractable DO in PD, which is associated with a risk for urinary retention and the need for catheterisation. (C)
- LUT surgery for patients with Parkinson's symptoms is an option where MSA is excluded, provided evaluation is detailed (C).
- Stress incontinence surgery should not be offered to patients with significant detrusor overactivity (C).

5.2. Constipation and faecal incontinence

Lower gastrointestinal tract (LGIT) dysfunction is common in Parkinson's disease (PD). In control-based studies, the incidence of decreased stool frequency (< 3 times a week) in PD patients ranges from 20% to 81%, difficulty in stool expulsion 57-67%, and diarrhoea 21% [172, 173] (LOE2). All of these values are significantly higher than in the normal population (range, decreased stool frequency, 0-33%; difficulty in stool expulsion, 26-28%; diarrhoea, 10%). Faecal incontinence affects 10-24% in PD [172, 174] (LOE2). Therefore, constipation is the most prominent LGIT symptom in patients with PD. Indeed, PD is a risk fac-

tor for elderly nursing home residents to have constipation. Bowel dysfunction affects the quality of life in patients with PD. The rate of dissatisfaction for bowel dysfunction (59%) is significantly higher than for urinary (28%) or sexual dysfunction (29%), although the prevalence rate of all three dysfunctions is almost the same (more than 60%). The rate of dissatisfaction for the bowel dysfunction in PD is also significantly higher than in healthy controls (16%) [174] (LOE2).

Difficulty in expulsion and diarrhoea are more common in the higher grade of Hoehn and Yahr staging, suggesting a relationship between dopaminergic degeneration and LGIT symptoms. Faecal incontinence in PD occurs commonly with urinary incontinence, whereas no significant relation has been seen between bowel and sexual dysfunction. Constipation in PD is often associated with a low coefficient of variation in electrocardiographic R to R intervals [175] (LOE3). The findings indicate that parasympathetic dysfunction might underlie these abnormalities.

Intestinal pseudo-obstruction (IPO), also called paralytic ileus, is the most severe presentation of constipation in patients with PD and constitutes a medical emergency. Occurrence of IPO/ volvulus is reported as a potential complication [176] (LOE3). Although rare, emergency IPO needs hospitalization and may lead to a poor outcome. Therefore, preventative treatment of constipation, including consideration of prokinetic drugs is necessary, particularly in elderly PD patients.

There seems to be an association between the frequency of bowel movements and the future risk of developing PD [177, 178] (LOE1). This observation is in line with the pathological staging of PD by Braak et al. [179] (LOE1), in which disease process in the central nervous system starts earlier in the dorsal motor vagal nucleus than in the substantia nigra in PD. From a clinical perspective, it is of particular relevance that patients may see gastroenterologists or physicians first because of their bowel dysfunction, prior to a correct diagnosis of PD being made. Therefore, constipation as the initial presentation of PD is akin to urinary dysfunction as the initial presentation of multiple system atrophy.

Pathology and disease-specific problems

The enteric nervous system generates the peristalsis responsible for bowel content transit. The components of peristalsis are contraction on the oral side of the bolus, and relaxation on the caudal side. Cholinergic receptors have a major role in the contraction proximally. The strength of cholinergic transmission is regulated by opposing receptors; serotonin 5-HT4 receptor-mediating excitation and dopamine D2 receptor-mediating inhibition. Post-mortem studies of bowel in PD have shown decrease in dopaminergic myenteric neurons and the appearance of Lewy bodies along the proximal-distal axis, being most frequent in the lower oesophagus, but scarce in the rectum [180-182] (LOE2). Thus PD affects not only the central, but also the peripheral (enteric) nervous system.

LGIT function primarily consists of [1] colonic transport of the bowel content to the anorectum, [2] transient storage in the anorectum, and [3] defecation. In PD, constipation results primarily from decreased transport and/or disturbed anorectal evacuation. Faecal incontinence may result from disturbed anorectal reservoir function, or overflow secondary to constipation. Previous reports have shown that total colonic transit time (CTT) is increased beyond the normal threshold in 80% of PD patients, which translates into an increased average CTT ranging from 44 hours to 130 hours [172, 174][139, 141, 151] (LOE2), and 89 hours in de novo PD patients [48] (LOE2), all of which are significantly longer than the CTT in controls (range, 20-39 hours). Prolonged CTT has also been documented in PD patients without subjective constipation. Slow colonic transit is the major cause of decreased stool frequency. The slow colonic transit is likely to reflect a decrease in slow waves and spike activities of the colon [147].

In resting anal manometry, the anal pressure of PD patients is low or normal [172, 174, 183] (LOE2). The resting anal pressure may reflect sympathetic innervation in the internal anal sphincter, since lesions or anaesthetic blocks at T12-L3 (where the sympathetic preganglionic neurons are located) substantially lessen the anal pressure. Similarly, most PD patients have normal anal pressure increase on squeezing. This finding corresponds to a lack of neurogenic changes in the external sphincter EMG. Nevertheless, latent anal sphincter dysfunction may explain the faecal incontinence that occurs in most advanced cases. In slow-filling rectoanal videomanometry, PD patients had the same rectal volume at first sensation and a maximum desire to defecate, and the same rectal compliance as control subjects [90, 174] (LOE2). In contrast to the bladder, the normal rectum shows spontaneous phasic contraction. However, the amplitude of the spontaneous phasic rectal contraction in PD patients is significantly less than that in control subjects. The decreased spontaneous phasic rectal contraction may share the same aetiology with the altered CTT.

During defecation, healthy subjects utilize the final wave of spontaneous phasic rectal contractions. However, rectal contraction on defecation in PD patients is smaller than that in controls [174] (LOE2). In addition, abdominal straining is weaker in PD patients. Paradoxical anal sphincter contraction on defecation (PSCD), or anismus, is observed in studies using sphincter EMG, radiography, and anal pressure measurement. The mechanism of the impaired straining in PD may include rigidity and reduced contractility of the axial muscles, and a failure of coordinated glottis closure. However, neuronal degeneration in the brain of PD patients relevant to straining is yet to be clarified. Mathers et al. [184] consider PSCD a focal dystonia. Dysfunction in the suprasacral descend-

ing pathway to the external sphincter may be a contributing factor. Apomorphine was shown to lessen PSCD [184] (LOE2). This effect was not antagonized by domperidone, which does not penetrate the BBB, suggesting that CNS pathology may contribute to PSCD.

Disease-specific diagnosis and treatment

Insoluble dietary fibers produced an improvement in stool consistency and an increase in stool frequency in PD, which paralleled an improvement in levodopa absorption [185] (LOE3). Dietary fibers such as psyllium [186] (LOE2) and polyethylene glycol 3350 [128] (LOE2), or bulking and highly hydrophilic agent polycarbophil [129] (LOE2), improve constipation in neurodegenerative disorders, including PD. Although psyllium does not alter CTT or anorectal parameters in PD patients, polycarbophil shortens the total CTT, particularly in the proximal bowel segments.

It is possible that levodopa and other antiparkinson medication may affect bowel function in PD. Endogenous dopamine is thought to inhibit intestinal motility via D2 receptors. Tateno and Sakakibara performed the quantitative lower-gastrointestinal autonomic test (QL-GAT, a combination of colonic transit and manometry) in 19 early, untreated PD patients before and after administration of 200 mg/day of levodopa [187]. Levodopa augmented rectal contraction, lessened paradoxical anal sphincter contraction on defecation (PSCD, anismus), and thereby ameliorated anorectal constipation, without apparent adverse effects. This might be brought about by both peripheral and central dopaminergic stimulation.

Since levodopa is absorbed from the small intestine, bowel dysfunction in PD may interfere with levodopa absorption, worsen the motor disorder, or even lead to malignant syndrome [173, 188] (LOE3/4). Domperidone, a peripheral D2 receptor antagonist that does not cross the blood-brain barrier, causes a mean 12% increase in peak plasma levodopa concentrations that occurs a mean of 10 min earlier than when levodopa is given alone [189] (LOE3).

The selective 5-HT 4 receptor agonist cisapride [190], though no longer licensed, and newer agents such as mosapride [130] (LOE2) and tegaserod [191] significantly reduce CTT and ameliorate constipation in PD. Mosapride shortened total CTT (particularly the caudal segment), and augmented the amplitude in rectal contraction during defecation in patients with PD [130]. Notably, improvement of parkinsonism is more significant with pergolide-mosapride than with pergolide-domperidone, presumably reflecting better levodopa absorption. Similar results were obtained in PD by dietary herb extract Dai-Kenchu-To, one active component of which is hydroxy-beta-sanshool (5-HT3 receptor agonistic action) [131] (LOE2). A series has shown a role for Botulinum toxin A injections into the puborectalis muscle [192] (LOE3).

Conclusions

- Patients with PD often have abnormal anorectal function (LOE2).
- The most common bowel disturbances in PD are slow colonic transit, decreased phasic rectal contraction, weak abdominal straining, and paradoxical sphincter contraction on defecation (anismus) (LOE2).
- Bowel dysfunction such as constipation is common and has significant impact on quality of life of PD patients (LOE2).

Recommendations

- More studies on management of neurologic bowel dysfunction in PD are needed.

6. CEREBRAL LESIONS AND CEREBROVASCULAR ACCIDENTS

Lower urinary tract dysfunction (LUTD) may be an integrated part of the neurological syndrome (i.e. a neurogenic LUT dysfunction, most often urinary incontinence (UI)). LUTD may also be a consequence of associated deficits; particularly motor and cognitive dysfunction may lead to UI, which in this case is called "functional". Both neurogenic and functional UI may be combined. Patients themselves, however, rarely link the LUT symptoms to the neurological disorder. Correlation between specific LUT symptom (LUTS) and the lesion site caused by stroke has initially been studied by post mortem or surgical specimens. But with improving modalities of imaging, it becomes possible to correlate symptoms with smaller, more discrete abnormalities. As a rather new insight, slow, diffuse brain ischemia (white matter lesion) recently emerged as a significant factor to produce overactive bladder (OAB) in the elderly. Finally, management of LUTD in stroke is reviewed.

6.1. Stroke

LUTD in stroke may be a consequence of direct involvement of neural structures which are part of the brain neural control of LUT. The consequence is, as will be discussed later, in most events the overactive bladder syndrome (OAB; i.e. urgency and frequency of micturition, and urge UI). Furthermore, there often is a functional component (immobility and loss of initiative/cognition) [193].

Stroke, a major form of cerebrovascular disease (CVD), is a common brain disease that preferentially affects the elderly. LUTD significantly affects quality of life in post-stroke patients [194]. Reports of the prevalence of LUTS in patients with stroke, except for UI, have been scarce. Sakakibara et al. [195] reported on the bladder symptoms of 72 patients who had been admitted with an acute hemispheric stroke

in a neurology department. When assessed at 3 months, 53% were found to have significant LUTS. The commonest problem was nocturnal urinary frequency (36%), then urgency UI (29%) and difficulty in voiding (25%);. urinary retention was seen in 6%. Brittain et al. [196] reported an incidence of post-stroke LUTS as 64% (in 423 subjects) that was higher than in a control normal population (32%). The major urinary symptoms were: nocturia (49%), UI (33%), urgency (19%), frequency (15%), straining (3.5%) and pain (2.5%). In 1248 stroke patients, Williams et al. [197] found that 83.6% of survivors reported one or more abnormal LUTS at 3 months, nocturia being the most frequent (79.1%), followed by UI (43.5%; urgency type 37.0%, stress type 20.6%) and urinary frequency (17.5%).

Thomas et al. [198] reported UI in 40-60% of patients admitted to hospital after a stroke, with 25% still having problems on hospital discharge, and around 15% remaining incontinent at one year. Amelioration of UI in 25-45% of the patients may reflect amelioration of both functional component (mobility, initiative and cognition) as well as OAB component in this commonest brain disease. Kuptniratsaikul et al. [199] noted bladder/bowel dysfunction in 31.5% among 327 post stroke patients who started rehabilitation.

Studies reporting on stroke localization and LUTD stress the importance of the frontal lobe, and there are no clear reports of bladder dysfunction as a consequence of a single/focal deficit in the parietal, temporal or occipital lobe. Lesions of the anteromedial frontal lobe, its descending pathways and the basal ganglia may be important for bladder dysfunction in stroke patients. Khan et al. [200, 201] reported on post-stroke patients with LUTS, and the majority of patients had frontal cortex and/or internal capsular lesions. Bogousslavsky and Regli noted UI in 22% (6 of 23 cases) of anterior cerebral artery infarction that affects the frontal lobe [202]. Sakakibara and colleagues [195], analysing 72 post-stroke patients irrespective of the presence of LUTS, found a significant correlation between the occurrence of a urinary disturbance and hemiparesis and a negative correlation with hemianopia, brain imaging techniques confirming a more anterior location of brain lesions in the former group. Woessner et al. reported a urinary-incontinent patient whose stroke was localized in the cortical motor area of the bladder/sphincter [203].

Considering LUT neural control one expects LUTD also in brainstem infarcts. An analysis of LUTS of 39 patients who had had brainstem strokes showed that it was dorsally situated lesions that resulted in disturbance of micturition [204]. Forty-nine percent of all the patients had LUTS; nocturnal urinary frequency and voiding difficulty in 28%, urinary retention in 21% and UI in 8%. The problems were more common in those following haemorrhage, possibly because the damage was usually bilateral. MR scanning showed that the responsible lesions were in the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and the locus coeruleus. A correlation was found between LUTS and sensory disturbance, abnormal eye movement and inco-ordination. Lateral medullary infarction (Wallenberg syndrome) has been reported to produce voiding difficulty and DSD [205]. In another case, the lesion seemed to extend to basal medulla that produced hemiparesis [206]. Brain stem stroke cases suggested the region is located in the dorsolateral pons including the pontine reticular nucleus and the reticular formation, adjacent to the medial parabrachial nucleus and the locus ceruleus [207]. Yum et al. [208] analysed 30 brainstem infarction cases. They found LUTS in 70% of patients, comprising 46.7% storage disorder and 23.3% emptying disorder. In their series of patients, emptying disorder was more common in medullary lesion (55.6%) than pontine lesion (9.5%). Storage disorder was found only in pontine lesion (61.9%).

There are few reports on LUTD related to other brain areas. Cerebellar stroke has been reported to cause LUTD (detrusor overactivity) [209]. UI is seen in 13% (2/16) of right and 33% (10/30) of left anterior cerebral artery infarctions [210]. Sakakibara et al., however, did not see a clear relationship between stroke laterality and LUTS [195]. Similar findings were reported by others [211]. In contrast, Ersoz et al. [212] divided their post stroke patients with LUTD into infarction and haemorrhage. The infarction group had larger bladder capacity (250.3 ml) and larger post-void residual urine volume (136.1 ml) than haemorrhage group (194.9 ml, 29.5 ml, respectively), indicating a more severe bladder dysfunction. Han et al. [213] found that the infarction group had more detrusor overactivity but less detrusor underactivity (70.7%, 29.3% respectively) than the haemorrhage group (34.65, 65.4% respectively).

Khan et al. [200, 201] demonstrated detrusor overactivity (DO) in 79% of 33 post stroke patients with LUT symptoms. None of them had detrusor-sphincter dyssynergia (DSD) on voiding. The mechanism of DO seems not to be uniform; certainly DO has been described in patients with different locations of lesions in CNS, but is also seen in patients without (obvious) neurological involvement. It is postulated that the micturition reflex is under tonic (mainly inhibitory) influences [214, 215] by the central cholinergic pathway [216] and the fronto-nigro-striatal, dopamine D1-GABAergic direct pathway [139]. Furthermore, it is postulated that in patients with brain lesions DO is an exaggerated spino-bulbo-spinal micturition reflex; PMC normally promotes micturition, and without inhibition, DO develops [141, 214, 215]. The exaggerated micturition reflex is abolished after chemical lesioning of the PMC in stroke rats.

Consequent urodynamic studies showed a more varied picture: in19 poststroke UI patients Gelber et al. [217] reported DO in 37%, underactive detrusor in 21%, and detrusor-sphincter dyssynergia in 5%. In an urodynamic study of 27 symptomatic stroke patients [218] DO was seen in 40.7% and detrusor areflexia in 3.7%. Similarly, a study of 38 symptomatic stroke

men by Nitti et al. [219] showed DO in 82% and outlet obstruction in 63%. In 57 poststroke patients, Natsume [220] also found detrusor underactivity in 35% men and 43% women; and most of them had so-called detrusor hyperactivity with impaired contraction (DHIC). In contrast to the pathophysiology of DO, little is known about the pathophysiology of 'brain shock' and DHIC [100]. Within the brain, it is known that there are both micturition-inhibiting and micturition-promoting areas. The latter includes A10 ventral tegmental area (VTA)-mesolimbic dopaminergic pathway, D2-subthalamic indirect pathway, and the glutamatergic pontine micturition center (PMC) adjacent to the locus ceruleus and sacral cholinergic preganglionic cells [139]. These pathways might also be involved in many brain diseases affecting the frontal lobe. Gupta et al. [221] found DO in 90% and DSD in 27.5% in their 40 patients with post-stroke UI. Urodynamics in 11 symptomatic patients with brainstem lesions showed DO in 8 (73%), low compliance detrusor in 1 (9%), acontractile detrusor in 3 (27%), non-relaxing sphincter on voiding in 5 (45%) and uninhibited sphincter relaxation in 3 (27%). No statistically significant correlation could be demonstrated between any particular lesion site and urodynamic findings [222].

Early UI following a stroke is a specific indicator of poor prognosis. Wade and Langton-Hewer analysed the symptoms of 532 patients seen within seven days of their stroke and found that the presence of UI appeared to be a more powerful prognostic indicator for poor survival and eventual functional dependence than was a depressed level of consciousness [223]. Others have also reported that the outcome was better in those who remained or became dry [224, 225]. Rotar et al. [226] demonstrated post-stroke UI is a predictor of greater mortality not only at the end of the first week, but also at 6 months and 12 months after stroke.

Gelber et al. [217] found that post-stroke UI was associated with large infarcts, aphasia, cognitive impairment, and functional disability. Nyberg and Gustafson [227] noted a strong link between easy fall and UI. van Kuijk et al. [228] reported that among 143 poststroke patients, activity of daily living (modified Barthel index) and discharge rate to their own home are negatively related with UI. Landi et al. [229] reported that among 355 poststroke patients, functional (mobility and activity of daily living) decline is related with UI. Pettersen and Wyller [230, 231], among 355 poststroke patients, noted a relation between UI and poor mobility. Paolucci et al. [232] and Daviet et al. [233] reported that, not only immobility and dementia, but also unilateral spatial neglect (mostly due to right hemispheric lesion) strongly correlates with UI after stroke. It seems likely that UI is a strong predicting factor for poor prognosis of stroke for a number of reasons: the same lesion might cause neurogenic bladder dysfunction (neurogenic UI), motor or cognitive impairment (functional UI), or both; falls, gait difficulty and cognitive decline are all marked in severe, bilateral brain lesions; finally UI may secondarily cause psychological depression and also generally interfere with rehabilitation and quality of life.

6.2. White matter lesions and urinary incontinence in the elderly

Urinary incontinence (UI) is a major concern in geriatric populations, which have grown rapidly in recent decades. In addition, the incidence of urinary frequency/urgency (OAB), with or without UI, is high in the general population over 40 years old and it increases significantly with age. It is widely acknowledged that urinary frequency and poor bladder control have a negative impact on the quality of life, that LUTD in elderly persons adds to their caregivers' burden, and that LUTD is an important factor leading to institutionalization. The mechanisms underlying OAB and UI in the frail elderly are multi-factorial; the factors may include age-related changes in the bladder itself or central nervous system changes innervating the bladder.

Atherosclerosis and subsequent ischemia of the bladder occurs in patients with pelvic peripheral vascular disease. Atherosclerosis is a systemic condition which also affects cerebral arteries supplying the brain. Cerebral white matter disease (WMD) is a common chronic bilateral ischemic brain disease in the elderly. WMD progresses insidiously, and the likelihood of WMD increases significantly with age, It has been proposed that WMD is the pathoanatomical substrate in the brain aetiology of OAB. Thus, it is proposed that WMD leads to three different geriatric syndromes; vascular dementia, vascular parkinsonism, and 'vascular incontinence' [234].

In relation to the cerebral vascular component in vascular incontinence, Sakakibara and colleagues [235] investigated 63 subjects (mean age 73 years) with varying degrees of cerebral WMD or leukoaraiosis. Magnetic resonance imaging (MRI)-defined WMD was graded on a scale of 0 to 4. The prevalence of nighttime urinary frequency in cases of grade 1 WMD was 60%; grade 2, 58%; grade 3, 93%; and grade 4, 91%, respectively, giving an overall prevalence of nighttime urinary frequency of around 75%, which was a more common and earlier feature than UI (40%). Of particular importance was the fact that OAB was not always accompanied by gait disorder or dementia **(**Grade 1 of WMD**)**, so that it appeared that OAB might be the first clinical manifestation of the observed WMD [235]. Detrusor overactivity (DO) is the major underlying urodynamic observation of vascular incontinence. The incidence of DO in WMD cases is reported as 70%–91% of patients. In Sakakibara's study [235], urodynamic studies were performed in 33 of the subjects. They found that subjects with grade 1–4 WMD had DO significantly more commonly (82%) than those with grade 0 WMD (9%). Post-micturition residuals, low compliance, DSD and uninhibited sphincter relaxation were also more common in grade 1–4 WMD than in grade 0 WMD, though not significantly so.

Population-based MRI studies suggest that the incidence of moderate WMD (periventricular WMD grade >4/9 and subcortical white matter volume >1.5 mL) is approx. 10% (7.6%–24%) in the general population of individuals over 55 years of age. WMD can develop into three different geriatric syndromes: [1] vascular dementia; [2] vascular parkinsonism; and [3] 'vascular incontinence' [235, 236]. These three syndromes can present in any combination, but clinically, urinary and gait disorders are more prominent than dementia, and usually precede dementia.

Two studies have shown significant relationship between OAB/UI with WMD [236, 237]. Tadic and Griffiths [236] studied 25 older women (age 71.5 + −7.5 years) with urgency UI, and they reported that brain responses to bladder filling during self-reported 'urgency' were most prominent in the frontal regions. Regional activations became more prominent with increased global WMD. Looking at the fiber tracts, the main effect activations and deactivations were superimposed with anterior thalamic radiation and superior longitudinal fasciculus. These results indicated that WMD, particularly the anterior portion, is clearly related to OAB in cognitively intact, elderly persons.

A survey was carried out to look at relationship between DO and higher brain function in 40 WMD patients with OAB (age 60–89 years) [43]. DO was independent of general cognitive status (the mean MMSE score or any of its subdomains). In contrast, the presence of DO was significantly associated with the inhibitory control subdomain in the FAB test. This finding is in agreement with the fact that brain perfusion is most severely reduced in the frontal lobe of subjects with WMD [238]. What exactly this finding means is a matter of debate. One explanation might be that the bladder is under general inhibitory control concerning decision-making [239] and emotion [240] by the prefrontal cortex. In patients with WMD, this neural network might be impaired, leading to both frontal cortex-related behaviour changes and DO.

Both age-related WMD (also called vascular dementia) and Alzheimer's disease (AD) are common causes of elderly dementia, and are known to be independent risks for OAB/UI. A survey was carried out among 49 mild/moderate dementia patients irrespective of OAB (mean age, 76 years), including AD alone in 9, AD+WMD in 15, and WMD alone in 25 [241]. OAB was most common in WMD alone. Therefore, WMD is a more significant contributor to OAB and UI than AD in elderly dementia patients. It should be mentioned that in WMD, LUTD occurs independently from dementia. The pathological mechanisms for LUTD in AD and WMD remain obscure. However, a single-photon emission computed tomography (SPECT) study showed that frontal hypoperfusion is common in WMD, whereas parietal-temporal hypoperfusion is common in AD [238]. This is in accordance with the finding that in AD, dementia is the predominating symptom, and early UI is extremely rare [242].

6.3. Management of LUTD in stroke patients

An approach for the care of patients with LUTD in brain diseases is applied as a general LUTD treatment regimen, which should depend on the pathophysiology and be individualized. As discussed above, UI in brain diseases can be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition). These two types of UI may occur together. However, management of two types of UI differs significantly. Management of neurogenic UI includes anticholinergic drugs to treat bladder directly, and management of functional UI includes behavioural therapy (timed/prompted voiding with physical assistance; bladder/pelvic floor training) and drugs to treat gait (Parkinson's disease drugs) as well as cognition (Alzheimer's disease drugs) that further facilitate continence.

In 2005, Thomas et al. [198] undertook meta-analysis of interventions aimed at reducing the occurrence of post-stroke UI. Seven trials with a total of 399 participants were included. Four trials tested an intervention against usual care, including acupuncture, timed voiding, and two types of specialist professional intervention. One cross-over trial tested an intervention (oestrogen) against placebo. One trial tested a combined intervention (sensory-motor biofeedback plus timed voiding) against a single component intervention (timed voiding alone). One trial tested a specific intervention (oxybutynin) against another intervention (timed voiding). The interpretation was that there was insufficient data. A review of behavioural therapies for post-stroke UI was done by Dumoulin et al. [243]. Tibaek et al. [244] reported on effectiveness of pelvic muscle training in 24 women with post-stroke UI (irrespective of type of UI) with a randomized, controlled and blinded study.

In contrast to the intervention of functional UI (due to immobility and loss of initiative/cognition), drug trials for OAB wet in patients with brain diseases are scarce. Propiverine, an anticholinergic, has been used to treat idiopathic as well as neurogenic DO including brain diseases [245]. Sakakibara et al. [246] used an anticholinergic drug imidafenacin in 62 OAB patients following brain diseases, including 29 with WMD. They found an improvement of OAB after 0.2 mg/day imidafenacin, without cognitive decline. Another study used tolterodine in 13 OAB patients following brain diseases, including five with WMD, showing an improvement of OAB with 4mg/ day tolterodine [247]. The addition of propiverine (a peripheral anticholinergic) to donepezil (a central acetylcholinesterase inhibitor) ameliorates OAB without worsening cognitive function in elderly OAB patients with dementia [248]. Mirabegron, a novel selective adrenergic beta-3 receptor agonist, seems to be promising for lessening DO, with fewer central side effects [249].

For ameliorating post-stroke UI, alternative/ complementary therapies have also been studied. Electro-

acupuncture showed an improvement together with a bladder capacity increase in post-stroke patients [250]. Electro-acupuncture is also used to treat incomplete bladder emptying after stroke [251].

Newer modalities such as botulinum toxin have been applied to post stroke UI. Kuo [252] applied 200U suburothelial injection of botulinum-A toxin in 24 patients with DO due to stroke in 12 and suprasacral spinal cord diseases in 12. He found 91.6% achievement of continence in spinal cord diseases but 50% achievement in stroke.

Transcranial magnetic stimulation at the motor area or the prefrontal cortex was able to lessen DO in multiple sclerosis [253] and Parkinson's disease [254]. In stroke, no similar studies are available.

Conclusions

- Incidence of lower urinary tract dysfunction (LUTD) in stroke patients ranges from 14-53%, principally due to overactive bladder (OAB), being higher when involving the frontal cortex (LOE3).
- White matter disease (WMD) is a chronic, bilateral form of cerebrovascular disease, leading to the high prevalence of OAB (LOE3).
- Since WMD is common particularly in elderly, WMD might be one of anatomical substrates for elderly OAB. (LOE4)
- Neuroimaging studies have shown relationship between LUTD and the frontal cortex in stroke and WMD that regulate the micturition reflex.
- Data on other brain diseases, particularly affecting deep brain structures, are limited. A small infarct affecting the brainstem leads to either OAB or urinary retention. (LOE4)
- Neuroimaging studies have shown relationship between LUTD and the periaqueductal gray and the pontine micturition center that directly relay and modulate the micturition reflex.
- Urinary incontinence (UI) in stroke/WMD can be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition). These two types of UI may occur together, but management differs substantially. (LOE3).
- Management of neurogenic UI/OAB includes anticholinergic drugs that do not penetrate the blood-brain barrier easily or beta 3 adrenergic agonists (LOE3).
- Management of functional UI includes behavioural therapy (timed/prompted voiding with physical assistance; bladder/pelvic floor training) and drugs to treat gait as well as cognition that facilitate continence (LOE4), in order to maximize the quality of life in stroke patients.

Recommendations

- Urinary incontinence (UI) in stroke/WMD should be divided into two types: neurogenic UI (OAB wet) and functional UI (immobility and loss of initiative/cognition) (A).
- Neurogenic UI/OAB needs anticholinergic drugs that do not penetrate the blood-brain barrier easily. (B).
- Functional UI needs behavioural therapy (A).

7. MENINGITIS-RETENTION SYNDROME

Meningitis retention syndrome (MRS) is one of the diseases that could cause a relatively uncommon urinary retention in childhood, young adults, and in women [255]. Spina bifida occulta/ tethered cord syndrome is one such disorder known to lead to urinary retention without marked neurological abnormalities, except for saddle anaesthesia. Fowler's syndrome is another disorder that causes urinary retention, particularly in neurologically-intact young women, and isolated urethral sphincter hypertonicity underlies this condition. Benign inflammatory nervous diseases also cause acute urinary retention, in which patients lack apparent urethral outlet obstruction, but exhibit only minor neurological as well as cerebrospinal fluid (CSF) abnormalities. Based on the mechanism of urinary retention, these disorders can be divided into two subgroups: disorder of the peripheral nervous system (PNS) (e.g. sacral herpes, with unilateral sacral pain, sensory signs and often skin rashes in the same area); and disorder of the central nervous system (CNS) (e.g. meningitis-retention syndrome), with fever, headache, stiff neck, and minor pyramidal signs). Previously the latter condition has been only occasionally reported, but now it is recognized as a specific category [256, 257], which is considered to be a very mild form of acute disseminated encephalomyelopathy (ADEM). True prevalence of MRS has not been fully investigated due to the rarity of the condition.

It is postulated that ADEM appears after vaccination or after exanthematous infections, and serological and pathological studies have suggested that ADEM is of parainfectious/ autoimmune origin [258]. Antecedent/ comorbid infections are diverse, e.g. human herpes virus 6 [259]. A combination of signs of encephalitis (e.g. disturbance of consciousness, epilepsy, and hemiparesis), signs of myelitis (e.g., sensory disturbance below the level of the lesion, spastic paraplegia, whereby flaccid parapalegia may occur in the initial shock stage), and lower urinary tract (LUT) / bowel dysfunction typically occur in patients with ADEM. Lesions observed in brain MRI are usually confined to the white matter. Lesions in the spinal

cord involving the conus are also seen. CSF pleocytosis, increased protein, mildly decreased glucose content, increased myelin basic protein (MBP)/oligoclonal bands, and a lack of increased viral titres, are all features of this disease.

Patients with ADEM commonly exhibit LUT dysfunction [260, 261], which varies from urinary retention to urgency incontinence. LUT dysfunction appears to be related to pyramidal tract involvement, and most probably reflects the severity of the spinal cord lesion. Urodynamic findings have included detrusor overactivity in the storage phase, brisk bulbocavernosus reflex, and DSD (reflective of a suprasacral spinal cord lesion); detrusor areflexia in the voiding phase (reflective of either acute spinal shock or conus lesion); and neurogenic sphincter EMG in one of four patients studied (reflective of a conus lesion). The responsible lesion sites in cases of LUT dysfunction have appeared to be the cervico-thoracic spinal cord, and, to a lesser extent, the conus [262] and possibly the spinal nerve roots in patients with ADEM. In addition, cases of ADEM presented with LUT dysfunction as the only remaining consequence of the disease, thus suggesting that LUT innervation was selectively vulnerable in these cases. It is also reported that cases of ADEM/ parainfectious myelitis initially presented with urinary retention [263] or leaves urinary retention as the sole sequel [264].

Although aseptic meningitis is a common neurological disorder, a combination of aseptic meningitis and acute urinary retention (MRS) has not been previously well recognized. The clinical manifestations of Sakakibara's three cases [256] are mostly the same as those of the six reported cases in the literature (including cases written in Japanese). The clinical manifestations of MRS cases differ markedly from those of ADEM, because, other than presenting with aseptic meningitis, MRS cases lack the following: apparent encephalitic signs such as disturbance of consciousness, epilepsy or aphasia; and myelitic signs such as gait abnormalities, or sensory-level abnormalities. Whereas brain and spinal cord lesions typically appear in ADEM, such change is not observed in MRS. However, a reversible splenial lesion was noted in the brain MRI of a patient with MRS [265].

7.1. Disease specific diagnosis

Cerebrospinal Fluid (CSF) examination showed a mononuclear pleocytosis of 38-370 /mm3, normal to increased protein content (up to 260 mg/dl), and normal to mildly decreased glucose content (up to 33% of that in the serum). All viral titres studied in the CSF and the serum of such cases were negative. Nevertheless, it appears likely that the urinary retention in such patients is of neurologic aetiology, since none of the patients appear to exhibit urologic abnormalities such as prostatic hyperplasia, and also because a strong chronological association is observed between the onset of urinary retention with, or just after, the occurrence of the aseptic meningitis. As it is observed in ADEM, antecedent/ comorbid infections or conditions with MRS include angiostrongylus cantonensis [266], Epstein Barr virus [267], and herbal medicine use [268], whereas such antecedent influences are not apparent in the remaining cases [269].

Urodynamic study results have shown that all patients examined had detrusor areflexia, which results in an inability to contract the bladder on voiding, and some patients had an unrelaxing sphincter. Detrusor areflexia originates from various lesion sites along the neural axis; most commonly, peripheral lesions are observed. However, CNS lesions that affect the spinal cord or the brain can also cause detrusor areflexia, which is particularly seen in the acute shock phase of patients with transverse myelitis (often immune-mediated) or ADEM. A case report described repeated urodynamic studies in one patient, in which an initially areflexic detrusor became overactive after a 4-month period, suggesting an upper motor neuron bladder dysfunction [270]. As described above, encephalitic features are absent in patients with MRS. However, three MRS patients (including Sakakibara's cases 1 and 3) showed the brisk lower extremity reflexes suggestive of mild myelitis. In one of Sakakibara's cases, MBP was increased, which is suggestive of CNS demyelination. Therefore, it appears possible that MRS is a very mild variant of ADEM, which selectively affects LUT innervation.

Arriving at a diagnosis is easy when a combination of aseptic meningitis and acute urinary retention is confirmed, although such a diagnosis should be made both urologically and neurologically, in order to exclude sacral herpes, a benign variant of Guillain-Barre syndrome (inflammatory radiculitis), typical ADEM, myelitis with leg weakness [271], herpetic brainstem encephalitis, chemical meningitis, focal subarachnoid bleeding, and other common causes of neurogenic urinary retention (e.g. diabetic neuropathy, lumbar spondylosis, etc.). For the differential diagnosis, detailed history, brain/spinal MRI and nerve conduction study are necessary.

The term "Elsberg syndrome" has been occasionally used, which is rather vaguely assigned to sacral myeloradiculitis of undetermined aetiology, sacral herpes, sacral vasculitic neuropathy, possible MRS, possible ADEM, or conus infarction. However, in contrast to the majority of "Elsberg syndrome" cases, Kennedy, Elsberg, and Lambert (1913) reported five cases of pathology-demonstrated cauda equina radiculitis. Clinical pictures of these cases were characterized by rare CSF abnormalities (only one of the four cases described showed an increased cell count as well as increased protein levels); no clinical meningitis; subacute/chronic course (in one case the course of disease was subacute: 3 months, but in the remaining four cases, the course of disease was chronic: 4.5-36 months); the patients presented with typical cauda equina motor-sensory-autonomic syndrome (in particular, four of the patients had apparent muscle atrophy/weakness in the lumbosacral segment); Wallerian degeneration of the spinal afferent

tracts; and mild upper motor neuron signs. The authors assumed that the aetiology of these cases was either inflammatory or toxic. The exact cause of these five cases remains uncertain, although clinical pictures of these cases resemble, at least in part, those of paraneoplastic or autoimmune lumbosacral radiculoplexus neuropathy [272]. Clinical features of sacral herpes or MRS differ markedly from those of Kennedy's cases.

7.2. Disease specific management

Since MRS has a benign and self-remitting course (i.e., a duration of 2-10 weeks), the effectiveness of immune treatments (e.g., steroid pulse therapy) remains unclear, although such treatments may shorten the duration of the disease. Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension (LOE4).

Since MRS is rare, true prevalence has not been fully investigated and evaluation of this is warranted in future research. Similarly, in order to shorten the urinary retention period, the effectiveness of immune treatments (e.g. steroid pulse therapy) in MRS remains unclear, and future research is desirable.

Conclusions

- Meningitis-retention syndrome, with fever, headache, stiff neck, and minor pyramidal signs, is thought to be a very mild form of acute disseminated encephalomyelopathy (ADEM) encountered by both urologists and neurologists (LOE 2)
- Initially the bladder is areflexic, but soon becomes normal or overactive during the course of the disorder. (LOE 2)

Recommendation

- Management of the acute urinary retention is necessary to avoid bladder injury due to overdistension in patients with MRS (B)

8. ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Acute disseminated encephalomyelitis (ADEM), also known as post-infectious encephalomyelitis, is a demyelinating central nervous system (CNS) disorder that usually follows infection, or more rarely vaccination [273]. ADEM can be confused for MS; indeed, the early symptoms of ADEM are similar to an acute relapse of MS. Presence of constitutional symptoms such as fever and headache, and the simultaneous involvement of various parts of the CNS may help differentiate this condition from MS. However, it can be difficult to distinguish the two, and the only sure way is follow up and the observation of any relapses over time.

ADEM is a disease that is characterized by an inflammatory reaction and demyelination in the brain and spinal cord. In contrast to MS, there is a tendency for perivenous localization of pathological changes [274]. Bladder dysfunction is common in ADEM. In a consecutive series of sixty one patients with ADEM, 20 (33%) had evidence of LUTD [261].

Lesions in the cerebral and spinal cord white matter result in LUTD. Both voiding and storage symptoms are reported in ADEM, however the pattern of bladder dysfunction depends upon the time point at which they are assessed. In the acute stage, Panicker et al. reported that voiding dysfunction is more common; in their series of 20 patients, 16 were in urinary retention [261]. Urodynamics demonstrated detrusor overactivity in four patients and underactivity in four patients. Incontinence was reported more often in patients with frontoparietal white matter changes in MR imaging (LOE 3/ 4). In the series of Sakakibara et al., patients were followed up for 3 to 38 months, and seven of nine patients with retention were able to pass urine once again, five had difficulty in voiding and four developed urinary frequency or urgency incontinence. Motor unit analysis of the external sphincter revealed polyphasic neurogenic changes in only one of four patients. They also observed that bladder disturbances in ADEM seemed to be as common and severe as in MS [260] (LOE 3/ 4). LUTD is common especially in patients with lower limb pyramidal involvement [261].

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of ADEM. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction often recovers. If suitable, IC could be considered. Patients with overactive bladder symptoms are likely to benefit from an anti-muscarinic medication, once it is confirmed they are not retaining urine.

For future research, there are currently only limited studies evaluating the natural history of LUTD in ADEM and patients should be followed up to assess lower and upper urinary tract changes with time. There is a dearth of information about the role of botulinum toxin or sacral neuromodulation in this condition.

Conclusions

- In the acute phase of ADEM, LUTS may be seen in a third of patients (LOE3/4).
- Both voiding and storage dysfunction are observed in ADEM (LOE3/4).
- Recovery of LUT functions occurs, along with the recovery of motor weakness (LOE3/4).

Recommendations

- Patients with ADEM and bladder symptoms should be managed according to their symptoms, and the findings on urodynamic tests, particularly post-void residual (C).
- LUTS can change as the disease stabilises; re-evaluation during follow-up is therefore recommended (C).
- Patients with overactive bladder symptoms are likely to benefit from antimuscarinic pharmacotherapy, once they are shown not to be retaining urine.

9. SPINAL CANAL STENOSIS

It is not uncommon to develop pelvic floor dysfunction including urinary symptoms in patients with spinal canal stenosis (SCS). It is thought about half of the patients with intractable leg pain in spinal canal stenosis will have urinary difficulty with high post-void residual (PVR) and reduced flow rate and/or incontinence indicating effects on the cauda equina. Such symptoms, including urinary incontinence usually improve after surgical decompression.

One third of patients with achondroplasia developed SCS [275], especially at the lumbar level, and 77% of these had urinary incontinence. According to Johnsson and Sass [276] in the County of South Jutland, Denmark during a 5-year period (1996-2000), the annual incidence of SCS was 272 per million inhabitants. Of 340 cases diagnosed with SCS during that period, only one patient presented with acute cauda equina syndrome. This was a 74-year-old woman with SCS from L2 to L4, who presented with urinary retention and faecal incontinence (FI) for the preceding 24 hours; after urgent surgery she recovered from her anal sphincter paresis within 5 days and from her bladder paresis within 5 weeks.

Goh and colleagues [277] carried out a comprehensive retrospective review of the clinical features, radiological changes and outcome of 75 patients with radiologically diagnosed lumbar SCS; imaging of the lumbar spine showed that moderate to severe central spinal stenosis correlated with complaints of weakness and abnormal motor power on clinical examination. The commonest symptom was numbness or tingling of the legs. According to the study of Inui[4] 58.8% of the 34 patients were diagnosed with neuropathic bladder; however there was no difference in the cross-sectional area of dural sac between those with and without neurogenic bladder dysfunction in patients with lumbar SCS. Nonetheless, the anteroposterior diameter of the dura was shorter in those with bladder dysfunction, and a critical size for the dural sac of patients was reported as 8 mm.

Usually signs and symptoms of compressive neuropathy of multiple lumbar and sacral roots is an indication for surgical intervention, but relatively unknown as a post-operative complication [278]. Four years after diagnosis, 65% had undergone surgical decompression; a third of patients felt that their symptoms had improved while a quarter felt that they had worsened. Imran and Halim [279] reported a 63-year-old man who developed acute cauda equina syndrome due to fat graft compression after decompressive laminectomy, posterior instrumented fusion with pedicle screw fixation for spinal stenosis of L5 and S1 vertebral levels and free fat grafting to cover the exposed dura; three days postoperatively, gradual neurological deficit started with sensory loss and weakness of the affected dermatomes and myotomes followed by FI on the 12th postoperative day; and immediate removal of the fat graft resulted in recovery from cauda equina syndrome. Another case was reported by Tubbs [280]; a Caucasian girl who had idiopathic growth hormone deficiency and Klippel-Feil and Duane's syndromes with symptomatic stenosis of the first cervical vertebrae presented with episodes of loss of tone with subsequent falling, facial cyanosis, UI, hand weakness, and difficulties with swallowing; following suboccipital craniectomy and the removal of the posterior arch of the atlas, her symptoms were resolved and UI improved.

9.1. Disease specific diagnosis

To demonstrate narrowing of the lumbar canal with compression of the cauda equina, CT or MRI is often recommended, to reveal either bony or soft tissue compression [281]. Miyata and colleagues [282] studied the relationship between bladder function and roentgenographic changes in the spinal canals of ossification of posterior longitudinal ligament (OPLL) patients. CO_2-filling cystometry, uroflowmetry and PVR were measured and the vertical extent of OPLL and the degree of SCS was estimated by X-ray films and CT. The occurrence of abnormal detrusor activity had no relationship to the degree of canal stenosis, while the occurrence of an areflexic or underactive detrusor correlated with the vertical extent of OPLL . Yamanishi et al. [283] found DO in 14 lumbar canal stenosis patients (29%) and most of them had voiding symptoms and had storage symptoms which seemed to be caused by the irritation of sacral roots.

9.2. Disease specific management

Of 10 patients followed up after surgical decompression, DO disappeared in 5 patients, improved in 1 patient and remained unchanged in 4 patients [283]. Lee and colleagues [284] did an expansive cervical laminoplasty in patients with non-traumatic cervical spondylosis with myelopathy and found that age greater than 60 years at the time of presentation, duration of symptoms more than 18 months prior to surgery, preoperative bowel or bladder dysfunction, and lower-extremity dysfunction were associated with poorer surgical outcome.

Conclusions

- Patients with spinal stenosis, especially at lumbar levels, may present with bladder and bowel involvement – urinary retention/ incontinence and faecal incontinence (LOE 3/4)
- Lumbar canal stenosis may cause either detrusor underactivity/acontractility or overactivity (LOE 3)
- Imaging helps diagnose spinal stenosis, while urodynamic study categorises neurogenic bladder dysfunction (LOE 3/4)
- Acute symptoms of incontinence or urinary retention may recover after decompression of spinal stenosis (LOE 3/4)

Recommendations

- Surgical decompression is recommended in patients with spinal stenosis having acute symptoms of urinary retention/incontinence and faecal incontinence (A)

10. CAUDA EQUINA SYNDROME

There can be some confusion related to this syndrome. An anatomical discrepency lies in the fact that the vertebrae and the nerve roots do not correspond all the way down to sacrum. The spinal cord terminates at the level of L1 vertebrae and there is thick column of nevres below this level resembling a horse tail, hence the term “cauda equina” has been coined to describe this arrangement. Damage to these nerve roots produces a characteristic pattern of symptoms called the cauda equina syndrome, which can entail pelvic floor dysfunction in all 3 compartments (including bladder, bowel, sexual abnormalities).

Central lumbar disc prolapse compresses sacral nerve fibers to and from the bladder, the large bowel, the anal and urethral sphincters, and the pelvic floor. Cauda equina syndrome due to central lumbar disc prolapse is relatively rare, the incidence being from 1 to 5% of all prolapsed lumbar disc [285-287]. An annual incidence of 3.4 per million and a prevalence of 8.9 per 100,000 population has been reported. It has been suggested that damage to cauda equina is more common in middle aged men whilst in younger patients it was the conus lesion that was more prevalent [288].

The common causes of cauda equina syndrome are summarised in **Table 15** (below). It is thought that spinal fracture in young men, disc herniations in middle aged and spinal operations in elderly are the main factors leading to cauda equina syndrome (CES) [288].

Table 15. Causes for cauda equina syndrome

Compressive	Noncompressive
Central prolapsed intervertebral disc* Trauma- vertebral fracture* Tumour- primary, metastatic Spinal canal stenosis Pott’s disease- tuberculosis Abscess	Ischemia- spinal AV malformation causing steal syndrome Iatrogenic- spinal surgery* Following spinal anaesthesia- rare* Inflammation

Can present acutely

10.1. Pathology and disease specific LUT problems

There can be a diverse presentation of CES. This includes low-back pain, bilateral sciatica, saddle anaesthesia, and urinary retention, loss of urethral sensation as well as constipation and erectile dysfunction [286, 289]. Those patients with cauda equina syndrome usually have some sensory disturbance in the sacral dermatomes. A retrospective cohort study with prospective clinical follow-up showed that bowel dysfunction at presentation was associated with sexual problems at follow-up [290].

The most common urinary symptom associated with lumbar disc prolapse is acute urinary retention [291]. At the onset, acontractile detrusor with impaired bladder sensation is a typical urodynamic finding [291, 292]. Severe denervation of pelvic floor [291] and external urethral sphincter is also frequently demonstrated. Detrusor overactivity may occur [283, 291]. Urinary disorders usually follow or accompany more obvious neurologic symptoms, such as lumbar pain and perineal sensory disturbances that prompt the appropriate diagnosis. However, sometimes voiding disturbances may be the only or the first symptom of this condition, which makes it more difficult to diagnose. There can be associated bowel disturbances that might be either constipation or faecal incontinence [288].

The presence of sexual dysfunction can be particularly disabling. There is impairment of sexual sensations and this is associated with erectile dysfunction. However, a combination of these two leads to orgasmic dysfunction which becomes the most bothersome symptom in this group of patients [293].

10.2. Disease specific diagnosis

There should be a high index of suspicion in patients who present with the features described above. The presentation can be either in an acute or chronic setting. The acute symptoms manifest generally after disc herniation or post surgery. The classical presentation includes severe sudden bilateral back pain radiating down both lower limbs with numbness and tingling in saddle region and loss of bladder function. However, only a fifth of patients present with these

classical symptoms [294], as in the majority low back pain, sacral sensory loss and some urinary symptoms are more prevalent. Similar to acute presentation, the symptoms are the same in chronic presentation, though the onset is more insidious.

All patients should undergo a detailed neuro-urologic examination. This includes assessment of sensory, motor and reflexes of lower limbs and anal reflexes [288, 295]. There should be an assessment of post void residual. An urgent MRI assessment is recommended in all patients who present with new onset urinary symptoms concomitantly with lumbar back pain or sciatica, because it is impossible in a significant proportion of patients to exclude the diagnosis of prolapsed intervertebral disc in the context of referral with suspected cauda equina syndrome.

In chronic setting the same investigations are required, though probably not with the same urgency. There might be a need to undertake electrophysiological studies to confirm the diagnosis. Additionally urodynamics and anal manometry might be required to establish the bladder and bowel dysfunction respectively [296].

10.3. Disease specific management

Emergency surgical decompression has been reported to increase the chance of satisfactory neurological recovery in patients with cauda equina syndrome due to central lumbar disc prolapse [297-299]. In a meta-analysis of surgical outcomes, a significant improvement in sensory and motor deficits as well as urinary and rectal function occurred in patients who underwent the surgery within 48 hours, compared with those who had the surgery more than 48 hours after the onset of the cauda equina syndrome [299]. Although there is still a controversy [290], most other reports support the concept that decompression performed within 48 hours of onset of this syndrome resulted in improved functional outcomes [287, 300]. However, acontractile detrusor is usually irreversible, even after immediate decompression [301, 302], although many patients can empty their bladder postoperatively, this may achieved only by straining or changing voiding postures [302]. In contrast to bladder dysfunction, urethral function shows a better recovery after surgery [303].

The management of pelvic floor dysfunction in an established CES patient requires careful support. The patient needs to start self-catheterization if there is significant residual urine. The patient should be encouraged to relax to pass urine and avoid straining. They need to be monitored with urodynamics owing to the unpredictable nature of recovery [304]. Similar to bladder, the bowel management needs to be optimised according to the individual patient dysfunction. The constipation is relatively easier to control compared to faecal incontinence [296]. The erectile dysfunction can be treated with oral medications but there is no specific treatment available for sensory impairment.

The patients could be put in touch with support groups like www.caudaequina.org

10.4. Research for Cauda Equina Syndrome

For future research, good epidemiological studies on the occurrence of pelvic floor dysfunction are needed. This is increasingly relevant with the advent of new, minimally invasive treatment options for disc prolapse.

Conclusions

- Cauda equina syndrome is a relatively rare complication of lumbar disc prolapse (LOE 3)
- Bladder and bowel manifestations of lumbar disc prolapse include: urinary retention, loss of sensory functions, decreased sexual functions (LOE 3)

Recommendations

- Emergency surgical decompression is the treatment of choice: the optimum timing is considered to be within 48 hours (Grade B/C)
- Full recovery of lower urinary tract functions, including bladder contractility, is unreliable (Grade C)

11. TRANSVERSE MYELITIS

This is a clinical syndrome characterized by an immune mediated process leading to neural injury in the spinal cord. There can be a varied presentation with weakness, sensor alterations and autonomic dysfunction. It can also present as part of a multifocal disease of nervous system. Transverse Myelitis (TM) is reported to have an incidence of 1-4 new cases per million, with bimodal peaks between the ages of 10 and 19 years and 30 and 39 years. There is no sex or familial predisposition.

TM is commonly parainfectious. It can occur in connective tissue diseases, infective myelitis, and idiopathic inflammatory demyelinating disorders including MS. It is thought that only true spinal inflammatory processes should be designated myelitis. Myelitis may selectively affect different parts of the nervous system. The inflammatory distribution is termed poliomyelitis when it is confined to the gray matter and leukomyelitis if it affects the white matter. When the entire thickness of the spinal cord is involved, it is called TM. TM can clinically be divided into acute or subacute depending upon the speed of onset of symptoms and signs. These can affect any of the motor, sensory or autonomic nerves. As a general rule there is well defined upper border of sensory dysfunction.

Lumbar puncture and spinal MRI will usually show signs of acute inflammation. At the height of inflammatory condition about half of patients lose all movements of their legs with almost all having bladder dysfunction. The bladder symptoms are generally a combination of storage and voiding with urgency, difficulty to empty. Additionally, there can be associated bowel dysfunction. The Transverse Myelitis Consortium Working Group has proposed diagnostic criteria looking at motor, sensory, and autonomic dysfunction [305]. The diagnostic criteria include presence of symptoms attributable to spinal cord inflammation, a defined sensory level, and presence of immunoglobulin G with progression to nadir between 4 hours and 21 days. They also proposed a set of exclusion criteria including a history of previous radiation, and abnormal arterial flow patterns of imaging suggestive of another neurologic disease.

TM can present with a diverse array of clinical neurological manifestations. Bladder dysfunction is common and may be the only consequence of TM. Ganesan and Borzyskowski [306] described urinary tract dysfunction after TM in 10 children, with ages ranging from 8 months to 16 years. Nine of 10 children had voiding symptoms and all developed storage symptoms within a month of presentation. Videourodynamics showed a combination of detrusor overactivity and detrusor sphincter dyssynergia (DSD) in most patients. With a median follow-up of 36 months, all had residual bladder dysfunction, with only four being asymptomatic. The degree of bladder recovery was not related to the motor recovery.

In another study Cheng et al. [307] reviewed the long-term urological outcome of 5 children with TM over 15 years. The median length of follow-up was 5 years (2–10 years). Four children recovered completely from paresis; two had no urinary symptoms with normal voiding. However, follow-up urodynamics 3 years later revealed that four out of the five children, including one without any urinary symptom, had residual bladder dysfunction.

Leroy-Malherbe and colleagues [308] studied 21 children at the mean age of 8 years. Bladder dysfunction was present in 85% at presentation. Complete regressive course was noted in 38% of patients, minor sequelae in 39%, and major sequelae after 6 months in 23%. No upper tract deterioration was noted after 3 years. Factors of favourable prognosis were early motor function recovery and early management of bladder dysfunction

Kalita et al. [309] evaluated voiding abnormalities in TM and correlated these with evoked potentials, MRI, and urodynamic findings. Patients with TM had a neurological examination and tibial somatosensory evoked potential (SSEP) and motor evoked potential studies in the lower limbs. Urodynamic studies showed an acontractile or hypocontractile bladder in 10, detrusor overactivity with poor compliance in two, and DSD in three. Persistent abnormalities included detrusor overactivity, dyssynergia, and acontractile bladder. The urodynamic abnormalities correlated with muscle tone and reflex changes but not with sensory or motor evoked potentials or MRI signal changes.

Sakakibara et al. [310] reported 10 patients with TM. Seven patients had urinary retention and three patients had voiding difficulties within 1 month after the onset of the disease. At 40 months of mean follow-up 9 still had mixed urinary symptoms.

Berger et al. [311] found abnormal detrusor function in all six patients with TM. Computerized tomography scans and myelograms were inconclusive and CSF studies were normal. On recovery the functional outcomes were uniformly good. Bladder abnormalities persisted despite motor recovery. Urodynamic studies revealed DSD in six patients with 2 revealing detrusor overactivity. Sexual dysfunction was reported by 3 men. The authors concluded that prolonged bladder and sexual dysfunction may persist despite a systemic neurological recovery. They recommend urodynamics for initial and follow-up management.

The clinical manifestations of TM is described as a dysfunction of motor, sensory, and autonomic pathways [312]. At maximum deficit, 50% of patients had completely paraplegia with almost all having some degree of bladder dysfunction.

11.1. Treatment of bladder dysfunction in TM

The management of bladder dysfunction is tailored to the abnormality present. The detrusor overactivity and DSD is treated with a combination of antimuscuranics and self catheterization. Persistent overactivity can be controlled with Botulinum toxin A. Monitoring should be undertaken with urodynamics and the management adjusted accordingly.

In longitudinal case series, broadly one-third of patients recovered with little or no long-term sequelae, one-third are left with moderate degree of permanent disability, and one-third has severe disabilities. The predictor of poor outcome is thought to be rapid progression of symptoms, back pain and spinal shock. In a follow-up study Bourre [313, 314] reported on 85 cases to evaluate the rate of conversion to MS as well as predictive factors of long-term disability during a mean follow-up of 8.7 years. They confirmed that presence of oligoclonal bands in the CSF and brain MRI abnormalities increases the risk for conversion to MS. Long-term follow-up of urological function is recommended for all patients with TM.

Conclusions

- Transverse myelitis is an immune mediated process leading to neural injury in spinal cord
- There can be a varied presentation, with weakness, sensor alterations and autonomic dysfunction (LOE 2). It can also present as part of a multifocal disease of nervous system (LOE 2)

- Uniform diagnostic criteria looking at motor, sensory, and autonomic dysfunction have been proposed (LOE 4)
- Presence of defined sensory level and immunoglobulin G with progression to nadir between 4 hours and 21 days is included in the diagnostic criteria (LOE 4)
- Bladder dysfunction is common and may be the only consequence of TM (LOE 2)
- At maximum deficit 50% of patients were completely paraplegic, with almost all having some degree of bladder dysfunction (LOE 3)
- The management of bladder dysfunction is tailored to the abnormality present (LOE 2)

Recommendations

- Uniform diagnostic criteria looking at motor, sensory, and autonomic dysfunction should be used (GR 3)
- The management of bladder dysfunction should be tailored to the abnormality present (GR 2)
- Long-term follow-up of urological function is recommended for all patients with TM (GR 3)

12. NEUROPATHIES AND MUSCLE DISORDERS

12.1. Guillain Barre syndrome

Since the eradication of poliomyelitis, Guillain-Barré syndrome (GBS) has become the most common cause for acute, flaccid paralytic disease in many parts of the world [315]. It presents as a rapidly progressing ascending areflexic motor paralysis, with or without sensory and autonomic dysfunction. Following an initial acute progressive phase, which by definition reaches a nadir within four weeks, there is a plateau phase and finally a recovery phase. Symmetrical limb weakness is the common presentation, however there may be in addition cranial nerve and respiratory muscle weakness. The disorder affects children and adults of all ages and both sexes. GBS is amenable to treatment with intravenous immunoglobulin or plasma exchange. However despite this, 4% to 15% of patients die from this syndrome, most often due to cardiovascular autonomic disturbances, respiratory compromise or aspiration. Nearly 20% have persistent disability [316].

Autonomic dysfunction is a frequently-overlooked complication. Cardiovascular autonomic dysfunction is recognized in up to 60% of GBS patients [317]. However, bladder and bowel dysfunction occurs much less often. Indeed, the presence of bladder or bowel symptoms at the onset of disease, or their persistence, casts doubt on the diagnosis, so that other conditions, such as spinal cord disease, need to be excluded. During the acute phase, it is often difficult to assess LUTD specifically due to neurological dysfunction. Patients are often catheterized as part of their general nursing care to monitor water balance or maintain hygiene [316]. Furthermore, patients may be on medications such as opiates and tricyclic antidepressants, which in themselves can affect bladder and bowel functions. In the largest study to date, Sakakibara et al. [318] studied 65 patients with definite GBS (meeting clinical and neurophysiological criteria) and LUTD was observed in 27.7% (LOE3/4). This figure is similar to that quoted by Guillain and others in the early papers [319]. The condition is characteristically a symmetrical radiculo-neuropathy predominantly due to demyelination (Acute Inflammatory Demyelinating Polyradiculoneuropathy, AIDP), but also there are subtypes where axonal damage prevails (Acute Motor Axonal Neuropathy, AMAN). There is a dearth of systematic studies evaluating LUTD in GBS. In a few reports [320, 321], detrusor areflexia and disturbed bladder sensation were the common findings, and a non-relaxing urethral sphincter was also seen (LOE3/4). In the study by Sakakibara et al. [318], patients most commonly reported voiding symptoms in 24.6%, including urinary retention in 9.2%. Storage symptoms were noted in 7.7%, urinary urgency in 7.7%. None of the patients in this study became incontinent. Urinary dysfunction was more common in AIDP (39%) than AMAN (19%), although the prevalence of urinary retention was almost the same (AIDP, 7%; AMAN, 11%). Factors that were associated with bladder symptoms included age, severity of motor weakness (Hughes motor grade) and concurrent bowel dysfunction. When patients were followed up, improvement in bladder symptoms paralleled improvement in motor weakness. Interestingly, there was no correlation between the presence of cardiovascular autonomic dysfunction and bladder dysfunction.

Urodynamic studies performed within eight weeks of disease (n=9) showed variable results, demonstrating detrusor underactivity (n=2), DO (n=3), both DO and underactivity (n=5) and non relaxing urethral sphincter (n=2). Three patients had an elevated post void residual and one patient had reduced bladder sensations [318] (LOE3/4). Their results were similar to the urodynamic findings from Gabavac et al. [321](LOE3/4).

Urinary dysfunction in patients with GBS tends to appear after the onset of motor weakness However, in two patients with axonal GBS, it was reported that voiding difficulty and motor weakness appeared almost simultaneously [322, 323] (LOE3/4). A close relationship between severity of GBS and bladder dysfunction has been reported (LOE3/4). Lichtenfeld [324] (LOE3/4) has reported urinary retention in one-third of patients requiring ventilator assistance. Even though up to 11% of GBS patients may develop urinary retention at the peak of motor weakness, it will

most often improve along with other neurological signs after supportive patient management, with or without immunomodulation. However bladder dysfunction can persist, and it is reported that urinary retention failed to recover for 10 months, even after a patient (with axonal GBS) regained the ability to walk [323] (LOE3/4).

GBS primarily affects the large myelinated fibers, but pathological studies have demonstrated moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord [315]. It has been postulated that LUTD in GBS may be arising from inflammatory or immunologically mediated damage of of the autonomic fibres of the lumbosacral nerves [315] (LOE3/4). Contrast magnetic resonance imaging (MRI) has demonstrated enhancement of the nerve roots of the cauda equina in GBS [325] (LOE3/4). The possible mechanism for DO might be abnormal spontaneous depolarisations in demyelinated nerve fibres, and impairment of inhibitory spinal cord interneurons, both of which can result in lumbosacral autonomic hyperactivity [326] (LOE3/4).

12.2. Treatment of bladder dysfunction after GBS

Management of LUTS is essentially supportive. Patients complaining of LUTS should have their post-void residual checked regularly during the progressive phase of the disease. If retaining urine, an indwelling catheter may be preferable during the acute phase. The need for catheterisation should be reviewed regularly as voiding dysfunction can recover in parallel to recovery of motor weakness, but in some cases this might be delayed. If suitable, IC should be considered. Wosnitzer et al. reported a successful case of sacral neuromodulation for urinary retention that persisted 18 months after GBS [327] (LOE3/4). Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic medication once it is shown they are not retaining urine. Of specific consideration to GBS is the side effect of tachycardia, as many patients may have concomitant cardiovascular autonomic dysfunction.

Follow-up and further research

There are only limited studies evaluating the natural history of LUTD in GBS and long-term follow-up studies of patients are required. Studies evaluating the correlation between LUTD and other evidence for autonomic dysfunction (such as cardiovascular autonomic dysfunction) should be specifically evaluated.

Conclusions

- In the acute phase of GBS, about 25% of patients demonstrate LUT functional problems (LOE3/4).
- Both voiding and storage dysfunction are observed in GBS (LOE3/4).
- Recovery of LUT function occurs along with the recovery of motor weakness. However, in rare cases it might take months (LOE3/4).

Recommendations

- Recovery of LUT functions is expected in GBS; supportive care, including an indwelling catheter or IC, is the treatment of choice for urinary retention (C).
- Patients with overactive bladder symptoms are likely to benefit from an antimuscarinic, once they are shown not to be retaining urine.
- A systematic evaluation of LUTD during the acute phase and recovery following GBS is required to optimize therapy (C).

12.3. Bowel Dysfunction in GBS

Bowel dysfunction occurs less commonly in GBS, in up to 15% of patients [328] (LOE3/4). Adynamic ileus was noted in 17 out of 114 GBS patients. However, cardiovascular symptoms coincided with ileus in only 5 patients, suggesting a different pathophysiology for these two manifestations of autonomic dysfunction. Indeed in 4 patients, mechanical ventilation and immobilization was implicated. In 8 patients, pre-existing conditions such as prior abdominal surgery or incremental doses of opiates could also be linked to ileus. However, case reports by Gazulla Abio et al. (LOE3/4) [329], Sawai et al. (LOE3/4) [322] and Nowe et al. (LOE3/4) [330] have also shown that paralytic ileus can be the initial presenting symptom in GBS.

There is a lack of good systematic studies on bowel disorders in GBS during the acute and chronic phase of GBS. However, there are some reports suggesting an involvement of bowel autonomic fibres in GBS. Sawai et al. (LOE3/4) [322] performed a detailed bowel function test in a 47-old man with acute motor axonal neuropathy (AMAN) type of GBS who presented with ileus (also called intestinal pseudo-obstruction) by an abdominal X-ray. Sitzmarks showed prolonged total colonic transit time (86.4 hours; normal 16.0-48.0), suggesting slow transit constipation. Pathological studies of GBS have revealed moderate to severe loss of small myelinated fibers and inflammatory cell infiltration in the lumbosacral spinal roots, sympathetic chain, and spinal cord. Therefore, involvement of bowel autonomic fibers might also occur in GBS.

Adynamic ileus or intestinal pseudo-obstruction occurs in up to 15% of patients during a course of GBS, particularly in those with severe motor dysfunction. Recovery of bowel function usually occurs along with the recovery of motor weakness in GBS, after an intensive immune therapy including intravenous immunoglobulin. There is still a lack of a detailed functional evaluation of the bowel in GBS patients. Such studies are needed in order to optimize the therapy in the future.

Conclusions

- About 15% of patients demonstrate bowel functional problems particularly in the acute phase, but they can also be presenting symptoms (LOE3/4).
- Constipation and intestinal pseudo-obstruction are observed in GBS (LOE3/4).
- Recovery of bowel function usually occurs, along with the recovery of motor weakness.

Recommendation

- Supportive care, including laxatives or enemas, is the treatment of choice (C).

13. FAMILIAL AMYLOID POLYNEUROPATHY

Familial Amyloid Polyneuropathy (FAP) is a rare autosomal dominant neuropathy affecting predominanatly the peripheral autonomic nerves. Neuropathy starts insidiously in the lower limbs and is characterised by lancinating pains, numbness and impaired temperature sensations.

Autonomic manifestations are common and may be the intial manifestation in nearly 25% of patients [331] (LOE3/4). These include erectile dysfunction, orthostatic hypotension, bladder dysfunction, distal anhydrosis and abnormal pupils. LUTS generally appear early on and are present in 50% of patients within the first three years of the disease. Patients most often present with voiding dysfunction and incontinence (LOE3/4). Often, however, bladder dysfunction may be asymptomatic and uncovered only during investigations. Urodynamic studies have demonstrated reduced bladder sensations, underactive detrusor, poor urinary flow and an open bladder neck. There may be failure of relaxation of the smooth and striated sphincters as well. Ultrasound scans of the bladder may show bladder wall thickening, a finding which becomes more prominent as the disease progresses, and may represent either amyloid deposition in the bladder wall or detrusor hypertrophy secondary to functional obstruction (LOE3/4). 10% of patients with FAP type I may proceed to end stage renal disease [332] and bladder diaries may demonstrate global polyuria. Bladder dysfunction is likely to be due to small nerve fibre damage and deposition of amyloid substance in the detrusor muscle.

Treatment of bladder dysfunction in FAP requires that patients should be followed up regularly, as over-distention is likely to contribute to bladder dysfunction. In the early stage of disease, post-void residual urine will often be less than 100 ml and bladder scheduling and double voiding is often sufficient. However when bladder emptying deteriorates, intermittent catheterization is required.

Lower gastrointestinal dysfunction results in alternating constipation and diarrhea. This occurs concomitantly with other manifestations such as episodic nausea, vomiting, and malnutrition. Anorectal physiology studies have demonstrated prolonged colonic transit time, low anal pressure at rest and loss of spontaneous phasic rectal contractions during squeeze, suggesting an enteric neuropathy [333] (LOE3/4).

Liver transplantation remains the only potentially curative treatment and gastrointestinal symptoms improve in about half of cases [331]. Studies suggest that bladder dysfunction does not improve following transplantation [334] (LOE3/4). Interestingly, the occurence of urinary incontinence pre-operatively appears to predict higher post-operative mortality [334].

14. FAMILIAL DYSAUTONOMIA

Familial dysautonomia (FD) or Riley-Day syndrome is the best known of the hereditary sensory and autonomic neuropathies (HSAN). This autosomal recessive condition is characterised by autonomic and small fibre sensory dysfunction.

LUTD occurs in this condition and patients most often present with incontinence, which is mainly stress incontinence, but also overactive bladder symptoms. The limitation of using antimuscarinics is that it can exacerbate an already dry mouth from the underlying autonomic neuropathy. Less often, patients may have voiding dysfunction manifesting with hesitancy for micturition and high post-void residual volumes, and may be predisposed to recurrent urinary tract infections [335] (LOE3/4).

15. CHARCOT-MARIE-TOOTH DISEASE

In a questionnaire based study, bladder and bowel complaints were significantly higher in patients with Charcot-Marie-Tooth disease compared to healthy controls [336] (LOE3/4). Lower urinary tract dysfunction has been reported in a family with proximal lower limb weakness, where it manifested as loss of bladder sensations and urinary retention with detrusor underactivity demonstrated in urodynamics. A hypotonic bladder was reported in urodynamics in a patient with parasympathetic dominant autonomic dysfunction in Charcot-Marie-Tooth Disease Type 2J with the MPZ Thr124Met Mutation [337].

16. AUTONOMIC NEUROPATHIES

A number of autonomic conditions can lead to pelvic floor dysfunction in general and bladder dysfunction in particular. Some conditions are:

1. *Acute Idiopathic Autonomic Neuropathy*. Bladder dysfunction is well recognized in acute idiopathic autonomic neuropathy (acute pandysautonomia). Acute onset autonomic dysfunction is the hallmark, and is thought to be due to lesions of the pre- and postganglionic sympathetic and parasympathetic fibres. Urinary retention and voiding difficulty are common and cystometry demonstrates detrusor areflexia. Bladder dysfunction tends to resolve earlier than other features of autonomic dysfunction, such as orthostatic hypotension. Constipation is common [338] (LOE3/4).
2. *Autoimmune Autonomic Ganglionopathy*. Presentation is with rapid onset of severe autonomic failure: orthostatic hypotension, gastrointestinal dysmotility, anhidrosis, bladder dysfunction, erectile dysfunction and sicca symptoms. Impaired gastrointestinal motility manifesting as gastroparesis and severe constipation is reported in nearly 70% of patients. Bladder dysfunction generally manifests with voiding difficulty and incomplete emptying. Severity and distribution of autonomic dysfunction appear to depend upon the level of antibody titers [339] (LOE3/4). Roughly 50–60% of patients with Autoimmune Autonomic Ganglionopathy have circulating antibodies to the α3 subunit of the ganglionic acetylcholine receptor (AChR) in the acute or subacute stage.
3. *Pure Autonomic Failure*. PAF is a degenerative postganglionic autonomic disorder. Nocturia and voiding dysfunction are common and bladder emptying is often affected. Bladder diaries may demonstrate nocturnal polyuria. Urodynamics may however demonstrate detrusor overactivity in some patients [340]. Bladder dysfunction in PAF appears to be as common as, but less severe than, MSA and this could possibly reflect slower progression of the disease [340] (LOE3/4). Constipation is common.

17. DISORDERS OF THE NEUROMUSCULAR JUNCTION

Widespread autonomic dysfunction is a hallmark of Lambert-Eaton myasthenic syndrome (LEMS). This is associated with antibodies to voltage-gated calcium channel (VGCC) of the P/Q-type and patients can present with erectile dysfunction, constipation and bladder dysfunction [341].

In the more common disorder of the neuromuscular junction, myasthenia gravis, LUTS are rare. This is presumably because the auto-antibodies are directed against the nicotinic acetylcholine receptors, rather than the muscarinic. However voiding difficulties have been reported and urodynamic studies have revealed detrusor underactivity in these patients. In fact, voiding dysfunction may herald a new diagnosis of myasthenia or an exacerbation of the disease process [342] (LOE3/4). The proposed mechanism is involvement of acetylcholine receptors in the detrusor muscle or pelvic ganglia. Ganglionic acetylcholine receptor antibodies may be present in some patients [343]. Urinary incontinence is a listed side effect of anticholinesterase medications which are used in treating myaesthenia gravis [British National Formulary (online)], though in clinical practice this is rarely observed. Intestinal pseudo-obstruction has been reported in patients of myasthenia gravis with subacute autonomic failure.

18. MUSCLE DISORDERS

18.1. Muscular Dystrophies

Case series in boys with Duchenne Muscular Dystrophy (DMD) [344] have reported the occurence of overactive bladder symptoms, and DO has been demonstrated in urodynamics. Symptoms improve with antimuscarinic medications in Becker's muscular dystrophy [345]. The exact mechanism for DO is uncertain, though it is likely to be due to a disturbance of neural control rather than myopathy of the detrusor or external sphincter. Patients may have severe scoliosis as a consequence of their muscle disorder and this, as well as spinal fusion surgery for correcting scoliosis, can contribute to LUTS because of spinal cord compression. The commonest genito-urinary complaints reported in a population based study of males with Duchenne and Becker muscular dystrophy were urinary tract infections, voiding dysfunction (most commonly urinary retention) and renal calculi [346].

Urological and gastrointestinal dysfunction are reported by patients with dystroglycanopathies more commonly than household controls and can negatively impact quality of life [347].

Myotonic dystrophy (MD) is an autosomal dominant disorder caused by unstable trinucleotide repeat expansions. Urinary and bowel complaints are commonly reported, more often in women [348]. The commonest bowel complaint is constipation, however most disabling is fecal incontinence. EMG has demonstrated myotonia and myopathic changes in the external anal sphincter. Bowel incontinence is often refractory to treatment and procainamide (300 mg twice a day) has been proposed as a treatment option [349]. Constipation is usually treated with prokinetics, laxatives and enemas. Bladder dysfunction is variable and less often reported with detrusor overactivity or atonia being documented in urodynamics [350] (LOE3/4).

18.2. Mitochondrial cytopathy

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a rare autosomal recessive disorder characterized by gastrointestinal, extraocular, peripheral nerve and cerebral white matter involvement. The gastrointestinal disease manifests with intermittent diarrhea and pseudo-obstruction. Mitochondrial DNA abnormalities and/or thymidine phosphorylase mutations in the proper clinical setting are diagnostic [351]. Bowel dysmotility has also been reported in Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, acronym DIDMOAD) [352]. LUTD has been described and may be associated with urinary retention and dilated upper urinary tracts [352] (LOE3/4).

Conclusions

- Lower urinary tract and bowel dysfunction can occur in a variety of neuromuscular disorders (LOE3/4).
- Both voiding and storage dysfunction are observed in these conditions (LOE3/4).

Recommendations

- Patients with neuromuscular disorders with bladder symptoms should be managed according to their symptoms and the findings of urodynamic tests (C).
- LUT and bowel dysfunction can change as these diseases progress and therefore follow-up is recommended (C).

19. PERIPHERAL NEUROPATHY DUE TO IATROGENIC LESIONS (FOCAL NEUROPATHY)

Surgical procedures in the abdomen and pelvis can lead to a variety of pelvic floor dysfunctions. This can occur from damage to the nerves innervating the pelvic organs, anywhere in the course of these nerves through the cauda equina, the spinal nerve roots, the sacral plexus, or to the various individual nerves that arise from the plexus. Most injuries to these nerves are iatrogenic. Extensive pelvic surgery, such as abdomino-perineal resection for rectal cancer, radical hysterectomy, and aorto-iliac surgery are all likely to damage the pelvic parasympathetic nerves to the bladder and genitalia. Of course this listing is not complete and almost any surgery in the pelvis could damage some nerves e.g. adenomectomy, radical prostatectomy, prolapse surgery. Additionally, pelvic irradiation, apart from directly affecting the irradiated tissue, could cause damage to the adjacent nerve fibers, resulting in altered functions. A variety of types of voiding, erectile and fecal dysfunctions can result.

19.1. Hysterectomy (simple and radical)

It is difficult to attribute certain dysfunctions to neuronal damage alone, since hysterectomy directly affects static and dynamic functions of the pelvic structures. Parys et al. [353] (LOE 3) studied 126 women after simple hysterectomy. The results show that 47.0% had DO, 36.7% had urethral obstruction and 24.8% stress incontinence. Sekido et al. [354] (LOE 3) described 9 women treated with radical hysterectomy more than 10 years before the study. Voiding symptoms and/or urinary incontinence were observed in 7 patients. Cystometry revealed impaired bladder sensation, detrusor acontractility, straining on voiding, and impaired relaxation of the sphincter in all investigated patients. In addition, decreased bladder compliance was observed in 5 patients. Axelsen [355, 356] (LOE 2) studied 100 women after radical hysterectomy and found that those women who reported incontinence had lower urethral pressure. In a prospective study of over 1000 women Jackson et al. found hysterectomy to be an independent risk factor of incontinence [357] (LOE 2). Plotti et al. analysed literature between 1952 and 2010 and found that in studies with follow up longer than 12 months, 34% of patients demonstrated DO and lowered compliance [358] (LOE 2).

The introduction of nerve sparing hysterectomy appeared to reduce urinary and sexual dysfunctions in comparison with the standard radical hysterectomy. It was found that autonomic nerve preservation significantly improved morbidity 6 months after treatment [359-362] (LOE 3). There is, however, significant lack of long term observations of patients after radical hysterectomy in terms of lower urinary tract neurogenic dysfunctions.

19.2. Abdominoperineal resection and total mesorectal excision

Retrospective analysis of 52 patients after abdominoperineal resection was performed by Eickenberg et al. [363] (LOE 3). Neurologic bladder dysfunction of various degrees was found in 50% but represented a long-term problem in only 10%. Baumgarner et al. [364], (LOE 3) studied 86 consecutive cases of abdominoperineal resection and described 11 cases of various functional problems of micturition. These reports lack specific tests of LUT functions and are not prospective. At 1 year follow up, dysuria incidence is higher after abdominoperineal resection than after anterior resection [364] (LOE 3).

Curative total mesorectal excision with autonomic nerve preservation can be done with high rates of preservation of such function. Pocard et al. [365] (LOE 3) investigated 20 patients (13 men, 7 women) following curative total mesorectal excision with autonomic nerve preservation for rectal cancer. There was no difference in preoperative and postoperative LUT function, International Prostate Symptom Score or urodynamic results, nor in the results of the quality of urinary function questionnaire. Sexual function and

potency were also unchanged in these men. The authors conclude that autonomic nerve preservation is possible and does not impair urinary and sexual function. Kim et al. [366] (LOE 3) also showed relative safety in preserving sexual and voiding dysfunction in total mesorectal excision with pelvic autonomic nerve preservation. Evaluation was based on uroflowmetry, voided volumes and residual volume, while symptoms were evaluated with the IPSS. There were significant differences in maximum urinary flow rate and voided volume, but no differences in residual volume before and after surgery. The IPPS increased after surgery from 6.2 +/- 5.8 to 9.8 +/- 5.9 ($p < 0.05$).

Similar results were reported by Turaldo et al. [367] (LOE 3) evaluating incidence and pathogenesis of LUT dysfunction after surgical treatment of rectal cancer in a series of 219 patients with normal urinary function pre-operatively. In the immediate follow-up, only 17 patients with dysfunction were observed, 14 stage II, 2 at stage III and 1 at stage IV according to Astler-Koller classification; six months later only 8 patients reported urinary dysfunction and 1 required catheterisation. However no urodynamic studies were performed. There was no correlation of LUT dysfunction with staging, radiotherapy, size of tumour, or surgical technique. However, worse functional results were observed in patients who underwent abdomino-perineal resection.

Lim et al. found that not only surgery but also preoperative intervention could cause lower urinary tract and anorectal dysfunctions [368]. The maximum resting anal pressures were unchanged after chemoradiation, but the maximum squeeze anal pressures were reduced. They concluded that pre-operative chemoradiation for rectal cancer carries a significant risk of pudendal neuropathy, which might contribute to the incidence of fecal incontinence after restorative proctectomy for rectal cancer [368] (LOE 3). However Langer et al. found that the surgery mostly responsible, not the pre-operative radiotherapy [369] (LOE 3).

Focal injury to peripheral innervation of the bladder and/or sphincter results in decentralization or denervation of the above mentioned organs. Therefore detrusor hypocontractility (acontractility) and/or sphincteric deficiency will be the result of such damage. This in turn will result in impaired bladder emptying and/or stress incontinence. No prospective studies referring specifically to the problem of functional disturbances of the LUT in focal iatrogenic neuronal injury in patients after hysterectomy or colorectal surgery have been performed.

Iatrogenic faecal incontinence can be caused by sphincter damage caused by surgery for anorectal problems, trauma, fistulae and abscesses. Vaginal delivery can cause not only sphincteric, but also neuronal damage to the innervation of the anal sphincter [370] (LOE 3). There is a significant paucity of epidemiological data regarding fecal incontinence after pelvic surgery.

Anorectal reflexes and anorectal manometry may predict recovery of function [371] (LOE 3). An experimental test in this specific patient population was described by Nordling et al. [372] (LOE 3). In patients after radical hysterectomy, those with significant denervation of the bladder had a greater rise in maximum urethral pressure during noradrenaline infusion (>20 cm H_2O) than normal subjects (1-15 cm H_2O). They concluded that urethral supersensitivity to noradrenaline may signify damage of the sympathetic innervation of the LUT.

19.3. Radical Prostatectomy

In a study of the 875 patients 19% developed de novo OAB following RP [373]. After adjusting for age, BMI, smoking status, cancer stage and nerve-sparing status, radiation therapy was associated with an increased relative hazard of OAB. Among men classified with de novo OAB, only 41% received treatment. Post-radical prostatectomy urinary incontinence continues to be one of the most devastating complications, which affects 9-16% of patients. Sphincter injury and bladder dysfunction are the most common causes of developing urinary incontinence.

19.4. Prevention and treatment of bladder dysfunction

Reduction of risk requires detailed knowledge of pelvic neuroanatomy and meticulous preparation of the structures adjacent to nerves potentially at risk [374-377] (LOE 3). Nerve sparing surgery seems to have favourable effect on bladder functions and continence in patients after radical hysterectomy [359, 376, 378] (LOE3). Thus it seems that it is the nerve function, rather than the biomechanics of the urethrovesical complex, which are responsible for incontinence. A method of intraoperative identification of the vesical branches of the pelvic nerves during radical hysterectomy was described by Kuwabara et al. [379] (LOE 3). Postoperative compliance of the detrusor in cases where this method was implemented demonstrated less decrement from pre-operative values than in cases with conventional approaches. These patients required significantly fewer days to achieve residual urine volumes less than 50 ml after surgery.

Nerve sparing technique and intra-operative identification of parasympathetic nerves seem also to play a role in rectal cancer surgery. Kneist and Junginger studied 62 patients undergoing mesorectal excision [380]. Pelvic autonomic nerve preservation was assessed macroscopically and with the aid of intra-operative electrical stimulation of pelvic autonomic nerves. In 46 patients, preservation of parasympathetic nerves was confirmed and these patients remained unchanged in early and long-term urinary function, contrasting with patients in whom preservation of the nerves was not confirmed [380] (LOE 3).

Should injury to the nerves innervating the bladder/urethra complex occur, the treatment should be based on standard principles and on the results of functional examination of the LUT. Zanolla et al. [381]

(LOE 2) suggested that early implementation of rehabilitative treatment (prompted voiding) allows satisfactory functional recovery of the bladder activity in 91% of the symptomatic patients after radical hysterectomy. Another interesting issue is the feasibility of the use of the artificial urinary sphincter to treat stress incontinence in patients with outlet denervation after colorectal surgery, hysterectomy and/ or radiotherapy. Only one study on this subject was identified [382] (LOE 3), describing a series of patients after radical prostatectomy and amongst them a patient after abdominoperineal resection with adjuvant radiation. The authors concluded that this method of incontinence therapy should be the method of choice, however there is a significantly greater risk of revision (38% versus 22% in the literature for low risk groups). Bulking agents may be considered after radical hysterectomy, if no other treatment options are possible. If not resulting from sphincter damage, fecal incontinence after colorectal surgery might be considered for sacral neuromodulation [383] (LOE 3).

19.5. Future research

Future research priorities include good epidemiological research, particularly prospective studies of the true incidence of peripheral injury-related functional disorders of micturition. Descriptive studies of diagnostic testing and therapy are needed. A registry database of urinary and fecal incontinence after different types of pelvic surgery would be a considerable benefit for insight into prevalence and preparation of guidelines on treatment/prophylaxis

Conclusions

- Injury to the bladder/sphincter innervation occurs in 30-50% of patients after extensive pelvic surgery (LOE 3)
- Pelvic irradiation could cause nerve damage affecting bladder and/ or bowel functions (LOE 2).
- Fecal incontinence due to iatrogenic innervation damage could occur after complicated labour, anorectal surgery and pelvic irradiation (LOE 3)
- Focal injury results in impaired detrusor contractions and/ or external urethral sphincter deficiency or detrusor sphincter dyssynergia (LOE 3-4)
- The key means to avoid these complications are nerve sparing techniques and intra-operative nerve identification (LOE 3)

Recommendations

- Patients after extensive pelvic surgery demonstrating functional disorders of micturition should be properly evaluated due to the varied potential underlying mechanisms (C)
- Early rehabilitation of the LUT and of the anal sphincter might improve function in a majority of patients (C)
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B)
- Autonomic nerve preservation should be considered when performing surgery for rectal cancer. Targeted voiding history before and after surgery and post-operative post-void residual urine measurements are mandatory to minimise risk of secondary detrusor damage through chronic urinary retention (B)

20. MULTIPLE SCLEROSIS

20.1. Epidemiology

Multiple sclerosis (MS) is the commonest progressive neurological disorder in young people, with a mean age at onset of 30 years, and a prevalence of 40-220 cases per 100,000 people in Europe [384-386], with similar rates in North America [387, 388]. The impact on the quality of life for patients with lower urinary tract dysfunction (LUTD) due to MS is significant. In a cross-sectional study, Nortvedt et al. [389] demonstrated that patients with LUTD had distinctly lower quality of life scores on the SF36 scale in comparison with the population of MS patients that is asymptomatic. The tools for evaluating quality of life taking into account LUTD in MS have been validated, so that variations in it over the course of the illness can be measured [390-392].

LUTD is multifactorial, and typically appears within the first 6 to 10 years of the progression of the illness [393-398]. Once LUTD has started (for 10% of cases LUTD is a primary feature [384]), they will present an increased risk of developing severe urological problems [399]).

The prevalence of LUTD in patients with MS is in the order of 30 to 96% [6-8, 10, 11, 13, 14, 16-32]. The range signifies the differences linked to the type of MS, to the duration of the illness, and to the degree of handicap, as well as to a probable under-evaluation by certain practitioners of any urological problems that develop progressively and slowly.

20.2. Urinary tract dysfunction in MS

Symptoms of the storage phase are most frequently reported: urinary frequency (38 to 99%), urgency (26 to 82%), and urgency incontinence (27 to 66 %) [384, 395, 397, 398, 400-402]. Stress urinary incontinence (SUI) has a prevalence of about 56% and patients often report mixed urinary incontinence [384, 403]. Symptoms of the voiding phase are less frequent with a prevalence of 6 to 49% [384, 395, 398, 401] and symptoms of both the storage and voiding phase coexist in about 50% of patients [384, 398].

Considering the very high frequency of LUTS, it is important that the most appropriate tools are used to

evaluate the urological problems, especially also taking into account that LUTD is often ignored by the doctors who take care of these patients at least partially due to the fact that the patients under-report their symptoms. It is therefore crucial to identify the groups of patients that are at risk so that complex examinations that are seen as risky are not imposed upon the entire population of patients who are suffering from MS [384, 395]. Short evaluation of LUTD in MS patients by neurologists and appropriate referral to urologists could accelerate proper diagnosis and treatment [404]. Thus, the coordinating role of neurologists in LUTD management may considerably improve quality of life in MS patients [404].

In a systematic review by de Sèze et al. [398], the duration of the progression of MS was one of the principal factors that influenced the prevalence of LUTD. Another important factor associated with LUTD was the degree of the patient's physical handicap as estimated by the Expanded Disability Status Scale (EDSS) [398]. This is also a common sense observation in daily clinical practice, i.e. a patient who can compensate for the urgency by going to the toilet beforehand may see the appearance of urgency incontinence following the appearance of a new motor or visual handicap. The appropriate management of this problem can allow the improvement of urinary disorders without any specific action on the bladder or the sphincter. Similar to patients with spinal cord injury, the clinical examination does not always allow the discovery of the specific neurological insults that are associated with LUTD. In addition, no correlation between radiological insults on the central nervous system (localization and intensity) and LUTD has actually been found [398].

Other factors have been controversially discussed as associated with LUTD, such as the type of MS progression (progressive or by crisis), the age at which MS started, sex, age and geographical location where the patient lives [398]. Importantly, older patients with MS will have the same problems as the general population (prostatic enlargement in men and stress urinary incontinence in women), and those problems will of course often be more difficult to treat than in the general population.

Lower urinary tract infections are reported in 13 to 80% (30% in average) [398, 405]. The occurrence of febrile urinary tract infection (pyelonephritis, orchitis, or prostatitis) is estimated at between 2 and 23% (9% on average). In addition to the risk of mortality, an aggravation of MS following an episode of urinary tract infection has been reported [389, 406, 407]. Neurogenic detrusor overactivity is probably a significant factor in the occurrence of upper urinary tract infections. Indeed, intradetrusor injections of onabotulinumtoxinA resulted in a relevant decrease of urinary tract infections [408].

A few studies suggest that the risk for bladder cancer is greater in patients with MS than in the general population, especially in patients under chronic catheterization and having been treated with immunosuppressants (for instance cyclophosphamide) [398, 409]. The overall incidence of bladder cancer in the MS population was 0.29% higher than in the general population (0.018 in men, 0.004 in women) and close to that of patients with SCI (from 0.27 to 9.6%) [398]. The risk for bladder cancer appeared higher in patients with indwelling (transurethral, suprapubic) catheters (incidence 0.7%) and in patients performing intermittent self-catheterisation (incidence 0.23%), with a maximum risk in the sub-population of patients under chronic catheterization having been treated with immunosuppressants (incidence 5.7%) [398, 409]

Complications of the upper urinary tract

Renal calculi were found in 2-10% of the cases, hydronephrosis in 1 to 16% and vesico-uretero-renal reflux in 2 to 15% of the cases [384, 398]. Contrary to patients with SCI and spina bifida, the risk of developing renal failure in patients with MS is generally low [410] and does not appear to be greater than within the general population [411]. However, in patients with MS progressed for more than 10 years, renal failure prevalence as high as 2 to 3% has been reported [384, 399, 412, 413].

Risk factors for urological complications

Although urological complications are less frequently reported in patients with MS compared to those with other neurological disorders such as SCI or spina bifida, they are not rare [384]. Risk factors for urological complications include the MS duration, post void residual, presence of an indwelling catheter, older age, male sex and urodynamic parameters (such as detrusor overactivity, detrusor sphincter dyssynergia, elevated intravesical pressure, low compliance bladder, vesico-uretero-renal reflux) [384, 398, 410, 414].

The role of urodynamics in MS

Urodynamic findings in patients with MS vary widely, and the following findings have reported: detrusor overactivity in 34-91%, detrusor underactivity in ≤37%, low bladder compliance in 2-10%, detrusor sphincter dyssynergia in 5-60%, detrusor sphincter dyssynergia combined with either detrusor overactivity in 43-80% or with detrusor underactivity in 5-9% [384]. Importantly, urodynamic abnormalities can change during the course of disease, pathological findings may be identified in asymptomatic patients and symptomatic patients may have normal urodynamics.

The role of urodynamics in MS is a topic of ongoing debate [384, 410]. Guidelines published by the UK National Institute for Health and Care Excellence (NICE) [415], a UK consensus statement (Fowler et al., 2009) and a Turkish consensus statement [386] recommend not to offer urodynamics (i.e. cystometry and/or pressure-flow studies) routinely to MS patients, whereas the International Francophone Neuro-

Urological Expert Study Group (GENULF) recommends using urodynamics in the initial diagnosis [398]. Thus, the inclusion of urodynamics in the routine assessment of patients with MS is determined by the available local guidance [384]. However, urodynamics are generally recommended in MS patients with risk factors predisposing to upper urinary tract damage, in those with concomitant stress urinary incontinence, in those whose symptoms have failed to respond to first-line treatment or if surgical treatment is being considered [384, 416].

Conclusions

- MS is the commonest progressive neurological disorder in young people (LOE 1)
- The most common LUTS in MS are storage symptoms, followed by voiding symptoms and in many patients both storage and voiding symptoms coexist (LOE 1)
- The risk of developing upper urinary tract damage and renal failure is much lower in patients with MS than in those with SCI or spina bifida (LOE 3)
- The role of urodynamics in MS is a topic of ongoing debate (LOE 2)

Recommendations

- Close collaboration between neurologist and urologist are mandatory and appropriate referral to the urologist is strongly recommended to improve quality of life in the MS patient (B)
- Urodynamics are generally recommended in MS patients with risk factors predisposing to upper urinary tract damage, in those with concomitant stress urinary incontinence, in those whose symptoms have failed to respond to first-line treatment or if surgical treatment is being considered (B)

20.3. Colorectal dysfunction in MS

Epidemiology

Digestive disorders are common in patients who have MS, and can have a significant impact on quality of life (LOE4) [389, 392, 417]. What is more, the patients tend to be ashamed of these problems and seldom report them. Clinicians have few tools at their disposal for evaluating this impairment. Consequently, digestive disorders are often undetected (LOE3-4) [413, 418].

Taking into account the great diversity of definitions in the several studies that are concerned with this problem, one is obliged to regroup the digestive symptoms into two large groups: those symptoms that can be defined as "retentive", including abdominal pain, flatulence, and constipation on the one hand, and those symptoms that can be defined as “irritant”, including false urges to defecate, diarrhea, and/or incontinence of stool and/or gas. Digestive disorders of both types were found in 45 to 68% of the cases (LOE 4) [417-422]. The prevalence of the “retentive” symptoms is higher, ranging from 31% to 54%, compared with 6 to 20% for irritant symptoms [417]. The authors who had sought to flush out the more exceptional episodes of incontinence found a frequency of at least one episode of that type in the months that preceded the interview in 29 to 30% of the cases [418, 419]. The figures were clearly more significant than in the general population, where the "retentive" disorders are estimated to be around 2 to 20% and the “irritant” disorders 2% [423].

Risk factors for digestive disorders in MS have not been identified. The duration of the progress of MS does not appear to be a factor that influences the prevalence of digestive disorders. The factor that seems to be the most important is the estimated degree of disability (LOE3c-4) [422, 424]. Thus, Munteis et al. [424] found in a case control study (LOE 3) a frequency of digestive disorders that exceeded 21.2% if the patients had an EDSS between 0 and 1, compared with 78% if EDSS was greater than 4.5. Other risk factors were suggested (LOE4), such as female gender, the existence of related urinary disorders, age, and taking anticholinergic treatments, but they seemed to have an influence that was less clear [417-422] [424].

Pathophysiology of MS-related digestive disorders

Few studies have been carried out specifically in patients who have multiple sclerosis. One of the difficulties is the frequent existence of related treatments that can themselves bring about the specific symptoms. The colonic transit times can be extended or shortened in those patients who present with digestive disorders [425-427]. Several anorectal manometry anomalies were in evidence: reduced tone and compliance, a reduced sensation of filling and incoordination of the external anal sphincter during expulsion, with an onset of the phenomenon known as paradoxical anal sphincter contraction. In patients with faecal incontinence, a decrease in anal canal pressures and hyper-reactivity of the rectal wall have been shown manometrically. In the most recent of these studies, Munteis et al [424] has found that the anomalies that are found the most often are those of maximal sphincter pressure, of anal inhibitory reflex (which occurred later than in the control population), and the presence of paradoxical contraction of the puborectal musculature during straining. These anomalies might be able to allow the proposal of biofeedback re-education in affected patients. However, at present the benefit of this approach has not yet been proven.

21. SPINAL CORD LESIONS

Spinal cord injury (SCI) can be a devastating consequence of a variety of insults to the spinal column including road traffic accidents, gunshot wounds, surgical injuries, disc lesions or as a result of sports. It can be accompanied by vertebral fractures. Unlike other neurologic diseases, once established the neurologic status generally remains stable.

21.1. Epidemiology and prevalence

SCI epidemiology has evolved over the last three decades. The incidence in women has increased over time. The male/ female ratio is now is 4:1. The mean age at injury is 37.7+/-17.5 years in 2000-2003 [428]. This comprises incomplete quadriplegics (28%), complete paraplegics (26%), complete quadriplegics (24%) and incomplete paraplegics (18%) [429].

There has been a steady improvement in life expectancy and quality of life after SCI. At present, the life expectancy of paraplegic patients is similar to the general population. This has been accomplished by development of multidisciplinary teams, introduction of clean intermittent self-catheterization (CSIC) and an improved and protocol driven follow-up plan.

The SCI is classified using the American Spinal Injury Association (ASIA) impairment **(Table 16)** scale of motor and sensory function [430].

Table 16: ASIA Impairment scale

A = Complete: No motor or sensory function is preserved in the sacral segments S4–S5.
B = Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4–S5.
C = Incomplete: Motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3.
D = Incomplete: Motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade of 3 of more.
E = Normal: Motor and sensory function are normal.

It separates into 5 clinical syndromes [4] as follows:

• **Central cord syndrome** is most commonly due to hyperextension injury and results in haemorrhagic necrosis of the central gray matter and some of the medial white matter. Arm function is less at risk than legs because more caudal fibers of the corticospinal and spinothalamic tract are localized in the spine more laterally so are better protected. Bladder dysfunction is also less common.

• **Brown–Séquard syndrome** is a unilateral cord condition. It presents as ipsilateral motor weakness and contralateral sensory impairment of pain and temperature. Bladder dysfunction in the pure condition is uncommon.

• **Anterior cord syndrome** is characterized by injury to the anterior aspects of the cord. The posterior columns and dorsal horns are preserved. There is a motor deficit and loss of pain and temperature sensation below the level of the injury.

• **Conus medullaris and cauda equina syndrome** result from damage to the conus and spinal nerve roots, leading to flaccid paraplegia and sensory loss. Sacral reflexes can be partially or totally lost.

It has been proposed to add an additional scale assessing the autonomic function [431] as it is generally impaired in SCI but not assessed in any classification. This scale involves an assessment of general autonomic function, lower urinary tract, bowel, sexual function and an urodynamic evaluation. The impact of SCI on the pelvic organ function constitutes a major part of this classification.

21.2. Bladder dysfunction after SCI

SCI can be divided into two phases; spinal shock and a chronic phase, and can be categorised according to the level of injury.

Spinal shock

Spinal shock is the period just after the injury. It lasts on average three months. It is characterised by loss of muscle tone and segmental spinal reflexes caudal to the SCI. There is detrusor areflexia and the bladder is acontractile but the bladder neck and proximal urethra remains closed. This areflexia cannot be reversed with bethanechol [432]. The only reflex activity that rapidly returns are the anal or bulbocavernosus reflexes. Spinal shock is initially managed with an indwelling urinary catheter. The recovery of bladder function usually follows that of skeletal muscle reflexes. The removal of an indwelling urinary catheter and initiation of self catheterization should be instituted as soon as practical.

Neurogenic Bladder Dysfunction in the chronic phase

Suprasacral lesions

The spinal shock phase is followed by the appearance of a segmental spinal bladder reflex. This relates to emergence of unmyelinated C-fibers afferent function [433]. As a result, some stimuli can come to influence bladder and sphincter activity that were seemingly irrelevant prior to injury [434, 435]. The sacral micturition centre is disconnected from the control of higher centres and produces what is functionally an isolated spinal cord segment. This results in neurogenic detrusor overactivity (NDO) and detrusor sphincter dyssynergia (DSD). DSD is defined as in-

termittent or complete failure of relaxation of the urinary sphincter during a bladder contraction and voiding. It has been reported to occur in 96% of individuals with suprasacral lesions. In addition to DSD, internal sphincter dyssynergia also has been reported, often occurring at the same time as DSD. Patients present with both storage and voiding dysfunction [436]. DSD can manifest with both complete and incomplete lesions. However, complete injuries are significantly more often associated with DSD. This leads to high voiding pressure, dis-coordinated voiding, residual urine and incontinence. If left untreated, this can lead to recurrent urinary infections, hydronephrosis and renal failure. Ambulatory patients with incomplete spinal cord may have significantly less urinary tract dysfunction, but the urodynamic parameters may still be abnormal.

Detrusor-(external) sphincter dyssynergia

Schurch et al. [437] assessed types of DSD in 105 chronic SCI males and evaluated the change in the DSD pattern over time. Results showed that those with an incomplete sensory and motor SCI presented with DSD type 1 whereas those with complete sensory and motor SCI lesion had DSD type 2 to type 3. At medium to long-term follow-up, a significant change was found in the DSD type. Generally, presence of DSD was determined by increased wire needle EMG activity and/or by dilated bladder neck and proximal urethra during detrusor contraction, in the absence of valsalva or attempt to inhibit voiding. De et al. [438] did a comparative study to explore the diagnostic congruence for DSD between needle EMG and voiding cystourethrogram (VCUG) in the neurogenic population. They found 60% agreement and 40% disagreement between EMG and VCUG for diagnosis of DSD. Binomial testing demonstrated significant disagreement in observed proportions. By retrospectively analyzing clinical data consisting of bladder and EAS EMG from 41 SCI individuals with NDO, Wenzel et al. [439] found that the onset of bladder contractions was detected within 1 sec of the start of the EAS contraction for both synergic and dyssynergic human subjects. They concluded that this detection could be used as a control signal to deliver inhibitory electrical stimulation to arrest nascent bladder contractions.

Autonomic dysreflexia

Autonomic dysreflexia (AD) is a clinical emergency in patients who have a SCI, usually at level T6 or above. It is caused by a massive sympathetic discharge triggered by either a noxious or non-noxious stimulus originating below the level of the SCI. The mechanism might be changes occurring within the spinal and peripheral autonomic circuits. There is a loss of inhibitory and excitatory supraspinal input to the sympathetic preganglionic neurons [440] secondary to the destruction of the descending vasomotor pathways.

AD is characterized by severe hypertension and reflex bradycardia, though tachycardia also may occur. An increase in systolic blood pressure greater than 20 to 30mmHg is considered a dysreflexic episode. The other symptoms could be severe headache, feeling of anxiety, profuse sweating, flushing and piloerection above the injury level with dry and pale skin below. It might also cause blurred vision, nasal congestion, cardiac arrhythmias and atrial fibrillation. It can vary in intensity from mild discomfort to life-threatening. Untreated episodes may cause intracranial haemorrhage, retinal detachment, seizures, and death.

The severity of AD symptoms increases with completeness of injury and higher level of lesion (27% of patients with incomplete quadriplegia vs 91% of patients with complete tetraplegia) [441]. The commonest trigger for AD is bladder or bowel distention.

Immediate recognition and reversal of trigger factors is essential [442]. The treatment consists of non pharmacologic interventions; removing the noxious stimulus, emptying the bladder, sitting the patient up, as recommended by the Consortium for Spinal Cord Medicine. If they fail, and systolic blood pressure continues to be at or above 150mmHg in an adult and 130mmHg in a child 6 to 12 years old, some type of pharmacologic agent should be used, usually Nifedipine 10 mgs sublingual.

Infrasacral lesions

In patients with injury to the sacral pathways there is decentralization of parasympathetic pathways to the detrusor with the loss of somatic innervation to the external sphincter. This results in loss of conscious awareness of bladder filling. There is partial preservation of pain sensation transmitted via hypogastric nerves in some people. Patients present with hesitancy, slow and interrupted stream, feeling of incomplete emptying, and are often in retention. The bladder has little or no contractile ability. Nevertheless, because of loss of compliance of the bladder wall, the bladder may still be subject to high intravesical pressure during filling, especially in individuals with conus medullaris lesions or with partial injuries. In the chronic state there is an increase in adrenergic innervation to the detrusor, resulting in change of functional role from beta- mediated adrenoreceptor relaxation to alpha-mediated contraction [443, 444]. The sympathetic nervous system supplies the main innervation to the urethra. However, there may be a contribution of the somatic innervation to external sphincter [445, 446]. The perineal floor electromyography shows denervation of the perineal floor and an underactive urethral sphincter in infrasacral cord lesions.

21.3. Natural History of Neurogenic bladder after SCI

SCI usually causes impairments of urinary functions such as urinary incontinence (UI) and/or difficulty in urination. The studies on prevalence of bladder management in chronic SCI [447-449] (see **Table 17**) demonstrate about 8%-11% of patients had normal voiding, not different from the time after initial rehabilitation; and more normal voiding in tetraplegics then paraplegics [449].

According to the study from Denmark [449], at discharge from the initial rehabilitation period of 233 traumatic SCI patients, bladder-emptying methods were as follows: 12% normal voiding, 57% suprapubic tapping, 19% abdominal pressure, 5% Crédé manoeuvre, 11% CIC, 2% SIC, 8% urethral indwelling catheter (IDC), 0.4% suprapubic catheter (SPC), 0.4% sacral-anterior-root-stimulation (SARS), and 5% use of condom-catheter or diaper. When dividing the patients by timing of injury (before 1981 and after 1980), there was a decreasing trend of using suprapubic tapping (drop from over 60% to 45%), abdominal pressure (from over 20% to 15%) and Crédé manoeuvre (drop from over 12% to 1%) but there was an increasing trend of using CIC (rise from 0% to 26%). Over time, 37.5% to 46% of SCI persons changed their bladder-emptying management; 28% found their bladder-emptying methods to be a problem; of these 58% were tetraplegic and the biggest bother in bladder management to the subjects was in the compression or straining group (over 50% of the subjects).

There was a significant difference in the frequency of urinary tract infection (UTI) between the bladder management options [447]; the frequency of UTI was high (about 70%) in the mixed group (65% used CIC with other methods) and the CIC group and less (less than 50%) in the groups with catheter free management. According to the study financed by Medicon Valley Academy and Coloplast A/S and done in Denmark, of those using CIC, 92% reported using hydrophilic-coated catheters [449], but there was no report about frequency of UTI.

Table 17. Studies reporting prevalence of specific bladder management methods in chronic SCI

Study (year)	Subjects	Methods of bladder management
Dahlberg et al. [447]	129 traumatic SCI in Finland; mean time since injury 18 years (SD 13)	Normal voiding: 11% Controlled voiding (assisted voiding or incontinence: 12% CIC: 12%; mixed (CIC with other methods):23% Suprapubic tapping 24% Compression or straining (usually with condom catheter): 12% Catheter or conduit: 5%
Hansen et al. [449]	233 SCI in Denmark (82% males, 47% tetraplegics, mean age at the time of follow-up of 50.5 years and mean time since injury of 24.1 years)	46% changed bladder-emptying method Normal voiding: from 12% to 8% CIC: from 11% to 36% SPC: from 0.4% to 6% Suprapubic tapping: from 57 to 31% Crede manoeuvre: from 5 to 19%
Patki et al. [448]	64 traumatic paediatric onset, ambulant SCI (mean follow-up 7 years; mean age 46 years)	Spontaneous voiding: initial 62.5%; 47.5% of them deteriorated CSIC: initial 31.2%; 25% of them improved SPC: initial 6.3% 37.5% required a change in urological management 68.7% had abnormal urodynamics at the last follow-up

In a large prospective cohort study, Drake *et al.* [450] reported the changes in bladder management method with advancing time after SCI, finding that 29% of patients with SCI for at least 20 years changed method over the 6 year period. Podnar et al. [296] studied 55 patients with chronic cauda equina or conus medullaris injury: 76% of the patients reported LUT dysfunction, 70% had urinary incontinence (56% of men and 71% of women); and a post void residual (>100 ml) was found in 40% of men and 17% of women. Perianal sensation was abnormal in 96%, electromyography (EMG) of the external anal sphincter (EAS) muscle in 88%, and sacral reflex in 84% of patients; using multiple linear regression analysis, perianal sensory loss and female gender had a significant positive effect on urinary incontinence score.

21.4. Disease-specific LUT mechanisms

Pontari et al. [451] analysed 7 bladder specimens from 6 cervical SCI patients and 1 L1 congenital myelomeningocele (MMC) and compared them with bladder specimens obtained from 8 organ transplant donors to determine whether the muscarinic receptor subtype mediating contraction alters, and found that whereas normal detrusor contractions are mediated by the M3 receptor subtype, in patients with neurogenic bladder dysfunction, contractions can be mediated by the M2 muscarinic receptor subtype.

Drake et al. found a marked reduction in the range of transmitters expressed in bladder nerves in SCI [452]. Haferkamp et al. [453] evaluated the role of neuropeptide Y in 31 patients with NDO and 7 patients with stress urinary incontinence (SUI) and concluded that the reduction of neuropeptide Y-containing nerves, inhibiting the contractile response of the detrusor, may play a role in the development and persistence of NDO in SCI patients. Oner-Iyidoğan et al.

[454] found that urine 8-iso PGF2alpha concentrations were significantly increased in SCI, and the lowest concentrations of urinary 8-iso PGF2alpha were observed in the areflexic group.

According to the study of viscerosensory pathway of the lower urinary tract (LUT) by Schmid et al. [455], after electrical stimulation (ES) of the posterior urethral mucosa (single square pulses of 0.2 ms, 2 to 3-fold sensory threshold, 60 mA in complete SCI patients), evoked skin sympathetic responses (SSRs) of the hand could be recorded in 14 of 15 sensory incomplete SCI patients with disturbed urethral sensation but not in 13 sensory complete SCI patients with loss of any urethral sensation. Electrically evoked urethral sensations resembled the subjective desire to void at full bladder reported by controls and patients.

Schmid et al. [456] did a comparative study of motor evoked potentials (MEP) and evoked pressure curves (EPC) from the urethral compressive musculature (UCM) in 9 healthy persons and 33 patients with neurogenic UI (15 SCL, 14 cauda equina lesion, and 4 multiple sclerosis). In healthy subjects the central latency was 19.0 msec, the peripheral latency was 4.25 msec, and the ratio between central and peripheral latencies was 4.4. In patients with incomplete SCL, the central latency was significantly delayed (22.7 msec), whereas the peripheral responses were normal, and the ratio (5.5) was increased. Those with a complete SCL showed no UCM reaction after transcranial stimulation, whereas peripheral responses were normal. The increased ratio of 6.0 indicated a spinal cord lesion. Ten patients with incomplete cauda equina lesions and UI had normal central latencies but prolonged peripheral latencies of 6.7 msec; the ratio of 3.4 indicated a lesion of the sacral caudal roots.

According to Dai and Xiao [457], the thresholds of stimulation on ventral roots were 0.02 ms duration, 0.2-0.4 mA, (mean 0.3 mA+/-0.07 mA), compared with 0.2-0.4 ms duration, 1.5-3 mA (mean 2.3 mA+/-0.5 mA) for dorsal root ($P<0.01$) to cause evoked potentials and EMG. Continuous stimulation for about 3-5 seconds on S2 or S3 ventral root (0.02 ms, 20 Hz, and 0.4 mA) could result in bladder detrusor contraction, but the strongest bladder contraction was usually caused by stimulation on the S3 ventral root in 7 of the 10 patients.

21.5. Assessment/investigations

A complete assessment is required for evaluation of bladder dysfunction [458-460], to screen for upper urinary tract damage, evaluate the risk factors and to adapt the management to the patient's disability.

The first detailed assessment is generally performed once the patient has recovered from spinal shock. It includes a complete clinical history, including prior surgery, medications, spinal cord injury date, spinal cord injury evolution, other past medical events, neurologic symptoms, spasticity or autonomic dysreflexia, mental status and comprehension, mobility and hand function and socioeconomic situation. It has also to include a special focus on urinary symptoms, bowel and sexual functions and possible warning signs, such as pain, infection, haematuria, and fever. A 3-day bladder diary could be recorded. However, the spinal cord outcomes partnership endeavour considers that diary-based measures of continence and voiding are not well standardized and have limited sensitivity, accuracy and reliability [461]. Quality of life should also be assessed, using validated questionnaire such as qualiveen, which has been specifically developed for assessing quality of life in relation to bladder function after spinal cord injury [462].

The recommended investigations are kidneys and bladder ultrasonography, creatinine clearance, videourodynamics (VCMG) or urodynamics and urethrocystogram. Other investigations could be performed, such as dimethlymercaptosuccinic acid (DMSA) renography or mercaptoacetly-triglycine (MAG3) renography, cystoscopy, abdominal CT scan, depending on the abnormalities detected on the initial investigations.

The renal ultrasound looks for upper urinary tract dilation, stone, pyelonephritic scars and atrophy, with bladder scan detecting stone, bladder wall thickness and any large mucosal lesions. A post-void residual volume assessment would be performed if the patient can pass urine spontaneously. In parallel, renal function should be assessed. Currently, creatinine clearance, rather than simply creatinine level, is recommended due to loss of muscle mass in these patients. In case of kidney ultrasound or of renal function abnormality, a renography (DMSA or MAG3), is indicated. Cystatine C has been proposed for assessing renal function in neurological patients [463].

In SCI patients, videocystometrogram (VCMG) is considered the gold standard for understanding bladder and urethral sphincter functioning and for assessing the upper urinary tract damage risks.

21.6. Urodynamic studies

Ockrim et al. [464] found that in men with SCI, cystometric variables and detrusor overactivity (DO) remained consistent over sequential studies while in those with LUT symptom of urgency, a significant decrease in the number and pressure of involuntary detrusor contractions (IDCs) in consecutive cystometries resulted in a reduction of observed DO from 72% to 63% and 48%, in the three studies. Chou et al. [465] did a retrospective study on urodynamic studies to provide reference ranges for "normal" variability in urodynamic parameters that can be considered as "no real change" from one study to the next. Fifty consecutive individuals with SCI had 2 trials (trial 1 and trial 2) of urodynamic studies done 5 minutes apart, and the following data were collected: maximum cystometric capacity, opening pressure, maximum detrusor pressure, volume voided, and postvoid residual (see **Table 18**).

Table 18. Variability in urodynamic parameters for 50 SCI individuals (adapted from Chou et al. [465])

Urodynamic parameters		Maximum 5th to 95th percentile		Maximum 10th to 90 th percentile		Maximum 25 th to 75 th percentile	
	Mean	Increase	Decrease	Increase	Decrease	Increase	Decrease
Cystometric capacity (mL)	234.63	+213.50	-158.05	+126.40	-74.60	+72.00	-27.00
Opening pressure (cmH2O)	54.56	+30	-18.00	+13.70	-12.00	+4.00	-9.50
Maximum detrusor pressure (cmH2O)	60.82	+17.35	-27.80	+10.00	-20.00	+4.00	-10.00
Volume voided (mL)	122.20	+177.25	-176.00	+105.60	-82.00	+50.00	-30.00
Postvoid residual (mL)	176.06	+197.25	-118.00	+131.00	-86.00	+50.00	-30.00

Generao et al. [466] did a retrospective review of SCI cases with 1-year minimum follow up to determine the effect of SCI on the developing bladder and kidneys using video-urodynamics and sonograms. In 42 children (average age at injury of 5.3 years and mean follow up of 5.5 years), 40 used CIC and 37 took antispasmodics. No patient had reflux, hydronephrosis or renal scarring. Safe bladder capacity, the pressure specific volume at 40 cm water or less, was less than the expected capacity in 80%, 58% and 50% of cervical, thoracic and lumbar injured patients but 100%, 76% and 67% respectively of the groups undergoing multiple urodynamics had increasing capacity with time.

Ersoz and Akyuz [467] investigated bladder-filling sensation in 73 consecutive traumatic SCI patients to examine the quality of the preserved sensation and to determine the potential for sensation-dependent bladder emptying. Bladder-filling sensation was present to some degree in all incomplete SCI patients, in 82.4% of the patients with complete lesions below T10, and 38.9% of the patients with complete lesions above T11. There were significant differences between three groups with respect to bladder sensation category. About 86% of the patients with incomplete lesions, 53% of the patients with complete lesions below T10 and 22% of those with lesions above T11 had bladder-filling sensation before P_{ves} reached 25 cmH2O and simultaneous bladder capacity of more than 150 ml was present in 61.2, 41.2 and 22.2% of the patients in the groups, respectively. Bladder-filling sensation investigations were reliable in terms of bladder filling sensation category in 36 SCI patients who had a second cystometric examination.

To measure bladder mucosal sensory function quantitatively, Ukimura et al. [468] used neuroselective Current Perception Threshold (CPT) tests in 8 healthy volunteers and 38 patients with NBD. Standardized neuroselective CPT measures were obtained from the left index finger and the mucosa of the posterior bladder wall. The CPT values in the bladder could be determined using the neuroselective measures in all patients but three who had no sensory response (absence of sensation) caused by complete SCI. In the 8 patients with NDO due to incomplete supra-sacral SCI, the bladder CPT value (4.0+/-1.9) at 5Hz was significantly lower than that in the controls (26.2+/-17.7). In the NBD determined to be underactive (n=11, including post pelvic surgery, post infrasacral level SCI and diabetes patients), the higher CPT values of bladder mucosal sensory functions were found at 5Hz ($p<0.05$), 250Hz ($p=0.07$), and 2000Hz compared to the controls. No fibre specificity has so far been found depending on frequency of current used or current type.

21.7. Urinary Tract Complications in SCI patients

Complications related to urethral indwelling catheterization (IDC)

During 2004-2006, at least three papers reported urinary complications related to prolonged urethral IDC: the catheter balloon of a Foley catheter inserted partially and a long-term IDC caused urethral erosion and a severe degree of hypospadias [469]; contracted bladder followed by autonomic dysreflexia (AD), gross haematuria and extravasation of contrast media due to improper technique of voiding cystourethrography [470]; and continuous incontinence despite a catheter and low bladder compliance leading to a urinary diversion to achieve continence [471]. In chronic SCI, IDC was associated with higher mean levels of C-reactive protein (CRP) while intermittent catheterization was associated with lower levels of CRP when compared with other methods of bladder management [472].

Vesicoureteral Reflux (VUR)

VUR seems common among SCI patients with upper motor neuron (UMN) neurogenic bladder. According to the study of Linsenmeyer et al. [473], there was an association of posterior position of ureteral orifices and reflux but no differences were found with regard

to bladder capacity, bladder wall compliance, or voiding pressures between the reflux group and non-reflux group.

Stone formation

Linsenmeyer and Linsenmeyer [474] found that the majority of bladder stones were calcium phosphate (46.8%) or struvite (26.7%). According to the retrospective study in 32 patients with NBD, Matlaga et al. [475] found renal stones were infectious in aetiology in 37.5% (12 struvite/carbonate apatite) and metabolic in 62.5%. All patients with struvite calculi were infected with urea-splitting bacteria.

Stone formation is usually related to IDC. Ke et al. [476] found bladder calculi with a nidus of hair that could have been introduced into the bladder accidentally during cystostomy catheter replacement. Over 17 years, 28% and 15% of 140 men were diagnosed with bladder and renal stones for a total of 59 and 25 episodes, respectively; bladder stone was more common in patients injured when aged > or = 24 years than in those injured when aged <24 years; patients with complete injury had a greater risk of renal stone formation than those with incomplete injury; renal stone was more common for patients with urethral catheterization than for those voiding spontaneously and for patients with bladder stone than for those without. According to the review by Ost and Lee [477], recurrent UTI, IDC, VUR, and immobilization hypercalcuria were major risk factors for the development of urolithiasis.

According to the retrospective study of Ozawa et al. [478], the incidence of bladder stone in urethral IDC was 1.11 times/100 months, cystostomy was 1.05, contemporary urethral IDC at night time only was 0.96, CIC-wet was 0.61, and CIC-dry was 0.21; and the urethral IDC group had significantly higher incidence of bladder stone than CIC-dry.

Linsenmeyer and Linsenmeyer [479] did a prospective cohort study by examination of IDC for encrustation at the time of removal for cystoscopy and found that 35% of 49 SCI individuals had bladder stones. Catheter encrustation was noted in 13 patients and 11 of them also had bladder stones i.e. a positive result for catheter encrustation had a positive result for bladder stones 85% of the time. Thirty-six individuals had no catheter encrustation; of these, 16% were found to have bladder stones.

Bacteriuria

In a retrospective study, Jayawardena and Midha [480] suggested that healthy asymptomatic SCI patients who came for annual evaluations should not have routine urine cultures if they are at low risk for UTIs; that is, <6 WBC/HPF in the urine and/or nitrite negative. Svensson et al. [481] studied the occurrence of bacteriuria in SCI patients with NBD who used CIC. Of 344 cultured samples, there were 285 isolates: coagulase-negative Staphylococci (27%), Enterococci (25%), Klebsiella spp. (19%), and Escherichia coli (12%); and bacteria grew at concentrations of 10^5-10^8 cfu/L, but only a few at 10^4 cfu/L. Levendoglu et al. [482] prospectively studied 27 SCI patients who applied CIC during the initial rehabilitation and 40 controls. E. coli was predominantly isolated from the urine and the urethral cultures of both female and male patients; there was concordance between urethra and urine cultures concerning the growth of E. coli; and Pseudomonas was colonized more in male patients. Waites et al. [483] found that among 77.1% of men with bacteriuria, uropathogens were shown in the perineum in 57.4% and in the urethra in 85.2%; differences in the occurrence of uropathogens in men with and without bacteriuria were statistically significant, and organisms were present in higher numbers in men with bacteriuria.

Fournier's gangrene is a recognised risk [484, 485]. Nambiar et al. [485] reported a C4 tetraplegia man presenting with a necrotic ulceration on the ventral aspect of the penis and scrotum of 2 days duration and diagnosed with fulminant Fournier gangrene. Vaidyanathan et al. [486] reported cases of a perirenal haematoma due to warfarin and a tumour like of necrotic slough and debris in the bladder.

Bladder cancer

The reported prevalence is between 0.1 and 10 %. The risk of bladder cancer is greater in SCI patients than in the general population [487, 488](58;59). The histological subtype is a squamous cell carcinoma in up to 80 % of the cases. Symptoms are often non-specific, such as recurrent tract urinary infections or incontinence, and diagnosis is often delayed. The risk factors are indwelling catheter, stones and recurrent urinary tract infections. It is recommended that patients with long term catheters should undergo surveillance cystoscopy and biopsies [489]. However, other groups have performed surveillance cystoscopies and have failed to detect any cancers [490, 491]. The cytology is often abnormal due to chronic inflammation.

Quality of life (QoL)

Oh et al. [492] conducted a prospective trial involving 132 SCI patients and 150 controls matched to age and sex to determine the psychological and social status of patients using CIC. According to health-related quality of life (HRQOL), the Medical Outcomes Study 36-Item Short-Form General Health Survey (SF-36) scores did not reveal any significant differences between the men and women in the patient group. When patients and controls were divided into two groups according to sex and age, the SF-36 scores of the patients were significantly lower than the controls across both sex and all age groups, other than the energy and vitality scale, the differences for which were not statistically significant in women and those younger than 50 years. Later Oh et al. [493] used the Beck Depression Inventory (BDI) with SCI patients on CIC and control group and found that the

average total BDI scores were 20.3+/-1.0 in the patient group and 11.4+/-0.5 in the control group, respectively; 69.6% of 102 the patients reported severe depression; female patients had a 3.8-fold higher risk of depression than male patients; and those who were unable to perform catheterization independently had a 4.6-fold higher risk of depression than those who were able to perform self-catheterization.

21.8. Treatment of NLUTD post SCI

The management is based on a multidisciplinary approach including urologists, rehabilitation physicians, physiotherapists, specialist nurses and often neurosurgeons and gastroenterologists. The goal of management of urinary tract in SCI patients is to preserve the upper urinary tract and renal function, to avoid urological complications and to improve patients' quality of life. There are several guidelines for management of neuropathic bladder dysfunction after SCI related neurogenic bladder [458, 460].

The treatment of bladder dysfunction following a SCI can be divided according to the level of injury (**Table 19**).

Table 19: Treatment of NLUTD associated with spinal cord injury

Bladder dysfunction in suprasacral injuries
To decrease neurogenic detrusor overactivity
Pharmacotherapy
Clean intermittent self-catheterization
Neurotoxins (Vanilloid receptors inactivators)
Botulinum toxin A
Neuromodulation
Sacral anterior root stimulator
Clam cystoplasty
Continent urinary diversion
Ileal conduit
To overcome external sphincter dyssynergia
Pharmacotherapy
Botulinum toxin A
Sphincterotomy
Urethral stents
Bladder Dysfunction in sacral injuries
To improve bladder emptying
Pharmacotherapy
Clean intermittent self-catheterization (clean & self)
Valsalva or crede maneuver
To improve sphincter function
Pharmacotherapy
Bulking agents
Slings
Artificial urinary sphincter
Bladder neck closure (females)

21.9. Treatments to manage neurogenic detrusor overactivity

Medications

Antimuscuranics competitively inhibit acetylcholine at muscarinic receptors. This is associated with detrusor relaxation and lower intravesical pressures. Several antimuscarinics drugs are available, including oxybutynin, tolterodine, propiverine, trospium, solifenacin, darifenacin and fesoterodine. Only a few studies have assessed efficacy and safety of antimuscarinics in NDO [494]. They are broadly equally efficacious, with slightly different side effect profiles (dryness of the mouth, blurred vision for near objects, tachycardia, constipation and drowsiness).

Desmopressin, synthetic analogue of vasopressin, reduces the urine production and has been shown to be useful for the treatment of polyuria in spinal cord injury [495].

Vardenafil has been reported to decrease maximum detrusor pressure and improve maximum cystometric capacity [496].

Intermittent catheterisation (IC)

IC is recommended as the safest method of bladder emptying for SCI persons with NBD, especially for those who have sufficient hand skills or a willing caregiver to perform the catheterization. Mizuno et al. [497] reported a paraplegic woman using CIC for 27 years who had no complications and absence of UI due to underactive and normal capacity bladder. However SCI men on CIC, according to the retrospective comparative study of patients on CIC had a 7.0-fold higher risk of epididymo-orchitis.

Previously, recommended bladder training with CIC was time-dependent, however, some experienced bladder over-distention, especially in those with polyuria, that made an IC programme unmanageable [498]. Polliack et al. [499] compared volume-dependent IC (VDIC) following bladder volume measurement by a portable ultrasound device in SCI patients with time-dependent IC (TDIC). After 12-30 days follow-up, the number of IC per patient per day, the time required to perform volume measurements and IC, and

their total cost, were approximately 44, 49, and 46% lower in the VDIC group than in the TDIC group. UTI was found in three patients in the TDIC group and in none in the VDIC group.

In developed countries, there is a variety of urethral catheters available for SCI individuals. However, in reviewing all controlled trials comparing methods of using catheters in people with neurogenic bladder dysfunction, Jamison et al. [500] could not draw any conclusions regarding the use of different types of catheter. According to the multi-centre RCT of De Ridder et al. [501], 57 SCI male patients completed the 12-month study; 64% of those using the SpeediCath hydrophilic-coated catheter experienced 1 or more UTIs compared to 82% of those using the uncoated polyvinyl chloride (PVC) catheter. Twice as many patients in the SpeediCath group were free of UTI. According to another multi-centre study of Bjerklund Johansen et al. [502], of 378 patients (the mean duration of IC was 4.6 yr) who completed a 12-d trial of the novel hydrophilic catheter: LoFric Primo, 55.2% of the patients were happy to continue with the novel device, which was 74% of patients using standard PVC catheters and 36% of those using prelubricated PVC.

Ozawa et al. [478] applied a contemporary (reusable) balloon catheter at night time only. After a mean follow up of 41 months, the incidence of febrile episode was as follows: CIC-wet 3.36 times/100 months, IDC 2.96, cystostomy 1.26, the contemporary catheter 0.57, and CIC-dry 0.42. The incidence of febrile episode in CIC-wet and IDC were significantly higher than in CIC-dry. The incidence of bladder stone was as follows: IDC 1.11 times/100 months, cystostomy 1.05, the contemporary catheter 0.96, CIC-wet 0.61, and CIC-dry 0.21.

Botulinum toxin type A

This has revolutionised the treatment of NDO since being popularised by Schurch and colleagues [503]. Botulinum toxin is a potent neurotoxin produced by the gram-positive anaerobic bacterium Clostridium botulinum. In the bladder, botulinum toxin has a direct effect on the presynaptic vesicular release of acetylcholine but also on sensory pathways [504]. It is associated with a significant improvement in urinary continence (40–80% of patients became completely dry), a decrease in mean maximum detrusor pressure (which became less than 40 cmH2O in most studies), an increase in maximum bladder capacity and an improvement of patients' quality of life. Injections are performed under local or general anaesthesia using flexible or rigid cystoscopy. Median duration of effect ranges from 7 to 9 months. This treatment has to be considered for individuals with SCI suffering from NDO with urinary incontinence refractory to oral antimuscarinics. The majority of patients have to perform CIC before and after botulinum injections. As a result of pivotal studies [505] a dose of 200U is licensed. A long term study has shown consistent results with repeated injections [506, 507].

Neuromodulation

Electrical stimulation has been used to manage bladder dysfunction in SCI since 1950s. Sacral neuromodulation (SNM) can be used as a second line treatment to control NDO in incomplete spinal cord injury. Sievert and colleagues [508] have demonstrated that use of SNM early in the injury recovery can prevent detrusor overactivity and maintain continence, in addition to preserving bladder capacity, reduced urinary infections and an improved bowel function. This was sustained for more than 2 years.

Sacral Anterior Root Stimulation

Sacral anterior root stimulation (SARS) with sacral deafferentation was first reported by Brindley in the 1970s [509], and results of small case series have been published [510, 511]. Detrusor overactivity is abolished by deafferentation. The electrodes are placed on the sacral anterior roots (S2, S3 and S4) to stimulate detrusor contraction, leading to bladder emptying. This can be used only in patients with complete lesions. The success rate is reported to be around 70%. In addition, this can be used to manage bowel dysfunction and achieve erections with separate programs. Importantly, men have to be informed that posterior rhizotomy will interrupt reflex erections.

Augmentation Cystoplasty

A number of procedures have been proposed to decrease detrusor overactivity and increase bladder capacity including detrusorotomy to subtrigonal cystectomy and ileal bladder substitution [512]. The one that has stood the test of time is clam cystoplasty, this technique involves bivalving the bladder and inserting a 20-30 centimetres of intestine segment in the defect.

The long term results indicate good control of overactivity and incontinence [513]. Generally, this is offered to patients who have failed to respond to botulinum toxin A injections or those with very low compliance bladder and in patients at risk for upper tract damage. If the patient has difficulty performing CIC via the urethra, a cutaneous diversion can be fashioned as well. Bladder augmentation is contraindicated in severe inflammatory bowel disease, significant pelvic irradiation related bowel damage and in patients who refuse CIC. These patients require life-long follow up. They can get a variety of problems including mucus production, persistent asymptomatic or symptomatic bacteriuria, stones, hyperchloremic metabolic acidosis, deterioration of renal function, bowel disturbances and cancer [514].

Cutaneous continent diversion

This is reserved for patients who cannot perform CIC via the native urethra because of congenital abnormalities, obesity, strictures and poor hand mobility. The principles are similar to bladder augmentation but a drainage channel is created between bladder and umbilicus or lower abdominal wall using either appendix (Mitrofanoff procedure) or ileum (Yang-

Monti procedure). Usually, the bladder outlet is left accessible as a safety mechanism. If the native bladder cannot be preserved, a substitution cystoplasty using ileum or colon can be performed. The complications are the same as described above for cystoplasty, with the additional risk of perforation, which can prove fatal if not diagnosed early.

Ileal conduit

This is generally reserved as a fall back option. It is a non-continent procedure, undertaken when there is severe motor and/or cognitive disability or in case of severe complications, alteration of renal function, or urethrocutaneous fistula. A cystectomy is often performed simultaneously as there is a risk of bladder cancer, pyocystis and spasticity. It can be performed laparoscopically [515]. The complications are mainly related to the uretero-ileal anastomosis, stomal hernia and pyelonephritis.

21.10. Treatments to overcome external sphincter dyssynergia

Medications

A number of medications have been proposed to overcome sphincter dyssynergia but the level of evidence is low. Baclofen can be used orally and intrathecally. High dosages are required with a significant risk of side-effects [516], including effects on erection and ejaculation [517]. The α-blockers that have been evaluated include indoramine, urapidil and tamsulosin. Alpha blockers have been reported to improve flow rate, increase voided volume and improve quality of life with a decrease in maximum urethral pressure. Abrams and colleagues reported that with tamsulosin treatment (0.4 and 0.8 mg once daily), 71% of patients reported an improvement of symptoms with good tolerance and decrease in dysreflexic symptoms [518]. Oral nitric oxide donors have been proposed to decrease urethral resistance in SCI patients [519].

Botulinum toxin A for sphincter

Botulinum toxin type A was first used to control DSD in the 1980s. It can be injected directly in the urethral striated sphincter. It is associated with an improvement in flow, with a decrease in postvoid residual volume and maximal urethral closure pressure. The benefits are variable, between 53 and 100 %, and lasting for 1 - 9 months [520]. These results have not been universally reproducible.

Sphincterotomy

This is a destructive procedure. The aim is to relieve the bladder outlet obstruction by cutting into the external urethral sphincter. It can be performed only in men because patients become incontinent and a condom has to be placed to collect urine. Endoscopic sphincterotomy was developed for the treatment of DSD in the 1950s. It has been demonstrated to be effective for both treatment of DSD and the prevention of genitourinary complications. However, this technique is associated with a failure rate of 15–50%, erectile dysfunction in 4–40%, perioperative complications such as septicaemia and haemorrhage in 5% of cases, and is irreversible [521]. Balloon dilatation has also been explored but is not advocated due to high failure rate.

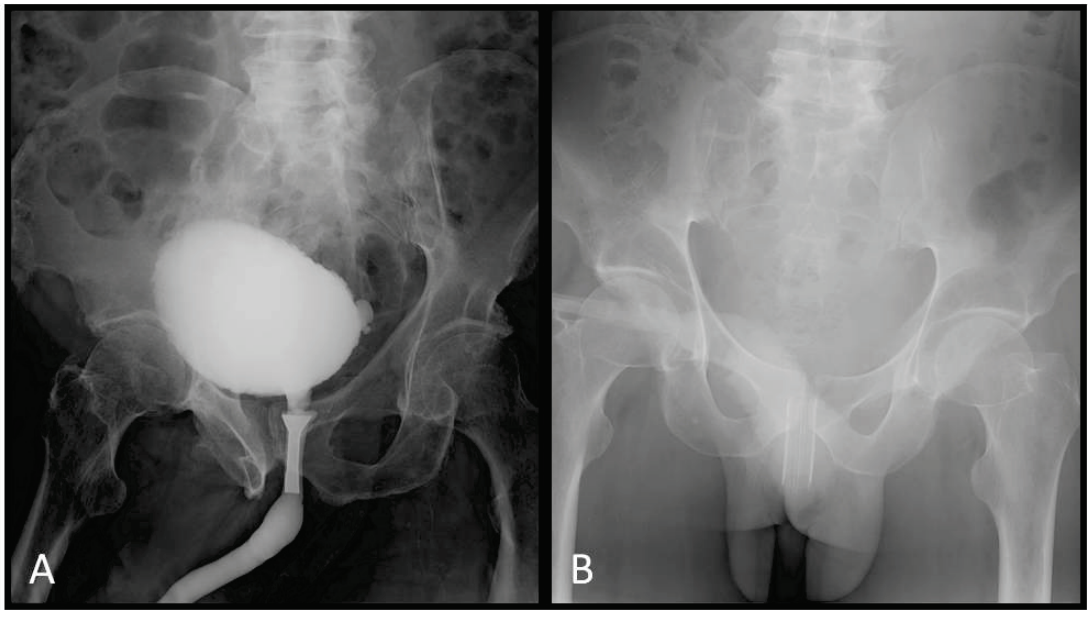

Figure 5: Quadriplegia patients with a temporary urethral sphincter stent (A) and a permanent urethral sphincter stent (B) Adapted from (525)

Urethral Stents

These were popularized in the 1990s. There are 2 varieties available: permanent and temporary stents. The temporary stents could be used as a test to ensure the acceptability of the voiding method, verify the efficacy on bladder emptying and give the patient time to think regarding a definite management strategy. It can also be used as a reversible treatment in patients with a transient problem whilst awaiting for recovery or rehabilitation of the upper limbs. Following temporary urethral sphincter stenting, 70 % of the patients choose a permanent one [522].

The long-term complications with permanent stents (Urolume) are stent encrustation, migration, bladder neck obstruction and if required, difficult stent removal [523]. The complications with temporary stents (Memokath) include a higher rate of stent migration, stent blockage with stone or calcification and recurrent urinary tract infections [524].

21.11. Bladder emptying in sacral injuries

Pharmacotherapy

There are no established medications to facilitate bladder emptying. Bethanechol chloride has been used with only limited success, and bothersome side effects including flushing, headaches and diarrhoea.

Clean intermittent self-catheterization

This is the mainstay to facilitate effective bladder emptying in an underactive detrusor. It is not a difficult technique to master but requires support from healthcare professionals. Generally, a size 14F catheter is used in males and a 12F in females. A variety of catheters are available and it is not uncommon for patients to try 2 or more types of catheter before finding the most convenient one.

Valsalva or crede maneuver

This entails emptying the bladder by increasing the intra-abdominal pressure. This can be performed by either valsalva technique or bending forward and compressing the lower abdomen. This is not an ideal method but for some SCI patients works quite well, if there is no outflow obstruction. In the absence of recurrent UTI this can be an acceptable technique for bladder emptying in some patients.

21.12. Treatments to improve sphincter function

Pharmacotherapy

These are no longer used as there has been a very limited benefit with their use. The drugs used include pseudoephedrine and phenylpropanolamine. Duloxetine has been shown to increase urethral resistance. Although some studies have shown improvement in continence rates this is generally limited to mild type with quite bothersome gastrointestinal side effects. It has not been specifically tried in neuropathic sphincter incontinence.

Bulking agent injection

This is a minimally invasive technique. It is performed endoscopically. Initially collagen based beads were implanted but they degraded over time. Currently, hyropolymers or silicone based substances (Macroplastique-polydimethylsiloxane) are used. They are effective in 60%-80% of cases but the effects are short lasting and quite often multiple injections are required [526]. The main advantage of this therapy is

being minimally invasive and it does not prevent further treatment.

Slings

These are used in females. They can be either autologous or synthetic. They are placed vaginally in the mid urethra. At present the synthetic slings are gaining popularity [527]. The reported efficacy is about 70%. The complications include difficulty in self catheterisation and development of de novo detrusor overactivity. Further research is needed to understand outcomes and risks.

Artificial urinary sphincter

This is the most effective method of achieving continence both in males and females, although the success rate is lower and complications higher than in non SCI patients. The complications include mechanical failure, erosion of the cuff or infection requiring removal of the implant.

Bladder neck closure

This is generally the last resort when other methods have failed. Bladder neck closure is usually performed when the urethra is almost destroyed- generally as a result of long-term catheterization. It is mainly employed in females, as sheath collection of urine cannot be employed, and can be performed either vaginally or abdominally. The initial success rate is about 50%, as the tissues are scarred secondary to infections and trauma and another 25% can be salvaged after a second procedure.

21.13. Prevention of UTI

According to 2 double-blinded, placebo-controlled RCTs [528, 529] studying the effectiveness of cranberry supplement (400-mg cranberry 3 times a day for 4 weeks and 2 g per day for 6 months, at preventing UTIs in SCI individuals with NBD, bacterial count, white blood cell (WBC) count, bacterial counts in urine, urinary pH or episodes of symptomatic UTI did not differ between the placebo and cranberry groups. According to another RCT to determine the effectiveness of methenamine hippurate (MH) (1 g twice-daily) and of cranberry (800 mg twice-daily), MH as well as cranberry did not have a significantly longer UTI-free period compared to placebo [530]. In addition, when taking phosphorus supplementation, there was no significant change in urine pH during the 2-week period compared to when the patient was off supplementation [531].

Antibiotic prophylaxis

Some centres advocate antibiotic prophylaxis for recurrent UTI [532]. Salomon determined the safety and efficacy of a weekly oral cyclic antibiotic (WOCA) regimen consisting of the alternate administration of an antibiotic once per week over a period of at least 2 years to prevent UTI in SCI adult patients; symptomatic UTI dropped from 9.4 to 1.8 per patient-year, no severe adverse events and no new cases of colonization with multiple drug resistant bacteria were reported [533].

Bladder irrigation

Waites and colleagues [534] conducted a randomized, double-blind comparison of twice daily bladder irrigation using 1 of 3 different solutions for 8 weeks with 30 mL of (a) sterile saline, (b) acetic acid, or (c) neomycin-polymyxin solution in community-residing persons with NBD who used IDC. Results showed that the 3 irrigants had no detectable effect on the degree of bacteriuria or pyuria. There was no significant development of resistance to oral antimicrobials beyond what was observed at baseline, but all groups had a significant increase in urinary pH.

Treatment of UTI

Bycroft and colleagues [532] found few centres routinely treating asymptomatic UTI in SCI individuals using catheters; and the range of recommended duration of treatment for symptomatic UTI was 3-14 days (mean 6.3).

Guidance for further research

Most of the papers relating to epidemiology and pathology of urinary incontinence in spinal cord lesion patients were case series; few papers were clinical trials or RCTs relating to pharmacological treatments. As UTI is a common complication among SCI individuals, further RCT should be done to prove whether a weekly oral cyclic antibiotic for UTI prophylaxis is effective, as well as optimal dosage, effectiveness and safety of bladder relaxants. Regarding types of catheter, RCT should be conducted to prove whether to re-use of catheters is safe. In addition, to make an automatic, event-driven electrical stimulation for the treatment of NDO suitable in a clinical setting further investigations are needed.

21.14. Urological follow-up practice

According to cohort studies [304, 450, 535] there was evolution of bladder management by time, outcomes and complications in both paediatric onset and adult onset SCI; treatment was modified in a substantial proportion of patients over the observation periods. Regular urodynamic follow-up is warranted for protection of the upper urinary tract (UUT) and maintenance of continence, however, urological follow-up practice varied: in Bochum, Germany, follow-up included urodynamic evaluation, sonography of the UUT and LUT, urine examination, and evaluation of renal function and treatment modifications were based on the urodynamic findings [536]; in the Spinal Injuries Units of U.K., all units performed routine upper tract screening, ranging from annually to every 3 years [532].

According to the retrospective chart review of Sepahpanah et al. [537], the 24-hour creatinine clearance (CCr) was highly variable from one evaluation to the next and the within-subject standard deviation (SD)

for CCr was 25.9mL/min; for all comparisons of repeatability, variability, and reliability, serum creatinine was superior to CCr, and renal ultrasound results and post-void residuals were the major factors in changing medical management with regard to renal function preservation. To determine the accuracy of bladder stone detection by abdominal x-rays of individuals with SCI, 13/62 (21%) of stones found during cystoscopy were detected by the x-ray; the detection by x-ray was 33% for stones 1.0 cm to 1.49 cm, 33% for stones 1.5 cm to 1.9 cm, and 54% for stones > or = 2.0 cm; and 57% for volumes > or = 1.0 cm^3 [474]. In addition, long-term SCI individual with aged 50 to 60 or more should be screened for prostate and bladder cancer [538, 539]; however, PSA cannot be used in patients with IDC and diagnosis should be based on prostatic biopsies [539].

Although SCI patients need lifelong follow-up, no studies have been done on the optimum frequency of follow-up to determine the frequency and the investigations required to achieve this goal. There is an urgent need to undertake prospective evaluation of SCI patients to draw evidence based conclusions for optimal follow-up protocols.

Conclusions

- The profile of muscarinic receptors in the bladder may be altered in patients with neurological disease (LOE 3)
- Skin sympathetic responses and motor evoked potentials may help assess autonomic and somatomotor pathways of the lower urinary tract. (LOE 3)
- In patients with neurological disease, individuals often change their method of bladder management, influenced by a range of factors including renal function. (LOE 2)
- Long-term urethral indwelling catheterization leads to bladder and urethral complications (LOE 3)
- Encrustation of a catheter is predictive of bladder stones; abdominal x-ray is not an adequate method to detect bladder stones (LOE 3)
- Volume-dependent intermittent catheterization may offer advantages compared with time-dependent intermittent catheterization. (LOE 3)
- Combined clean intermittent catheterization during the day time with indwelling contemporary balloon catheter at night time showed less urinary infection than clean intermittent catheterization with incontinence and permanent urethral indwelling catheterization. (LOE 3)
- Increased dosage of Tolterodine or Trospium gave a better effect to control neurogenic detrusor overactivity with incontinence. (LOE 2)
- Urethral flora may be a bacterial source for the development of urinary infection. (LOE 3)
- Low bacterial concentrations in the urine ($<10^5$cfu/L) of patients on intermittent catheterization might be due to contamination. (LOE 3)
- Cranberry extract, methenamine hippurate or phosphorus supplements were not found to be effective in acidifying urine or preventing urinary tract infection. (LOE 2)
- A weekly oral cyclic antibiotic seemed efficacious in preventing UTI. (LOE 3)
- Bladder irrigation was not effective in reducing bacteriuria in persons with neurogenic bladder using indwelling catheterization. (LOE 2)

Recommendations

- Regular urological monitoring, at least annually, is appropriate to early detect complications and to adjust bladder management in patients with neurogenic bladder dysfunction. (A/B)
- Recommend urine culture only if there is high risk of current urinary tract infection. (C)
- Routinely inspect catheters for encrustation, as an early indicator of risk of bladder stone formation. (C)
- Cystoscopy is necessary if bladder stones are suspected. (C)
- Adjust urinary tract management according to results of urological evaluation and emergence of complications. (B)
- Clear diagnosis of DSD requires VCUG facilitated by EMG. (C)
- Clear instructions on catheter management can help to reduce risk of complications. (B)
- Dosages of bladder relaxant drugs in excess of the licensed doses have been used in attempting to control neurogenic detrusor overactivity and incontinence; if side-effects cannot be tolerated, intravesical botulinum toxin injection are effective. (B)

21.15. Faecal incontinence in SCI

Epidemiology and prevalence

According to Dvorak and colleagues [540], in patients with central cord syndrome, bowel and bladder continence was reported by 81% in those with American Spinal Injury Association (ASIA) motor score improvement from a mean of 58.7 at injury to a mean of 92.3 at follow-up. However, neurogenic bowel dysfunction (NBoD) is common among spinal cord injury (SCI) patients. From 2004 to 2007, there were multiple studies reporting epidemiology of NBoD in chronic spinal cord injured (SCI), from various countries (see section below for details). Apart from SCI, there were

other spinal cord lesions (SCL) that cause NBoD, such as tumours (e.g. a conus medullaris ependymoma and filum terminale lipoma [541]; a clear cell meningioma along the thoracic and lumbar levels [542], neuroblastoma [543]; venous congestive myelopathy, mostly at thoracolumbar and/or conus medullaris levels [544]; and iatrogenic [545]. Tanaka reported 77% of 22 transverse myelitis (average age at onset 8.8 years, mean follow-up 7.1 years) had NBoD [546].

Table 20. Prevalence of neurogenic bowel dysfunctions reported in spinal cord injury patients

Study (year)	Countries	Subjects	Prevalence		
			Faecal incontinence	Constipation	Others
Liem et al. (2004) [547]	Canada	352 SCI (> 20 years)	41.8% (including diarrhea)	47.9%	
Ng et al. (2005) [548]	Australia	110 SCI (duration from injury, median 17 years)	41%	46% (including laxative use)	Abdominal pain 33% Abdominal bloating 22%;
Vallès et al. (2006) [549]	Spain	54 motor complete SCI (mean duration from onset 6 years)	85%	67%	
Vallès et al. (2007) [550]	Spain	109 patients 83% had spinal sacral reflexes (SSR)	31%	27% more in tetra A,B,C	
Pagliacci et al. (2007) [551]	Italy	403 SCI (duration from discharge to follow-up, mean 3 years)	2.7% (20.1% partial)		

21.16. Pathology and disease specific lower gastrointestinal (LGIT) problems

According to electromyography (EMG) of external anal sphincter (EAS), 18 and 22 of 64 patients with cauda equina or conus medullaris lesions had bilateral and unilateral EMG abnormalities [552]. Using anorectal manometry, the maximum anal resting pressure of a 26-lumbosacral SCI patients group with mixed symptoms of constipation and/or FI was slightly lower than that of a 13-normal volunteers control group [553]. During defecation, 88.5% of the patients but 7.7% of the control group significantly showed pelvic floor dysfunction (PFD). Rectoanal inhibitory reflex (RAIR) was identified in both groups. The rectal volume for sustained relaxation of the anal sphincter tone in the lumbosacral SCI patient group was significantly higher than the control group. The mean rectal volume to generate the first sensation was significantly higher in SCI patients than in the control group. Regarding constipation, its association with level of injury was supported by many studies, i.e. upper motor neuron vs lower motor neuron NBoD. Decreased colonic pressure activity was found during sleep in SCI individuals and may contribute to delayed colon transit time after SCI [554].

Furlan and Fehlings [555] examined the characteristics of the top 100 most frequently cited articles (so-called "citation classics") on traumatic SCI that were published between 1986 and 2003, and compared this selected professional literature with the consumers' perspective on the key issues in SCI research. From the SCI consumers' perspective, the areas of greatest interest included motor function, bowel and bladder control, sexual function, and pain. Motor function was the leading topic in the matching list between professional literature and consumers' perspective. According to Anderson's quality of life (QOL) survey of the SCI population [556], regaining arm and hand function was most important to quadriplegics, whereas regaining sexual function was the highest priority for paraplegics; and improving bladder and bowel function was of shared importance to both injury groups. Later, according to a web-based survey of 286 SCI patients aged 18 years or older, bladder and bowel concerns during sexual activity were not strong enough to deter the majority of the population from engaging in sexual activity; however, bladder and/or bowel incontinence during sexual activity was a highly significant concern in women with SCI. In addition, the occurrence of autonomic dysreflexia (AD) during typical bladder or bowel care was a

significant variable predicting the occurrence and distress of AD during sexual activity [557].

FI had 10 times more impact on QOL than those with no FI and NBoD had significant impact on their QOL [558]. They had significantly lower Gastrointestinal QOL score as compared with the normal persons. There were no statistically significant differences in satisfaction or QOL between those with colostomies and those with traditional bowel care programs; however, 55.7% of those with colostomies and 41.7% of those without colostomies were very unsatisfied with their bowel care program [559].

Conservative bowel management

According to the "Neurogenic Bowel Management in Adults with Spinal Cord Injury" Clinical Practice Guideline published by the Consortium for Spinal Cord Medicine, rectal stimulations help assist elimination of the stool: mechanical stimulations – digital rectal stimulation (DRS) and manual evacuation; and chemical stimulations – suppository and mini-enema (liquid suppository). Korsten et al. [560] used a manometric catheter to assess colonic motility at baseline, during DRS, and after DRS and evacuation of barium oatmeal paste in six subjects with SCI. Their results showed that manometric changes in response to DRS were accompanied by expulsion of barium oatmeal paste in every subject by the fifth DRS. In patients with cervical SCI, a significant increase in systolic blood pressure (BP) was induced by insertion of rectal medications and persisted during additional DRS, and AD induced by the manual removal of stool has been reported [561, 562]; however, systolic BP recovered to pre-program values within 5 min after defecation [561].

Uchikawa and colleagues [563] reported a successful bowel movement in 75% of 20 SCI patients by using a modified washing toilet seat equipped with a camera monitor and an electronic bidet to facilitate precise hitting of the anal area with water streams to stimulate bowel movement for a maximum of 30 minutes. Regarding transanal irrigation, a randomised study showed improvement in constipation, FI and symptom-related QOL in SCI individuals [564].

Push up, abdominal massage and a forward-leaning position may aid evacuation by increasing abdominal pressure. Ayaş et al. [565] studied patients with SCI and showed that abdominal message gave positive effects – increase in frequency of defecation per week, decrease in total colonic transit time and lesser FI.

Oral medications to enhance bowel movement have been used, but evidence of efficacy is lacking. Cisapride does not seem to have clinically useful effects in people with SCI [566]. Korsten et al. [567] did a randomized, blinded design, to test the efficacy of neostigmine in SCI persons with defecation difficulty by infusing one of three intravenous infusates (normal saline, 2 mg neostigmine, or 2 mg neostigmine + 0.4 mg glycopyrrolate – to prevent neostigmine's muscarinic effects) on separate days and determining bowel evacuation of the barium paste, heart rate and airway resistance. Their results indicated that both neostigmine and neostigmine + glycopyrrolate resulted in prompt bowel evacuation. Potentially, neostigmine may be administered by other routes [568].

21.17. Guidance for further research

Most of the studies reported were case series and used different definitions of faecal incontinence and constipation. Therefore further research should be based on internationally acceptable definitions so that they can be compared. In addition, RCTs on rectal or anal stimulations, both mechanical and chemical, as well as medications promoting bowel movement are needed.

Conclusions

- Constipation is more common than faecal incontinence among people with established SCI (LOE 3)
- Constipation is more common in those with preserved sacral reflexes, whereas faecal incontinence is more common in those without sacral reflexes. (LOE 3)
- Faecal incontinence has impact on the QOL of SCI individual and is a substantial concern for women with SCI during sexual activity (LOE 3)
- Digital rectal stimulations aid bowel evacuation in individuals with SCI, in part by increasing left-side colonic motility (LOE 3)
- Transanal irrigation with water improves constipation and quality of life in individuals with SCI (LOE 2)
- Abdominal massage may be effective in enhancing bowel movement and defecation (LOE 3)
- Anal stimulation by water stream may be effective in stimulating bowel movement and shortening bowel care time (LOE)

Recommendations

- Encourage adherence to the clinical practice guidelines on neurogenic bowel management in adults with spinal cord injury (A)
- Apply mechanical stimulation e.g. digital rectal stimulation, to aid bowel evacuation- especially in those with preserved sacral reflexes (B)
- Use chemical stimulants when mechanical stimulation fails (C)
- Beware of autonomic dysreflexia during bowel care, especially in those with a high SCI lesion (C)

- Consider transanal irrigation with water for those with severe chronic constipation and faecal impaction (B)

21.18. Sexuality

The majority of SCI patients (> 60 %) have alterations in sexual functioning. The degree of sexual dysfunction depends on the level and completeness of injury.

Male Sexual dysfunction

There is a significant impact of SCI on male sexual function. Erectile dysfunction occurs in up to 50 % of the patients. Less than 10% can ejaculate spontaneously. The patients with complete lesions above L2 level generally can have reflex and psychogenic erections. Patients with a complete lesion below S2 can generally have psychogenic erections. They have no reflex erections and ejaculation is rare.

As for non-SCI population, first-line treatment of erectile dysfunction is based on phosphodiesterase type-5 (PDE5) inhibitors. The three PDE5 inhibitors currently available are quite effective in treating erectile dysfunction in this patient group. Most of studies reporting the impact of PDE5 inhibitors in spinal cord injury used sildenafil. The reported erectile function improvement with sildenafil is more than 90% [569]. These treatments are also well-tolerated, with mild to moderate side effects including headache and facial flushing.

In case of failure of PDE5 inhibitors, the majority of patients are dissatisfied with a vacuum erection device, as they find it difficult to use- especially in patients with low hand dexterity. Intracavernous injections of vasoactive substances are effective, with a reported intercourse rate of up to 50 %. Priapism is not an uncommon occurrence, though the duration is variable. The injection can be performed by the partner in case of limited manual dexterity. When all conservative treatments fail, a penile prosthesis can be implanted. Like other implants the success rate is lower and complications higher in this patient group.

The majority of SCI patients cannot ejaculate. The most commonly employed technique to obtain semen is vibro-ejaculation. This is performed by a specially designed vibrator. The vibrator's plate is placed underneath glans penis and the vibrations are performed for 1-3 minutes. This is only effective in lesions above T10, as an intact spinal arc is required. The success rate is 60%-80% of cases. It can cause retrograde ejaculation. The complications include bruising and autonomic dysreflexia. In unsuccessful cases and for all patients with a lower motor neuron lesion, the ejaculate can be obtained by electroejaculation. This is performed with a probe in the rectum and stimulating the seminal vesicles with electric current. The success rate is around 98%. This is an invasive method and there is a risk of rectal injury. As it can be quite painful, it is generally performed under general anaesthesia or sedation for patients with an incomplete lesion.

Fertility in men is impaired after SCI due to erectile dysfunction, ejaculatory failure and abnormal semen characteristics. Alteration of sperm is promoted by urinary tract and genital infections, hormonal and hypothalamic-pituitary testicular axis abnormality, local temperature change and sympathetic nerve alteration [570]. Sperm retrieval is performed with vibro or electroejaculation. In the majority of cases, assisted conception techniques are required to achieve conception.

Conclusions

- There is a significant impact of SCI on male sexual function
- Erectile dysfunction occurs in up to 50 % of the patients
- Less than 10% can ejaculate spontaneously
- Patients with complete lesions above L2 can have reflex & psychogenic erections
- Patients with a complete lesion below S2 have psychogenic erections.

Recommendations

- Oral PDE5Is are the recommended first-line medical treatment (GR A)
- Intracavernous injections of vasoactive drugs (alone or in combination) are the recommended second-line medical treatment (GR A)
- Mechanical devices such as vacuum devices and rings can be effective and may be offered to patients (GR B)
- Vibrostimulation and transrectal electroejaculation are effective methods of sperm retrieval (GR B)

Female sexual dysfunction in SCI

There are only a few reports on female sexual dysfunction after SCI. The level and completeness of spinal-cord injury determines the preservation of psychogenic and reflex lubrication. Women with complete lesion above L2 have reflex lubrication. Those with a complete lesion between L2 and S2 have psychogenic and reflex lubrication and those with a complete lesion below S2 have psychogenic lubrication. Clitoral stimulation can lead to orgasm in patients with S2-S5 lesions.

It has been shown that all the domains of sexual function are altered in SCI women. Only 50% are able to achieve orgasm, with time to orgasm significantly increased. Female sexual function can also be altered by bladder and bowel incontinence and spasticity. Sildenafil has been reported to have a positive effect

on sexual dysfunction in a pilot study, with no associated adverse events [571].

Recommendation

- There is currently no effective medical therapy for the treatment of neurogenic sexual dysfunction in women (GR A)

The fertility in SCI women is not altered as compared to healthy individuals. The first months after injury are associated with amenorrhea but menstruations usually resume relatively soon. All contraceptive methods can be used.

Pregnancy in SCI women can be challenging. There can be issues with premature cervical dilatation and premature labour. The management of urinary tract infections and detrusor overactivity can be difficult as Botulinum toxin A injections are contraindicated in pregnancy. There are no guidelines on the use of antimuscarinics during pregnancy and the impact of these medications on the foetus has not been studied. Clean intermittent catheterization is maintained and often an increased number of catheters are required per day.

The management of labour is another problem. In women with an injury at level T6 and above there is an increased risk of developing autonomic dysreflexia. These women require frequent check-ups and early hospitalization if necessary. However, most women will have successful vaginal deliveries. SCI in itself does not constitute an indication for caesarean section. Probably the most important aspect of the management is involvement of a specialized multidisciplinary team.

Recommendation

- Management of fertility, pregnancy and delivery requires a multidisciplinary approach tailored to individual patient needs and preferences (GR A)

22. SPINA BIFIDA

22.1. Urinary incontinence

Spina bifida is one of the most common birth defects with an annual incidence of about 0.35 per 1000 live births in the US [572], potentially involving all levels of the spinal column but most commonly the lumbosacral area. Associated (Arnold-)Chiari malformation is seen in more than 80% of children, often requiring ventriculo-peritoneal shunting of cerebrospinal fluid. Ingestion of folic acid prior to conception and during the first trimester of pregnancy has significantly reduced the incidence of this problem and other associated neural tube defects. The neurologic defect produced is quite variable and cannot be totally predicted by the vertebral level of the lesion. Additionally the fibrosis associated with spine closure may tether the cord. Subsequent growth of the infant or child may produce further neurologic problems, manifesting as changes in bladder, bowel and lower extremity function.

The incidence of urinary tract dysfunction in spina bifida is not absolutely known, but most studies suggest it is very high (>90%). Similarly, anorectal dysfuction is very common, but its exact incidence has not been reported.

The two major neuro-urological consequences in patients with spina bifida are urinary incontinence and hydroureteronephrosis leading to renal failure, which can occur early or later in life. There are many studies documenting a variety of urodynamic findings of spina bifida patients such as detrusor overactivity, detrusor underactivity, low compliance, detrusor sphincter dyssynergia or static/ fixed external urethral sphincter [410, 414, 572, 573]

In the past, much attention has been directed at the significance of dyssynergia between the external sphincter and the detrusor, and the associated deterioration of the upper renal tracts in these patients. With the increasing use of IC, more emphasis has been placed on the pressure the bladder is able to generate prior to leaking as a prognostic factor in predicting upper tract deterioration.

Urodynamics is the cornerstone in the diagnosis of urinary tract dysfunction in patients with spina bifida. Urodynamic findings may predict the patients at risk of upper tract deterioration. Controversy continues regarding when to initiate these studies: as soon as possible after back closure; at the first sign of upper tract changes; or before considering management of incontinence. The preponderence of opinion suggests earlier diagnosis of potentially unfavourable factors is advisable.

As hydronephrosis and vesico-ureteric reflux are a consequence of detrusor dysfunction, synchronous fluoroscopic evaluation of the urinary tract is advisable at the time of urodynamics, i.e. video-urodynamics. Similarly, renal ultrasound has become an invaluable routine serial evaluation in these patients, assessing renal growth, development of scarring and, most importantly, hydroureteronephrosis. Repeat urodynamics and ultrasound have a relevant role in this patient population, however, recommendations for timing and frequency of these studies still need to be elucidated. Although renal scans are routinely used, especially in the spina bifida patient with hydronephrosis, the exact role of this study in these patients is not clear.

Urologic treatment depends on the age of the patient and the nature of the urinary tract dysfunction as characterized by urodynamics. Targeting the primary urological abnormality (the dysfunctional and usually poorly compliant bladder) allows implementation of effective treatments, including regular IC, in order to

preserve upper renal tract function and to achieve urinary continence. Associated postural abnormalities may complicate both conservative and interventional therapies.

The mainstay of treatment is IC and antimuscarinic medication. As continence is not at issue in the neonate and infant, treatment may be postponed, unless upper tract changes are present. Some evidence exists pointing to the fact that early initiation of treatment may prevent subsequent deleterious bladder changes. Although intradetrusor onabotulinumtoxinA injections have become an established treatment for refractory neurogenic detrusor overactivity incontinence [410, 414], the value in patients with spina bifida is unclear and there is a lack of high evidence level studies [574]. Surgical treatments should be reserved for patients refractory to conservative treatments, depending on the type of urinary tract dysfunction, and do not differ from the procedures for the general neuro-urological patients [410, 414].

In adult patients who in childhood underwent bladder augmentation surgery, it is thought that there is an increased risk of a development of bladder malignancies. However, this assumption is not supported by high level evidence and screening for bladder malignacies in spina bifida patients with an augmented bladder seems not to be cost-effective (LOE2) [572].

Lumbar-to-sacral nerve re-routing was suggested as an approach to restore voiding and bowel movement in spina bifida patients [575] (LOE3). Another interesting treatment option is fetal surgery, but *in utero* closure of spina bifida seems not to improve lower urinary tract function [576, 577] (LOE3).

Management of incontinence and/or upper tract deterioration mirrors the treatment of neurogenic lower urinary tract dysfunction. Variations in this algorithm include the use of vesicostomy in the younger child who has failed conservative measures and has evidence of deteriorating upper tracts. External sphincterotomy has no routine place in the management of these patients and the use of the appendicovesicostomy in continent LUT reconstruction (Mitrofanoff) has increased. Most studies on surgical management of neurogenic lower urinary tract dysfunction are descriptive (LOE 4) at best.

Data from adult and paediatric surveys show renal damage to be the single most prevalent cause of morbidity and mortality; even in children, 30-40% exhibit evidence of renal damage. Additional factors such as chronic infection and stone formation will then render the kidney more vulnerable to progressive loss of renal mass and subsequent chronic renal failure. Renal transplantation is now considered the optimal treatment for end-stage renal disease in all age groups. Although more prone to complications, recent data on patients with spina bifida or severely abnormal LUTs demonstrate good patient and graft outcomes [578] (LOE 3).

Guidance for further research

Further clarification of the role of fetal surgery to repair the neural tube defect is required, especially in term of prevention of damage to the lower urinary tract. Similarly the role of early intervention, conservative or surgical, needs to be understood better. The timing of surgical intervention needs further study, as well as better quality of life assessments and risk/ benefit analyses of LUT reconstructive procedures. The development of a tissue-engineered substitute for cystoplasy and nerve re-routing is being studied. Finally, the fate of the adult spina bifida patients, especially those who have undergone reconstruction, needs to be documented.

Conclusions

- Spina bifida is one of the most common birth defects (LOE 1)
- Incidence is decreased by appropriately-timed folate ingestion during pregnancy (LOE 2)
- Most patients have lower urinary tract dysfunction which can lead to incontinence and / or upper tract deterioration (LOE 3)
- The majority will derive significant benefit from conservative measures (LOE 3)

Recommendations

- Regular surveillance with urodynamics and renal ultrasound is mandatory from infancy. However the exact timing is not defined. One must observe the general rules for neurogenic lower urinary tract dysfunction (B)
- Early initiation of conservative measures (clean intermittent catheterization, antimuscarinic medication) generally provides protection of the upper urinary tract (B)
- The role of new treatment options, for example biotechnology and nerve surgery, needs to be evaluated (C)
- Extensive surgery is reserved for failed conservative treatment (B)

Bowel problems

Voluntary control of defecation requires rectal sensation, peristalsis and adequate anorectal sphincter function. Neurological defects in patients with spinal lesions may affect one or more of these components, resulting in different types of defecation disorders: fecal incontinence, chronic constipation or both. Incontinence is one of the major stigmas affecting patients born with myelomeningocele [579]. Bowel dysfunction occurs in most children with spinal cord impairment from disease or injury.

Although many different regimens have been used to manage this problem, none has had universal success. Behavioural modification and laxatives failed to

achieve an acceptable result because of the persistence of soiling. A small dose of laxatives alone accomplished nothing while administering a large dose to an incontinent patient only resulted in profound embarrassment [580]. Biofeedback was introduced for use in children with intact rectal sensation, but recent trials have reported less encouraging results. “Digital disimpaction” is unpleasant to perform and only succeeds in emptying the distal rectal ampulla.

Bearing in mind that few of these patients can resist the push of peristalsis, the most effective therapy is complete emptying of the colon, since it takes at least 24–48 h to refill again. This can be achieved nowadays by two ways: retrograde colonic enema (RCE) using a special balloon catheter, or an operative procedure which allows an antegrade continence enema (ACE). In neurological fecal incontinence, standard enemas are difficult, if not impossible, to administer, because there is inability to retain the enema- which flows out involuntarily through the weak anus during its instillation. Therefore a catheter-based RCE system has been developed by industry, the application of which can be applied either by the parents or even by children over the age of 7–8 years. Not all children tolerate this procedure, as colonic peristalsis creates pains in some of them. However the reported results are good according to Eire et al. [581]. Shandling et al. [582] reported 100% success in using the enema continence catheter in the management of patients with spina bifida. These authors regard the RCE as one of the best conservative methods of treatment for relieving fecal incontinence originating from myelomeningocele and other neurological problems.

The impact of ACE surgery in the management of patients with myelomeningocele was analysed by Lemelle et al. [579]. 47 patients were treated with ACE, of whom 41 still used the method at a mean time of 4.1± 1.9 years after the ACE operation. With ACE, faecal incontinence was significantly improved compared with conventional management, and neither retrograde rectal enema nor digital extraction were required. In most cases, ACE was performed using the appendix or the caecum. Six patients (12.8%) stopped using the ACE for various reasons, from conduit problems due to stomal stenosis or catheterization difficulties, lack of motivation or “too long time to empty the enema”. ACE stoma surgery was applied before, concomitantly or after urinary incontinence surgery in 5, 27 and 10 cases respectively. Enemas were performed at most three times a week, and tap water was used in the majority of patients. Mean volume for ACE was 1.2 L (range 0.25–3.0 L). Mean enema time for colonic washout with ACE was 50 ± 19 min (range 15–90 min), however mean washout duration for ACE tended to be shorter with implantation of the conduit on the left-segment of the colon.

Casale et al. [583] were unable to find any differences in the continence rate or stomal complications between total reconstruction (concurrent ACE and continent urine stoma) or staged reconstruction. However, because of shared pathology, the authors believe that most patients benefit from intervention in both the gastrointestal and the genitourinary tract. Therefore, a major advantage of total continence reconstruction is avoidance of the morbidity of a second major surgical procedure (LOE 3). Nevertheless, conventional treatment should be tested first, and the efficacy of RCE may be a predictor of the efficacy of ACE on bowel management. Moreover, percutaneous endoscopic insertion is fully reversible and does not present drawbacks potentially encountered with the catheterizable conduit [579]. Nevertheless, experience with the Malone procedure has proved that a suitable continent and catheterizable conduit can be obtained with an appropriate technique. In selected and motivated patients, and with the help of a specialist nurse providing close support in the postoperative period, surgical ACE procedure might be preferred according to the surgeon´s experience.

As no absolute indication has been defined for ACE, other criteria should be used to evaluate clinical outcome of bowel management, including health – related quality of life (HRQoL). The development of a disease-specific HRQoL measure for use with myelomeningocele has been proposed by Parkin et al. [584]. HRQoL assessment should be performed prospectively when ACE produce is planned and performed during pre and post-operative periods. According to Eire et al. [581] ACE procedure and RCE can be the best options for achieving the best social integration. For wheelchair users and other selected patients, the ACE (being faster and easier) is better than the RCE, which needs some help in its use [581, 585].

Sacral neuromodulation has been described also in the therapy of these patients, but the persistence of continence control and tolerance of the patient need to be evaluated for a prolonged period of time. Sacral neuromodulation may only be successful in a small selected number of patients, in whom preserved anatomy of the sacral nerves permits placement of the electrodes on the sacral nerves [586].

Conclusions

- Neurologic bowel dysfunction and bowel problems, including fecal incontinence and constipation, are prevalent among myelomeningocele patients (LOE 3).
- Fecal incontinence and methods of bowel care affect the QoL and social activities of myelomeningocele patients (LOE 3).
- The main goal is to empty the colon as much as possible, to achieve continence during the subsequent 24–48 hours. This can be achieved by retrograde colonic enema using a special ballon catheter, or by an operative procedure which allows an antegrade continence enema (ACE) (LOE 3).

Recommendations

- Colorectal problems require attention in the treatment of myelomeningocele patients (GOR B)
- Appropriate bowel programme / management should be properly designed for each person, after adequate counselling (GOR B)

23. DIABETES MELLITUS

23.1. Epidemiology

Diabetes mellitus (DM) has a prevalence of 1-6% in the United States, depending on the specific criteria utilized to identify the disease. The prevalence is significantly higher amongst the elderly: 21.8% of residents of nursing homes suffered from DM in a multinational eight countries study (the Services and Health for Elderly in Long TERm care (SHELTER) project [587].

Overall, up to 59% of diabetic patients will report urinary symptoms, while 75-100% of those with evidence of peripheral neuropathy will develop NLUTD [588] [589]. The classic “diabetic cystopathy” (impaired bladder sensation, increased capacity, increased post void residual) has been estimated to occur in 43% to 87% of insulin-dependent diabetics, with no sex or age differences [590].Typically, severely impaired bladder emptying is thought to occur in patients with more long-standing poorly controlled diabetes. It is also described in about 25% of diabetic patients on oral hypoglycemic treatment [591]. A Scandinavian study showed that in patients who have had diabetes for 10 years, the prevalence of diabetic cystopathy in those who were insulin-dependent was 2 to 4 per 1000 and in those on oral hypoglycemic agents was 1 to 3 per 1000. The correlation between diabetic cystopathy and peripheral neuropathy ranged from 75% to 100%. Nephropathy was seen in 30% to 40% of cases [589] (LOE 3). Urodynamic studies have noted a spectrum of findings in DM; those presenting relatively late with severe LUTS have a higher likelihood of impaired bladder sensation, detrusor underactivity and impaired emptying, while those investigated earlier are more likely to have detrusor overactivity and urgency incontinence [592].

23.2. Diabetes and Urinary incontinence

Large prospective studies are now available (the Diabetes Control and Complications Trial (DCCT; 1983-1993) and its observational follow-up study, the Epidemiology of Diabetes Interventions and Complications (EDIC; 1994- present, the Diabetes and Aging Study, NHANES, the Services and Health for Elderly in Long TERm care (SHELTER) project). These confirm the association between DM and incontinence. In gynaecological consultations, DM is a risk factor for incontinence, together with prolapse and gynaecological surgery [593] [587, 594]. In a controlled study, after adjusting for age, body mass index, parity and history of urinary tract infections, diabetes was significantly associated with any incontinence (OR: 1·99; 95% CI: 1·44-2·74) urgency incontinence (OR: 2·23; 95% CI: 1·38-3·61) and stress incontinence (OR: 1·54; CI: 1·07-2·22) [595] (LOE 1). Gestational DM is an independent risk factor for all types of UI. Compared with women without gestational DM, women with it tended to exhibit more severe symptoms of stress incontinence for up to 2 years postpartum, whereas for urgency or mixed incontinence, more severe symptoms were found only for 6 months postpartum [596].

Among women with type 2 diabetes white race, higher body mass index, higher parity, lower physical activity, current postmenopausal hormone use and diuretic use were risk factors for prevalent and incident UI, whereas hysterectomy, vascular disease and longer duration of diabetes were associated with increased odds of prevalent UI only (Nurses' Health Study I and II) [597]. Diabetes duration, treatment type, peripheral neuropathy, and retinopathy were significantly associated with severe incontinence in multiple regression models adjusted for age, education, and history of UTI [598] (LOE 3). Lewis et al. in a cross-sectional study of 50-90 year old women found that insulin dependent diabetes was strongly associated with UI, while non insulin dependent diabetes was not [599] (LOE 2). In other studies, both the use of insulin (OR 2.62, 95% CI: 1.67-4.13) and of oral glucose-lowering agents (OR 1.81, 95% CI: 1.33-2.45) were predictors of UI in community-dwelling frail older adults with DM [600]. Most, but not all, studies suggest that diabetic measures, such as glycemic control, may be associated with UI. In women with Type 1 diabetes, incident UI was associated with higher HbA1c levels, independent of other risk factors [601]. Among women with relatively controlled diabetes, each one-unit increase in HbA1c was associated with a 13% increase for any UI and a 34% increase in risk for only stress incontinence but was not significantly associated with urgency or mixed incontinence [602]. In a controlled study, after adjusting for all variables, high HbA1c levels were associated with OAB (odds ratio 1.24, 95% confidence interval 1.06-1.45), urge UI (odds ratio 1.20, 95% confidence interval 1.00-1.45) and nocturia [603]. Compared to women with normal HbA1c participants with DM type II had an increased prevalence of stress and urge UI (38.6% vs 52.5% and 21.7% vs 40.3%, respectively). Diabetes measures (glycemic control and insulin resistance) were each significantly associated with UI in univariable but not in multivariate models when adjusted for patient body mass index [604] . Also, in community-dwelling frail older adults with DM, UI was not associated with HbA1c level, but with geriatric factors such as the inability to ambulate or transfer independently [600]. In the Diabetes and Aging Study, HbA1c levels were again not associated with the presence or absence of incontinence, alt-

hough poor glycemic control (HbA1c ≥9%) was associated with more limitations in daily activities due to incontinence [605]. Also, there is level 2 evidence that poor glycemic control increases the frequency of UTI in women with type 1 diabetes. For every unit increase (1%) in recent HbA1c level, there was a 21% increase in UTI frequency after adjusting for race, hysterectomy status, urinary incontinence), sexual activity, peripheral and autonomic neuropathy and nephropathy [606].

Consequently, the question is whether improved glycemic control can lead to modification of the risk of UI. Available studies to date have demonstrated a variable, positive effect. In the Diabetes Prevention Program Outcomes Study which included 1778 female participants who had been randomly assigned to intensive lifestyle intervention, metformin or placebo, Intensive lifestyle intervention had a modest positive but enduring impact on UI (prevalence 46.7%, 53.1%, 49.9% urinary incontinence/week) [607] . In the Look AHEAD trial in a cohort of overweight/obese men with type 2 DM, intensive lifestyle intervention reduced the odds of prevalent UI by 38% at 1 year compared to diabetes support and education. The prevalence of UI decreased from 11.3% to 9.0% in the intensive lifestyle intervention group and increased from 9.7% to 11.6% in the diabetes support and education group. The intensive lifestyle intervention group also had almost twice the odds of UI resolving compared to the diabetes support and education group [608].

Van Poppel et al. [609] reported neuropathological examination of bladder biopsies from 14 patients with severe insulin-dependent adult-onset diabetes, compared with acetylcholinesterase and S100 staining of 38 control specimens. A decrease in acetylcholinesterase activity, due to axonal degeneration, was found in all cases. An increase in S100 positivity was found in the majority and is due to Schwann cell proliferation as a regeneration attempt after demyelination or axonal degeneration. When acetylcholinesterase activity decreases and an S100 density increase is found in a patient with diabetes, this combination is highly suggestive of diabetic cystopathy amenable to early symptomatic treatment (LOE 2). Because of the uncontrolled hyperglycaemia, patients with DM develop altered NGF activity, which may be a mechanistic factor in the development of diabetic bladder dysfunction [610] [611]. In this respect, electrophysiological studies offer support to associations between diabetic cystopathy and peripheral neuropathy. Hyposensitivity of unmyelinated C-fiber afferents at the distal extremities was found to be an indicator of early-stage diabetic bladder dysfunction in type 2 diabetic women. C-fiber dysfunction at the distal extremities appeared to be concordant with vesical C-fiber neuropathy [612].

Since the peripheral nerves are involved, the clinical manifestations of diabetic cystopathy might be very varied. Usually there is reduced sensation of bladder fullness, and decreased frequency of voiding. This is followed by slowing of the urinary stream and difficulty in voiding due to impaired detrusor contraction. Post-voiding dribbling may also occur. The impaired bladder emptying and urinary retention predispose to urinary tract infections. A prospective study investigated the temporal effect of DM on the functional disturbances of the LUT in diabetic patients. In a cohort of 181 women with type 2 DM, there appeared to be a time-dependent progression trend in the development of bladder dysfunction, advancing from urodynamic stress incontinence to DO and/or increased bladder sensation and eventually to impaired voiding function. The duration of DM was longer in women with voiding dysfunction (6.8 ± 2.8 years in women with stress incontinence, 7.3 ± 6.5 years in DO and/or increased bladder sensation, and 10.4 ± 8.3 years in women with voiding dysfunction) [613]. Earlier studies had suggested that urine output does not contribute significantly to diabetic cystopathy [614].

Retrospective studies support however an unfavourable effect of DM on detrusor contractile force. Mean maximal flow rate and $P_{det}Q_{max}$ and bladder contractility index were lower in the DM group, in whom mean DM duration was 9.24 ± 7.63 years and mean HbA_{1c} level 7.27 ± 1.43 %. DM duration was significantly correlated with Q_{max}, $P_{det}Q_{max}$, and BCI. Moreover, the HbA_{1c} level was negatively associated with Q_{max}, $P_{det}Q_{max}$, and BCI [615]. In diabetic women, poorer glycemic control was associated with an increased likelihood of PVR ≥ 100 mL (OR 1.30, CI 1.06-1.59 for each-one unit increase in HbA1c) [616].

Yamaguchi et al. studied 84 diabetic cystopathy patients [617]. In addition to large post-void residual and decreased sensation, urinary urgency, DO, and increased bladder sensation were seen in 55%, 42% and 14%, respectively. The prevalence of DO in patients with increased bladder sensation was 58%. DO increased with age, but not with the duration of diabetes. Urodynamic characteristics of DO are different between diabetic women and age-matched controls; amplitude of first overactive contraction, volume at first overactive contraction and maximal detrusor pressure were greater in diabetics compared with the non-diabetic group (16.00 cm H2O vs. 9.00 cm H2O, 309.00 mL vs. 167.00 mL and 76.48 cm H2O vs. 55.41 cm H2O respectively) [618]. In a brain MRI study of 32 cases, the prevalence of multiple cerebral infarctions in patients with DO was 76.5%. The authors concluded that urinary urgency is not uncommon in diabetic cystopathy. Both central and peripheral mechanisms are involved [619] (LOE 3).

Ishigooka et al. [620] (LOE 3) described the results of the ice-water test in diabetic patients with and without cystopathy. 12.5% of patients without cystopathy and 25% of patients with cystopathy did not feel the ice water sensation. Ueda et al. [621] (LOE 2) performed studies evaluating sympathetic skin response in correlation with cystometry. They found that patients without sympathetic skin responses had increased residual urine and decreased detrusor contraction pressure, while patients with lower amplitude of sympathetic skin response and more prolonged latency

than controls had a significant decrease in detrusor contraction pressure. The changes within the bladder function were observed as early as within one year from the diagnosis of diabetes.

Beylot et al. [622] (LOE 2) found that the presence of residual urine in diabetic patients, after exclusion of co-morbidities, was strongly associated with peripheral neuropathy. Ho et al. showed increased bladder sensation, followed by DO in 94 female diabetic patients undergoing urodynamic studies [623]. Those patients with OAB are more likely to have impaired voiding function. In a questionnaire based survey, OAB was twice as prevalent (24.2%) in diabetics compared to the general population, while the presence of symptomatic diabetic polyneuropathy significantly increased the risk for development of OAB [624]. Similarly, in a cross-sectional hospital-based survey of women with type 2 DM, peripheral neuropathy, nephropathy, and presence of metabolic syndrome were significantly associated with moderate to severe LUTS and OAB [625]. In a controlled, questionnaire-based survey, diabetic patients had higher OAB-q scores compared to the control group, with disease duration showing significant correlations with OAB-q scores (LOE1) [626]. In another controlled study DM patients had a significantly higher proportion of OAB symptoms compared with the controls (28.0% vs 16.3%), as well as nocturia (48.0% vs 39.1%)(LOE1) [603].

No specific treatment has been described in regards to the population of patients with diabetic cystopathy. Therefore general rules as for the other bladder conditions with impaired (absent) detrusor contractions should be followed. Sacral Neuromodulation has been used to treat LUTD in DM, with similar long term results as in non DM patients [627]. By contrast, in women undergoing mid-urethral sling procedures for UI lower cure rates were seen in diabetics (0.50; CI 0.35-0.74) [628]. Similarly, in a controlled study, the presence of DM was associated with a significantly smaller reduction of OAB symptoms when treated with antimuscarinics, but the effect attributable to diabetes was small relative to the overall treatment response (LOE1) [629].

Future research should endeavour to give epidemiological information on the incidence of both type I and II diabetes-related functional disorders of micturition, and specific results of therapeutic interventions on each type of incontinence as well as on urinary tract infections. Gender effects should also be investigated.

Conclusions

- Diabetic cystopathy occurs in up to 80% of insulin dependent diabetes mellitus (LOE3)
- Urinary incontinence is strongly associated with diabetes. The current evidence is stronger for insulin dependent diabetes compared with insulin independent diabetes (LOE 2)
- The frequency and severity of Overactive bladder is increased in diabetes, presumably reflecting both central and peripheral mechanisms (LOE 1,2)
- Patients with diabetic cystopathy generally can have OAB and/ or impaired detrusor contractions with increased post-void residual (LOE 3,4)
- The urodynamic characteristics of detrusor overactivity are different in diabetics compared to controls (LOE 3)
- There is an unfavourable effect of diabetes and poor glycemic control on the urodynamic contractile characteristics of the detrusor (LOE 3,4)
- Poor glycemic control is associated with higher risk of increased post-void residual (LOE 3,4)
- In type 1 diabetes, poor glycemic control is associated with higher risk of urinary tract infections (LOE2)
- Recurrent urinary tract infections might be a long term problem (LOE 3,4)
- Intensive lifestyle intervention in diabetics has a positive impact on the prevention and resolution of urinary incontinence (LOE1)
- There is a lack of specific treatment for diabetic cystopathy
- However, the presence of diabetes may negatively affect the outcomes of surgical treatment for stress UI and pharmacotherapy for OAB (LOE 1,2)

Recommendations

- Post void residual measurement and urine dipstick (optional culture) for patients with diabetes mellitus should be performed yearly (C)
- In case of increased post-void residual, prompted voiding might be useful (C/D)
- Treatment of choice for acontractile bladder in this group remains intermittent catheterization (B/C)
- Patients with diabetes and incontinence should receive consultation about the positive effect and consequent need for (intensive) lifestyle intervention and good glycemic control (A)
- Patients should be warned about the negative effect of diabetes on the improvement of stress incontinence and OAB symptoms following appropriate therapeutic interventions (C)

23.3. Faecal Incontinence

Caruana et al. [630] (LOE 3) found that diabetic patients with faecal incontinence showed increased thresholds of phasic external sphincter contraction and had reduced resting/ maximal voluntary anal

sphincter pressures compared with controls. Increased thresholds of conscious rectal sensation in some incontinent patients with diabetes may contribute to faecal incontinence by impairing the recognition of impending defecation. Nakayama et al. [631] (LOE 3) found that age and diabetes have an independent negative influence on faecal incontinence after stroke. Abnormal internal-anal-sphincter function could be contributory in diabetic patients with faecal incontinence [632] (LOE 3). Russo found that acute hyperglycaemia inhibits external anal sphincter function and decreases rectal compliance, which could explain the pathogenesis of faecal incontinence [633] (LOE 3).

Talley and colleagues [634] (LOE 3) studied gastrointestinal symptoms, frequent abdominal pain, bowel-related abdominal pain, reflux, dyspepsia, constipation, diarrhoea and faecal incontinence in diabetic patients. There was a clinically significant decrease in QoL scores in diabetics compared with population norms across all subscales. The impact on QoL in diabetes was predominantly observed in type 2 diabetics. For all the Short Form-36 subscales, GI symptom groups were significantly associated with poorer QoL in diabetes, independent of age, gender, smoking, alcohol use, and type of diabetes.

Cross-sectional analyses of data from the Nurses' Health Study revealed that obesity was associated only with urinary incontinence while type 2 DM was a stronger risk factor for fecal than urinary incontinence [635].

Conclusions

- Faecal incontinence in diabetes patients may be due to impaired anorectal sensation and/or decreased anal closing pressure after hyperglycemic episodes (LOE 3)
- Gastro-intestinal symptoms impact negatively on health-related QoL in diabetes mellitus (LOE 3)

Recommendations

- Patients with diabetes and fecal incontinence should have anorectal manometry performed before introducing therapy for fecal incontinence (C/D)
- More studies on neurologic bowel dysfunction and management in diabetes are needed (B).

24. SYSTEMIC AND OTHER CONDITIONS

24.1. Systemic Lupus Erythematosus

Nervous system involvement occurs in about half of patients with systemic lupus erythematosus (SLE) [636]. Neurological manifestations of SLE are subacute encephalo-myelopathy, subacute myelopathy (rarely) and chronic encephalomyelopathy. Seizures and psychiatric disorders are the most common manifestations, while spinal cord lesions are uncommon. Symptoms of LUT dysfunction can occur, however, data on prevalence are lacking. Several pathological urodynamic findings are reported [636-638]: slow urinary stream, high post-void residual, high maximum urethral closure pressure, detrusor overactivity, low compliance bladder, low maximum cystometric capacity, or loss of bladder sensation. LUTS in patients with SLE may also be caused by lupus cystitis, a rare entity often associated with lupus mesenteric vasculitis [639].

Conclusions

- About half of the patients with SLE show nervous system involvement. Subacute and chronic encephalomyelopathy may cause LUT dysfunction with varying patterns (LOE 4).

Recommendations

- Urodynamic investigations are necessary to define the underlying pathophysiology of the urinary symptoms, and are relevant to guide treatment (B).

24.2. Herpes Zoster

Herpes zoster (shingles) results from reactivation of the dormant varicella-zoster virus (VZV) resulting in vesicular eruptions of the skin or mucous membranes. Two distinct syndromes due to genital varicella zoster infection, cystitis and urinary retention, have been described. Cystitis classically presents with dysuria, frequency and hematuria and cystoscopic verification of local inflammatory changes on the bladder mucosa should be performed for the diagnosis of herpetic cystitis [640, 641] (LOE 3). Urinary retention may precede the emergence of the characteristic dermatomal skin rash [642], or it may follow initiation of zoster therapy [643].

The overall incidence of LUT dysfunction is 4% [644], however involvement is reported as high as 28 % if cases of lumbosacral involvement are considered. According to Chen et al., voiding dysfunction following herpes zoster can be; 1. Cystitis-associated, whereby direct involvement of the bladder wall results in herpetic cystitis, 2. Neuritis-associated, due to retrograde spread of infection by the VZV from the dorsal root ganglia of the sacral segments, or 3. Myelitis-associated, caused by herpetic myelitis. Occasionally, patients with skin rash in the lumbar or even lower thoracic dermatomes may develop bladder dysfunction and this is thought to be due to spread of VZV to the sacral segments.

Two case reports describe urodynamics findings in herpes-zoster patients. Usually patients develop complete urinary retention, with or without overflow incontinence due to detrusor acontractility and lack of

bladder sensation. Repeat urodynamic studies at week 10 after the onset of the disease demonstrated a return of the detrusor contraction, normalising after 14 weeks [645, 646] (LOE 4).

Herpes zoster-associated voiding dysfunction is a transient phenomenon and is not uncommon in patients with lumbosacral dermatome involvement. Treatment with IC or indwelling catheter placement is recommended in order to avoid secondary damage to the LUT due to chronic urinary retention or UTIs. The disease usually is of a benign clinical course, with recovery of bladder functions.

Conclusions

- 28 % of patients with Herpes zoster in the lumbosacral dermatomes show LUT dysfunction, with impaired voiding as the most common symptom (LOE 4).
- The most common symptom is overflow incontinence due to detrusor acontractility and lack of bladder sensation (LOE 4).
- Voiding dysfunction has a transient course and almost every patient will regain normal voiding within 3-4 months, or at the least achieve balanced bladder function (LOE 3).

Recommendation

- Till functional recovery takes place, urinary tract management with intermittent catheterisation or indwelling catheter is recommended (GOR B).

24.3. HIV

Urinary incontinence

HIV virus belongs to the family of retroviruses. This family of viruses is known for latency, persistent viremia, infection of the nervous system, and weak host immune responses. HIV has high affinity for CD4 T-lymphocytes and monocytes. HIV binds to CD4 cells and becomes internalized. The virus replicates itself by generating a DNA copy by reverse transcriptase. Viral DNA becomes incorporated into the host DNA, enabling further replication. HIV enters the nervous system early, at the time of initial infection, and may immediately cause symptoms, or it may cause delayed-onset symptoms, potentially at any time during the person's lifetime. All parts of the nervous system may be involved. Neurological disorders could be HIV-related, or due to secondary infections, malignancies, metabolic or nutritional problems and to therapy.

It is estimated that up to 80% of patients are symptomatic in terms of nervous system and for 30%, neurological symptoms are the initial clinical problem, in the absence of anti-retroviral treatment. Neurological syndromes may be the sole clinical problem or cause of death. The following brain symptoms have been described: meningitis, dementia, stroke, seizures, and degenerative disorders. For the spinal cord, transverse myelitis and progressive myelopathy have been observed.

Due to nervous system involvement in HIV infection, consequent effects on LUT function can be anticipated [647]. Shin et al. (LOE3) described a higher prevalence of incontinence in HIV-positive patients as compared to HIV-negative in nursing homes [648]. Whether this represents a true trend, or an observation related to the terminal stage of the disease and associated comorbidities, remains to be elucidated. Gyrtrup et al. (LOE 3) found voiding problems in 12% of HIV-infected patients, mostly in advanced stages of the disease [649].

Virtually all parts of the body could be involved in AIDS patients, either as the primary location of HIV infection or secondary to HIV-related complications. Among the different manifestations, particular attention should be paid to the primary locations as they develop early in the stage of the disease. HIV can affect all areas of the central and peripheral nervous system- for example, HIV-associated dementia, vacuolar myelopathy, distal sensory peripheral neuropathy and myopathy. Pelvic organ dysfunction has, however, been little studied. Patients may develop voiding dysfunction and chronic retention due to lumbosacral polyradiculopathy. Prior to the introduction of the newer anti-retroviral therapies in the 1990s, infection with cytomegalovirus was the most common cause [650] and other causes include lymphomatous infiltration, syphilis or a herpetic radiculopathy due to herpes varicella zoster or simplex. Mahieux et al. (LOE 3) described a case of acute myeloradiculitis due to cytomegalovirus as the initial manifestation of terminal stage HIV [651]. Matsumoto et al. (LOE 3) [652] reported a case of lumbosacral polyradiculopathy where voiding difficulties and lower limb paresis were the primary manifestation of HIV infection. Another pattern of LUT dysfunction is urgency incontinence and DSD [649] in the context of vacuolar myelopathy.

Bladder cancer is a recognised occurrence in these patients [653]. Though rare, they can occur in relatively young HIV-infected patients with a low CD4 nadir, presenting with haematuria. Most of them are smokers, and have aggressive pathological features [654-656].

Begara et al. (LOE 3) performed urodynamic studies in 10 patients with AIDS and voiding disorders and found that the most common symptom was urgency incontinence and the most common urodynamic finding was DSD [657]. In 3 patients they found demonstrable functional disorders of the LUT (2 patients had DO: one of them had a history of encephalopathy from HIV and the other patient had polyneuritis; the third patient had myelitis and a urodynamically-diagnosed sympathetic decentralization. Detrusor areflexia was described in 2 HIV-positive patients by Menendez et al. [658] (LOE 3). One of them had an ascending myelitis of probable herpetic origin, the

other had a cerebral abscess caused by Toxoplasma gondii.

Since during the course of the disease all parts of the nervous system can be involved, either as the primary location or secondary to AIDS-related complications, no disease specific diagnosis or treatment can be proposed. It is important to observe that sometimes functional disorders of the LUT can be the first manifestation of the HIV infection. When managing the patient with HIV infection one must bear in mind that both storage and voiding problems can occur and that both should be treated, potentially according to the results of urodynamic studies.

Future research needs to be supported by a stronger evidence base. All reports of HIV and voiding problems are rather anecdotal and no good prospective studies exist. The need for such studies is particularly important, when realizing that it takes up to 20-30 years from HIV infection to AIDS full manifestation, and that new antiviral treatment modalities could prolong the life of a patient with HIV significantly. Particular attention should be paid to primary nervous system involvement by HIV and the voiding dysfunctions that could be the side effects of HIV drug therapy.

Faecal incontinence

As diarrhoea is common in HIV infected patients, faecal incontinence can also occur, mostly due to anal sphincter weakness. The true incidence of HIV neuropathy-related faecal incontinence is not known and further studies are needed [659] (LOE 4). Many of the limitations of knowledge seen with urinary incontinence apply to faecal incontinence.

Conclusions

- HIV can influence the nervous system and LUT function in two ways: as a result of primary infection, or secondary to AIDS-related complications (LOE2/3).
- Nervous system manifestation of HIV infection can by the only sign of infection, and it is therefore important to take the possibility of HIV infection into consideration when facing unusual signs and symptoms from the LUT without any other obvious cause (LOE 3).
- HIV/AIDS is a progressive disease and dynamic changes to the LUT functions can occur during the evolution of the disease (LOE 2).
- Faecal incontinence in HIV/AIDS patients is usually associated with diarrhoea, however the true incidence is not known (LOE 4).
- Bladder cancer should be considered in any HIV patient with haematuria (LOE 4)

Recommendations

- Patients with HIV and nervous system pathological signs and symptoms should be evaluated for functional LUT problems (B).
- Due to the variety of LUT functional damage in HIV patients, dynamic evaluation of LUT function is essential for tailoring of therapy (C).
- No HIV-specific therapy of LUT problems and faecal incontinence is currently available. Due to the variety of functional damage, therapy should be individually tailored, according to the results of functional/ imaging studies (C).
- All HIV patients with haematuria should be screened for bladder cancer (B)

24.4. Neurosyphilis

Neurosyphilis results from longstanding infection with Treponema pallidum. Bladder dysfunction is common, though most classically in tabes dorsalis. The predominant neurological manifestations are sensory ataxia and spontaneous lancinating pains. Voiding dysfunction occurs due to involvement of sacral posterior roots and the dorsal column of the spinal cord, resulting in loss of bladder sensation and significantly elevated post-void residual urine. The bladder is atonic, though there may be some myogenic damage from chronic over distention. Some patients may demonstrate detrusor overactivity and DSD [660, 661]. The condition is rare and there is no contemporaneous epidemiological data.

I. INTRODUCTION

Older people have the highest known prevalence of urinary incontinence (UI) of any group, other than those with specific neurological disease (e.g., spinal cord injury). As the proportion of older people in the populations of the developed world increases, so will the absolute numbers of those with either urinary (UI) or faecal incontinence (FI) or lower urinary tract symptoms [1]. Even if improvement in physical functioning among older people continues, and research in the field is able to demonstrate continuing benefit whilst containing costs, the impact on future health care and long-term care costs will still be profound [2]. Early signals suggest however that the decrease in disability for older people observed in the last two decades of the twentieth century has not been seen in those aged 40 – 64 years [3].

No matter how those in later life, conventionally defined as those of 65 years and older, are described this population is characterized by its variety, ranging from active, community-dwelling, working, healthy nonagenarians to bed-bound, chronically ill, functionally and cognitively-impaired persons in their late 60's. Because the healthier group is closer in phenotype and physiology to middle aged than to frailer older people, information relating to the management of urinary and faecal incontinence in this group is integrated into the other ICI chapters. This chapter focuses on frail older people, emphasizing not only the different aetiologies and treatment of UI and FI, but the additional issues of disease burden, disability, altered responses to drug therapy and the role of caregivers. Those sections in the previous (5th) Consultation, dealing with catheters and the organization of care have been moved to the more relevant chapters. This Consultation sees for the first time a dedicated section dealing with continence at the end of life and examines the effect of both cognitive and physical frailty as the presence of each or both may need different considerations when offering treatments for incontinence.

The committee took the view that where there is a paucity of data reflecting the effectiveness or utility of approaches to the treatment of UI or FI in frail older adults, interventions aimed at community dwelling older adults should be employed with due regard to the likely benefits, harms, feasibility, expectations and outcomes of treatment, rather than not be attempted at all. The committee recognized that frail older people may be "victims" of therapeutic nihilism and may receive standards of care below those received by younger persons [4, 5].

The pathophysiology of UI in the frail elderly requires a broader conception of "disease," centring on patient-level factors rather than just the bladder or bowel and its neurological control. UI and FI in frail older people is normally a result of multiple interacting risk factors including age-related physiological changes, comorbidity, polypharmacy, functional and cognitive impairments and common pathways between them (Figure 1). Furthermore, the impact of UI or FI in frail older persons extends beyond the affected individual to their caregivers, leading to caregiver stress and an increased likelihood of institutionalisation [6]. Therefore, assessment in frail older persons requires a broader scope than that employed in the care of younger individuals. Failure to address the multifactorial nature of disease and treatment limits not only clinical care and research, but also important opportunities to improve function and quality of life [7]. Management of incontinence in frail older persons is necessarily multicomponent, and must address the many associated factors and shared underlying impairments with other geriatric syndromes (for example, by combining physical exercise with prompted voiding) [8]. Drug therapy must be placed in the context of altered pharmacology, pre-existing polypharmacy and an increased susceptibility to adverse events. The continuing challenge in providing a review of incontinence in frail older people is the relative dearth of Level 1 evidence for interventions. Thus the frail older person presents multiple challenges for research (not the least of which is substantial difficulty in recruiting to clinical trials due to either overt or covert exclusion

and the additional challenge of intervening illness and death) [9]. Despite the oldest-old (those of 80 years of age and above) forming the fastest growing group of affected individuals, intervention studies continue to be rare. Moreover, trial outcomes need to be more broadly based, incorporating caregivers, a range of care settings, alternative models of care, and goals of care unique to this population [10].

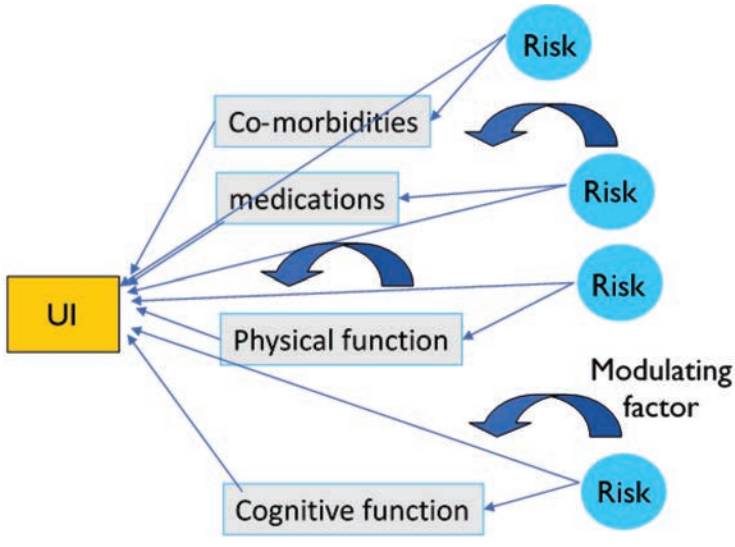

Figure 1. Incontinence as a geriatric syndrome

1. SEARCH STRATEGIES

Given the broad range of this report, we used multiple searches using the following MESH terms (in caps) and phrases, alone and in combination, using the PubMed and Ovid search engines: AGED, AGED OVER 80, ACTIVITIES OF DAILY LIVING, DEPRESSION, elderly, FALLS, frail, FRAIL ELDERLY, FRAILTY, function, geriatrics, LONG TERM CARE, MEDICATIONS, NURSING HOME, older, QUALITY OF LIFE, RANDOMIZED CONTROLLED TRIAL; and BLADDER, GYNAECOLOGICAL SURGICAL PROCEDURES, PELVIC FLOOR, PROSTATE, STRESS INCONTINENCE, SURGERY, URE- THRA, URINARY INCONTINENCE, URINATION DISORDERS, UROGYNECOLOGY, UROLOGY, VAGINA, VOIDING DYSFUNCTION , nocturia OR nocturia OR "night-time voiding" OR "night- time voiding" OR "nocturnal voiding" OR "night- time voids" OR "night-time voids" OR "nocturnal voids" OR "night-time frequency" OR "night-time frequency" OR "nocturnal frequency" OR "night- time urination" OR "night-time urination" OR "nocturnal urination" OR "night-time micturition" OR "night-time micturition" OR "nocturnal micturition" OR "night-time polyuria" OR "night-time polyuria" OR "nocturnal polyuria" OR nocturia) OR ((noctur* OR night*) AND (void* OR urination OR micturition OR polyuria OR pollakiuria OR "LUTS" OR "lower urinary tract symptoms" OR "BPH" OR "benign prostatic hyperplasia")) AND ("aged, 80 or over" OR aging OR elderly OR older OR "very old" OR senior OR "all aged" OR geriatric OR frail OR aged) AND ("double blind method" OR "double blind" OR placebos OR placebo OR "controlled clinical trial" OR "randomized controlled trial" OR "random allocation" OR "single blind method" OR "research design" OR "exp clinical trials" OR "clinical trial" OR "single blind" OR "double blind" or "triple blind" OR "single mask*" OR "double mask*" or "triple mask*") (longitudinal OR "natural history" OR cohort OR incidence OR remission OR progression OR prospective OR "community-based" OR "population-based" OR epidemiol* OR "follow-up"); TOLTERODINE; OXYBUTYNIN; SOLIFENACIN; PROPIVERINE; TROSPIUM, IMIDAFENACIN; DARIFENACIN; FESOTERODINE; fecal incontinence OR, constipation, R anal incontinence. Ovid Expert Search Filter; Publication years 2010-15. We included, where possible, information from non-English language articles where an English language abstract with sufficient information was available. References in retrieved articles were reviewed for additional relevant articles. We also searched the Cochrane Database and National Guideline Clearinghouse for relevant systematic reviews, meta-analyses, and evidence-based recommendations. A research librarian aided this process.

2. FRAILTY

The proportion of older persons in the population is increasing in almost every country around the world. By 2050, approximately 2000 million people will be aged 60 years or over, and 400 million will be over the age of 80. Frailty is essentially a sate of vulnerability to insult, which may be in the form of a relatively minor stressor, from which the individual does not

fully recover. The Consultation has defined "frail older persons" as those over the age of 65 with a clinical presentation or phenotype combining impaired physical activity, mobility, balance, muscle strength, motor processing, cognition, nutrition, and endurance (including feelings of fatigue and exhaustion). This is consistent with the Fried phenotypic approach to frailty in which there is a clear distinction between frailty and disability, and from the accumulation of diseases (deficits) model of Mitnitski and Rockwood [11]. Among persons meeting strict phenotypic criteria for fragility, only 22% also had both comorbidity and disability, 46% had comorbidity without disability, 6% disability with- out comorbidity, and 27% had neither comorbidity nor disability [12, 13]. Frail people do however usually have multiple chronic medical conditions, take multiple medications, require care from others and assistance to perform some or all of the personal activities of daily living (PADLs) (e.g., bathing, dressing, toileting, and mobility), are often homebound or institutionalized. They have a high risk of intercurrent disease, increased disability, hospitalisation, and death [1]. In the United Kingdom, an examination of 5,450 people aged 60 and over from the English Longitudinal Study of Ageing using Fried criteria found the overall weighted prevalence of frailty to be 14%. Prevalence rose with increasing age, from 6.5% in those aged 60–69 years to 65% in those aged 90 or over. Frailty was more common in women than in men (16% versus 12%). 93% of frail individuals had difficulties with mobility compared to 58% of non-frail individuals [14]. In the United States, using the Fried model of frailty applied to 7,439 participants in the 2011 baseline of the National Health and Aging Trends Study of persons aged 65 and older, 15% (95% CI: 14%, 16%) of the older non-nursing home population was frail, and 45% prefrail (95% CI: 44%, 47%). Frailty was more prevalent at older ages, amongst women, racial and ethnic minorities, those in supportive residential settings, and persons of lower income. Chronic disease and disability prevalence increased steeply with frailty [15]. In Latin America and the Caribbean, a meta-analysis of 29 studies including 43,083 people, of mean age of approximately 60 years, using a variety of frailty assessment scores, identified a prevalence of frailty of 19.6% (95% CI: 15.4-24.3%) with a range of 7.7% to 42.6% [16]. Likewise there have been an increasing number of epidemiological studies assessing the point prevalence of frailty, using a variety of definitions, across a number of countries such as Russia [17], China [18], South Korea [19] and Brazil [20] amongst others [21].

2.1. Frailty and incontinence

Several studies suggest that the relationship between urinary incontinence, faecal incontinence and frailty is not unidirectional. Incident UI in those over age 65 has been associated with a two-fold increased risk of impairment in ADLs, instrumental activities of daily living (IADLs – e.g., transportation, finances, shopping, laundry, housekeeping), and poor performance on three physical measures, suggesting that incident UI may be an early marker of the onset of frailty [6]. In a Taiwanese study of UI and its association with frailty among 440 men aged 80 years and older using the clinical frailty scale, the prevalence of UI was 19.1%. Frailty was more common among subjects with UI than those without (60.7% vs 32.3%). Men with UI also had more comorbidity, poorer physical function, were more likely to have depressive symptoms, impaired cognitive function, poorer nutritional status, more polypharmacy and a higher likelihood of fecal incontinence than those men who were not frail [22]. In a population-based study of older Mexican Americans, incident but not prevalent UI was independently associated with functional decline in ADLs, IADLs, and physical performance [23]. Another population-based study found an association between UI and IADL decline, but not ADL decline, nursing home admission, or death, after adjustment for age and comorbidity [2]. A Portuguese study showed that older people who presented with either "slowness" or "exhaustion" had a risk of UI almost five times greater than those without [24]. Although one early study suggested that older persons with UI had a higher mortality risk subsequent studies that more fully adjusted for comorbidity and functional status have not found any association [2, 25-27].

2.2. Frailty, continence and consequence

Several multivariate studies suggest that patients with new onset UI at the time of stroke have higher rates of death or disability at 2 years (OR 4.43; 95% CI 1.76 to 11.2) to 5 years (OR 3.21 [95% CI 1.04−9.91]), especially if UI persists (OR 7.47 [95% CI 2.29−24.42]) [28, 29]. Given its association with frailty, it is not surprising that UI remains a risk factor for nursing home admission, particularly in association with a dementia diagnosis. Studies showing a significant association between UI and institutionalisation have been done in Finland (in men, but not women, with urgency UI); [30] Germany; [31] New Zealand (persons > age 65) [32]; US (men more than women) [33], after hip fracture [34], among Hispanic elderly [23], and patients attending a dementia clinic in rural Japan [35]; and Hong Kong [36]. Two studies failed to find a significant association after controlling for comorbidity, using US [2] and Canadian databases [37]. It was estimated that the proportion of US NH admissions attributable to UI in men is 0.10 (95% CI 0.08–0.13) and in women 0.06 (95% CI 0.05–0.09) [38]. The prevalence of UI at NH admission in the U.S. shows variation of almost 50% and differs by race [39] suggesting that patient and caregiver factors and local resources affect the role UI plays in institutionalisation. An issue, particularly in studies of institutionalisation in people with a dementia diagnosis, is the failure to include UI as a risk factor or defining it only by a composite function score [40, 41]. The significant association of faecal incontinence and institutionalisation (odds ratio 1.79, 95% CI: 1.00-3.20), in one Canadian study was lost when adjusted for cognition, ADL dependence, and self-reported health, although a survey of US geriatricians found

that the presence of faecal incontinence was more likely to result in a referral to a nursing home than not [42, 43].

2.3. Cognitive Frailty

Whilst age associated cognitive impairment has received extensive research and clinical interest, cognition has not been conceptualised in a similar fashion to physical frailty. Frailty *per se* includes both physical and cognitive domains. The term cognitive frailty has been operationalised as an heterogeneous clinical manifestation characterised by the simultaneous presence of both physical frailty and cognitive impairment. The key factors defining such a condition include the presence of physical frailty and mild cognitive impairment and excluding concurrent dementia, reflecting reduced cognitive reserve [44]. The exclusion of the dementias may not be useful in that the two features are often intimately intertwined but conceptually the definition may have clinical utility in terms of continence management, where the application of treatment options may vary depending upon the predominant factor influencing frailty. To be able to distinguish those with a vulnerability to cognitive decline amongst persons either with or without physical frailty may be of use, but again, the pathophysiological mechanisms leading to both entities are common and probably shared.

2.4. Dementia

The proportion of people living with dementia, a group of conditions also associated with an impairment in quality of life and physical function increases; prevalence estimates suggest that globally in 2010 35.6 million people lived with dementia with numbers expected to almost double every 20 years, to 65.7 million in 2030 [45],[46]. In addition to the morbidity associated with urinary incontinence in older people, its presence with co-existent dementia increases the likelihood of institutionalisation [47]. Unfortunately, once there, there is evidence of institutional practices, such as *en masse* toileting, making incontinence more likely [48]. Likewise, caregivers identify looking after an older person with dementia and incontinence as being burdensome [49, 50]. Management guidelines for urinary incontinence and lower urinary tract symptoms seldom consider the implications for management in those patients with co-existing medical conditions [51-53]; few discuss management in those with a dementia diagnosis [54]. The likelihood of incontinence increases in association with the severity of dementia but until recently longitudinal studies did not identify an association with incident cases [55, 56]. One longitudinal study of 6,349 community dwelling women found that a decrease in mental functioning as measured by a modified mini mental status exam (MMSE) was not associated with increased frequency of urinary incontinence over 6 years, but did predict a greater impact [57]. Despite strong associations with baseline incontinence in the Canadian Study of Health and Aging, moderate or severe cognitive impairment, measured by the same modified MMSE, was not associated with incident UI over 10 years [58]. However, in a longitudinal study of 12,432 women aged between 70-75 years with a 3 year follow up there was a strong association with a dementia diagnosis (OR 2.34) [59]. Similarly, over 9 years follow up of 1,453 women aged 65, dementia was strongly associated with incident urinary incontinence (RR 3.0) [6]. Likewise, in a Scottish study, the prevalence of urinary incontinence increased with decreasing mini-mental state scores and was notably more common in those with impairments of attention and orientation, verbal fluency, agitation and disinhibition [60]. In a United Kingdom General Practitioner database, when compared with those without a dementia diagnosis, dementia was associated with approximately three times the rate of diagnosis of urinary incontinence. The incidence rates of first diagnosis per 1,000 person-years at risk (95% confidence interval) for urinary incontinence in the dementia cohort, among men and women respectively, were 42.3 (40.9-43.8) and 33.5 (32.6-34.5) [61]. When assessed urodynamically, most incontinence associated with dementia appears to be related to detrusor overactivity, resulting in urgency incontinence [62, 63].

Incontinence in dementia adds to caregiver burden [64], and influences decisions to relocate people to care homes [6]. Whether successful management of incontinence reduces either this associated burden or alters decisions to institutionalise these people is unknown, evidence is limited to case reports and anecdotal evidence. Family physicians identify dealing with incontinence in dementia as a significant challenge [65]. Likewise there is the concern regarding the influence of antimuscarinic medications on cognition, where there is increasing evidence of cognitive impairment and higher rates of incident dementia diagnosis associated with high antimuscarinic load and long exposure in older persons in epidemiological studies [66, 67], although data in persons with pre-existing dementia are less consistent [68].

Once institutionalised, urinary incontinence becomes a major factor in those with dementia, In a study in Austrian nursing homes, urinary incontinence was present in 84.2% of residents with dementia versus 53.2 % of those without and was highly prevalent even in those with early dementia, affecting 64% of the 277 residents studied [69]. Once admitted to a nursing home, the presence of a dementia diagnosis is associated with a hastening of loss of continence, compared to those residents without. Incontinence is associated with a reduced quality of life and impaired nutrition and mobility in older people with dementia [70, 71], but is sadly neglected in terms of the amount of attention paid to it despite the acknowledged adverse effect on quality of life and the associated costs of management [72].

2.5. Managing incontinence in dementia

Most people with a dementia diagnosis living in the community can potentially be managed in a similar way to any other community dwelling adult, in line

with current guidelines. As noted in the 5th International Consultation on Incontinence, the expectations of both patient and caregiver, the nature of the proposed treatments and likelihood of benefits and harms should be taken into account [73].

Successful and safe management of incontinence in people with more advanced dementia presents additional challenges. For the most part, successful delivery of conservative or behavioural therapies in late life requires the ability for the individual to learn or change behaviour; the active engagement of a caregiver is also required [73]. A dementia diagnosis should not preclude an attempt to manage incontinence with behavioural methods, but for those with a compromised ability to retain behavioural change this is clearly inappropriate. A stepwise approach to initiating interventions and assessing the results seems like a reasonable first step in management, recognising that older people do appear to be more likely to need drug therapy for urgency incontinence than younger persons [74]. For prompted voiding to be successful, a three day trial should result in either a 20% reduction in wet episodes or an increase in spontaneous requests to use the toilet [75]. If this is not successful then the mainstay of management is a strategy of check and change of appropriately assessed containment products [54, 76]. The remaining option is to introduce a fixed voiding schedule, which requires no behavioural change, but this too may be impractical in circumstances where there is limited caregiver support or availability. Even in adequately staffed institutions, evidence suggests that for those who need toileting, the average number of toilet assists per resident is around two per day, sadly short of that which might be needed [77, 78]. A recent systematic review examining the evidence for conservative management approaches for those with dementia living at home concluded, unsurprisingly that there was insufficient evidence to make any recommendation; little, if any, specific guidance for practice in the community exists [79, 80]. The England and Wales National Institute for health and Care Excellence guideline on incontinence in those with neurological disease recommends that treatment be tried on an individual basis [81].

Evidence on pharmacological treatment for UI in those with dementia is lacking; that which does exist is discussed in the pharmacological treatment section.

II. URINARY INCONTINENCE

1. AETIOLOGY & ASSESSMENT

1.1. Background

The aetiology of UI in frail older adults is grounded in the concept of a classical geriatric syndrome, involving multiple interacting risk factors, including age-related changes, comorbidity, and potentially common pathways between them. This section addresses these components.

1.2. Quality of the data

The data on aetiology of UI in frail older persons remain limited, and observational studies of varying quality constitute much of this literature. Additionally, longitudinal studies of large numbers of frail individuals are difficult to carry out because of paucity in recruitment and the high rate of natural attrition. Despite the lack of such studies, many relatively large, careful descriptive studies and case series, as well as expert consensus processes, have made important contributions to our understanding of the aetiology of UI in this population.

1.3. UI as a geriatric syndrome

In older adults, especially those who are frail, UI forms a classical geriatric syndrome, many of its risk factors are not directly related to the genitourinary tract [82, 83]. Geriatric syndromes have been defined as ''multifactorial health conditions that occur when the accumulated effects of impairments in multiple systems render an older person vulnerable to situational challenges" [82]. Thus, large numbers of different baseline as well as precipitating risk factors may interact with each other in influencing the ability of an older individual to remain continent in the face of common daily challenges. This multifactorial complexity, combined with the fact that most individual risk factors typically account for only a small proportion of the overall risk, have greatly complicated the development of a pathophysiological framework for the study of common geriatric syndromes [82]. **Figure 2**

Nevertheless, because common risk factors (e.g. arm and leg weakness, sensory and affective impairment) may be shared by different geriatric syndromes (such as UI, falls, and functional dependence) [84], they may represent particularly attractive sites for the development of interventions [82]. For example, the presence of brain white matter hyperintensities within critical periventricular and subcortical regions could represent key risk factors for the development of different geriatric syndromes such as falls, impairment in executive cognitive function, depressive symptoms, and UI [85]. Functional magnetic resonance imaging (fMRI) studies have identified central nervous system areas that are particularly relevant to urinary storage symptoms and urgency [86, 87]. Therefore, failure of activation within orbitofrontal regions may contribute to an older individuals' decreased ability to suppress urgency [88]. Connectivity pathways within the right insula and anterior cingulate gyrus may also play a role in maintaining continence supporting the concept that decline in connectivity [88] and coordination between different brain regions represent early critical events in aging. These findings suggest the possibility that interventions to prevent the development of white matter hyperintensities, such as

control of vascular risk factors, could also prevent UI.

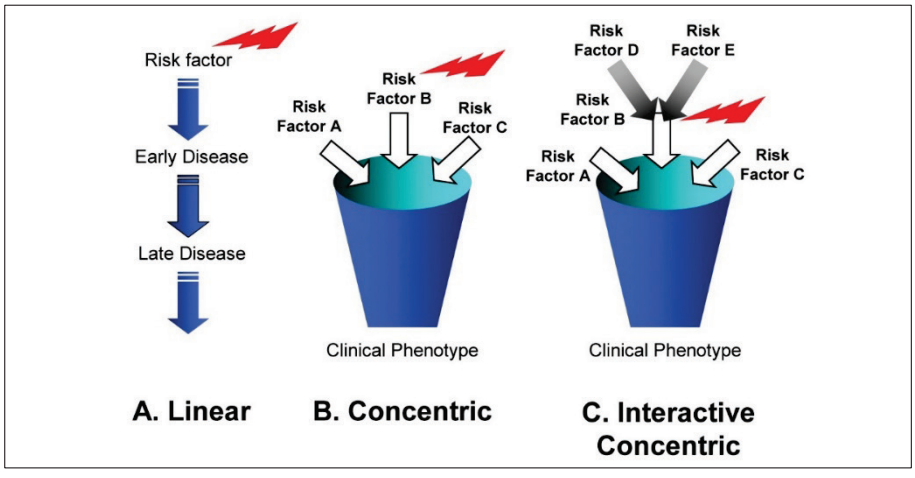

Figure 2. The mechanistic geriatric syndrome

2. AGE RELATED CHANGES RELEVANT TO UI IN FRAIL OLDER PERSONS

Age-related changes in the lower urinary tract (LUT) can function as risk factors for the development, continuation, and worsening of UI in frail elderly persons (**Table 1**). At the same time, they rarely are alone sufficient to cause UI, and in some persons have no effect on lower urinary tract symptoms (LUTS) or UI. Furthermore, the literature on "normal" LUT ageing has many potentially confounding methodological limitations. Normal ageing changes are difficult to study, because longitudinal data including large numbers of individuals spanning many years are necessary to definitively separate "normal LUT ageing" from confounding factors and comorbidity. Cross sectional studies are subject to confounding by comorbidity and time-dependent cohort effects, such as change in labour and delivery practices. Thus, to date many studies actually describe "age-related" associations, as opposed to normal ageing. Other limitations include: derivation of much of the cellular and neurochemical data from animal studies; morphologic studies based on cadavers with unknown parity, comorbidity, and LUT symptoms; "age-effects" derived from studies of symptomatic persons; and use of surgical patients at tertiary centres as "normal" controls. Even the definition of "normal" can be difficult: is it continence, absence of LUTS, lack of comorbid disease, or normal physiological testing [89]? The following sections focus on findings from more robust and, where possible, confirmatory studies.

Table 1. Age related changes in the lower urinary tract

Age-Related Change	**Potential Effects on Continence**
Bladder ultrastructure on electron microscopy Dysjunction pattern Muscle and axon degeneration	Bladder overactivity and urgency UI Impaired bladder contractility, increased residual urine, and decreased functional bladder capacity
Bladder function Decreased capacity Decrease sensation of filling Increased detrusor overactivity Decreased bladder contractile function Increased residual urine	 Increased likelihood of urinary symptoms and UI
Urethra Decreased closure pressure in women	 Increased likelihood of stress and urgency UI
Prostate	

Age-Related Change	Potential Effects on Continence
Increased incidence of benign prostatic obstruction Increased incidence of prostate cancer	Increased likelihood of urinary symptoms and UI
Decreased oestrogen (women)	Increased incidence of uandrogenital atrophy related symptoms Increased incidence of recurrent urinary tract infections
Increased night-time urine production	Increased likelihood of nocturia and night-time UI
Altered central and peripheral neurotransmitter concentrations and actions	Increased likelihood of lower urinary tract dysfunction
Altered immune function	Increased likelihood of recurrent urinary tract infections
Increased prevalence of white matter hyperintensities in brain	Increased prevalence of severe urge / urgency, link to cognitive impairment and impaired mobility

2.1. Bladder

Understanding age-related changes in the bladder is complicated by a paucity of longitudinal data, variable definitions of "normal," and use of potentially biased (and symptomatic) referral populations. It is difficult to isolate such factors as the role of decreased blood flow, poor voiding habits, comorbidity, central and peripheral nervous system innervation, and reflex patterns as determinants of bladder function in older persons. The research focus has been urodynamic function, neurohumoural responsiveness of detrusor smooth muscle, and ultrastructure. While the key role of the urothelium and afferent systems on micturition are increasingly appreciated (See Committee 2, Cell Biology; Committee 3, Neural Control; and Committee 4, Pathophysiology), there are only limited human data on urothelial changes with age. Urodynamic changes associated with age have typically included smaller voided volume, increased residual volume, smaller bladder capacity, and increased involuntary detrusor contractions (detrusor overactivity (DO)). Correlations with age are often small, suggesting that other factors are at least as important [90]. Urodynamic findings may not relate to symptoms: in a urodynamic study of community-based healthy persons over age 55, DO was found in 42% of continent women, one-third of whom were totally free of LUTS [89]. In another study, charts of 53 consecutive females over age 80 undergoing multichannel urodynamics according to ICS standards were retrospectively analysed. These elderly patients presented with LUTS, yet in 11% urodynamic studies were reported as being normal, with considerable other discordance between symptoms and urodynamic findings [91]. Nevertheless, in a cross-sectional study involving ambulatory, cognitively intact, community-dwelling older female volunteers, maximum urethral closure pressure, detrusor contraction strength, and urine flow rate all declined significantly with age, regardless of whether DO was present or not [92].

The ability of the bladder to empty efficiently also declines in healthy older men and women who have no evidence of bladder outlet obstruction (BOO) or significant confounding disease [89, 93]. A variety of different risk factors associated both with ageing and common comorbid conditions may contribute to age-related declines in detrusor contractile function, which may ultimately lead to detrusor underactivity [94, 95]. Decreased contractile function during voiding in older persons is associated with lower urine flow rates and a small increase in post voiding residual volume (PVR) (generally to < 50 ml) [94]. Even in men with BOO, an elevated PVR may reflect decreased bladder contractile function rather than obstructed voiding [95]. While some studies suggest a myogenic origin of impaired contractility, others suggest that impaired blood supply, with concomitant ischaemic-reperfusion injury causing patchy denervation, leads to decreased contractility (see Committee 3, Neural Control). More recently, Smith highlighted the potential contribution of age- and disease-related declines in bladder afferent sensory activity in contributing to impaired voiding performance seen with detrusor underactivity [96]. Incomplete bladder emptying from all such causes can reduce functional bladder capacity, and thereby contribute to the urinary frequency and nocturia common in frail older persons [94]. The recent development of a model allowing continuous uroflow in mice has led to studies evaluating the impact of normal aging on overall LUT performance [97, 98]. While aging did not influence measures of detrusor expulsive strength, pre-contraction pressures, intervoid intervals, per-void volumes and voiding flow rates all increased with aging [97]. Moreover, aged animals demonstrated a decreased homeostatic ca-

pacity to respond to the challenge of continuous bladder filling, with indirect measures suggesting a role for decreased bladder volume sensitivity [97, 99].

In human studies, the observation that bladder volume at the initial desire to void declines with age may be confounded by comorbid conditions and concurrent medications [100]. Furthermore, unlike the positive association between detrusor contraction strength and DO found in younger subjects, older adults demonstrate a decline in DO-associated detrusor contractile function [92] and detrusor contractility [101] . Moreover, many frail older persons with UI present with a combination of DO on filling and poor contractility during voiding, an association termed detrusor hyperactivity with impaired contractile function (DHIC) [62, 94, 102]. In such cases, the bladder contraction does not empty the bladder fully, leaving a large PVR otherwise not explained by BOO. Because DHIC symptoms can include urgency UI, stress and mixed UI, dribbling, frequency, and nocturia, they may be mistaken for other conditions. At the same time, DHIC may be mistaken for DO with normal contractility because significant detrusor underactivity may be present in the absence of any relevant symptoms. Thus, while it is not possible to speak of precise cutoffs when differentiating between "normal" and "abnormal" PVR values, PVR assessments do provide crucial information into age- and disease-related alterations in overall LUT performance [103].

Ultrastructural studies demonstrate cellular changes associated with age-related changes in detrusor function. One series of such studies involved symptomatic and asymptomatic persons aged 65 - 96, using urodynamic testing and electron microscopy of bladder biopsy specimens, which were read in a blinded fashion using explicit protocols [104-107]. A consistent, one-to-one correlation between specific urodynamic findings and bladder ultrastructure was observed, although there has been considerable debate about the veracity of these findings and they have not been reproduced and have been disputed by the findings of a later study which found the ultrastructural changes described evenly distributed between normal women (n = 15) and women with detrusor overactivity (n = 22) [108].The small number of asymptomatic patients with no DO, normal contractility, and no obstruction, detrusor muscle fascicles were largely intact, with two distinctive ultrastructural findings that may be related to ageing alone: muscle cell membranes characterized by numerous "dense bands" and markedly depleted caveolae, and slightly widened spaces between muscle cells with limited content of collagen and elastin. Depletion of caveolae may be related to de-differentiation of muscle cells, which could eventually result in the reversion of actively contractile cells to inactive, synthetically immature cells. A similar phenomenon has been reported in atherosclerotic blood vessels and postmenopausal myometrium, and may be related to reports of increased collagen in bladders from older women [104, 109]. Moreover, lack of oestrogen contributes to, and oestrogen replacement reverses, both caveolar depletion and detrusor fibrosis [110, 111]. Thus, both ageing and postmenopausal decline in oestrogen levels may contribute to bladder muscle cell differentiation and contractile function [94].

The natural history of these ultrastructural changes remains largely unknown. From the ultrastructural studies described above, a subset of 23 patients was followed longitudinally [112]. The previously observed one-to-one correlation between ultrastructure and function was maintained, but it was unclear whether urodynamic or ultrastructural changes occurred first in subjects who developed or had a change in LUTS. The pattern of dense-bands and non-disruptive muscle cell degeneration varied over time: the DO with dysjunction pattern developed in some subjects, and impaired detrusor contractility and the corresponding degeneration pattern was observed to progress in severity or develop. Other investigators have found similar results but without the one-to-one correlation (e.g., see Brierly et al [113, 114]). Clearly, further work is needed understand the associations between changes in ultrastructure, urodynamic features and clinical syndromes.

In addition to such alterations in ultrastructure, a variety of changes involving relevant nerve fibres, receptors and signalling pathways have also been described in bladder tissues from aged animals, and to lesser extent human biopsies. For example, with aging overall, sympathetic nerve fibre density may decrease [115, 116]. Bladder biopsies from older subjects with normal urodynamic profiles typically show little or no evidence of axonal degeneration and the density of some CGRP-positive sensory nerves is maintained in old age, yet the impact of aging on other categories of sensory fibres or on motor fibres remains unknown [104, 115]. Examples of other changes include decreased contractility and calcium fluxes in response to cholinergic agonists or depolarization [117]; increased responsiveness to adrenergic agonists with increased expression of the alpha 1D-adrenergic receptor [116]; declines in phosphodiesterase 5 (PDE5) levels and possibly signaling [118]; as well as decreased P2X1 purinergic receptor expression [119]. Unfortunately, the interpretation and generalisability of these findings is often limited by a failure to include intermediate age-points which would allow investigators to distinguish changes attributable to aging as opposed to maturational processes [120, 121].

More recent studies have suggested a role for decreased A2B receptor expression in lower ability of adenosine to relax the detrusor [122]. Also, use of permeabilised bladder muscle strips suggested that IP3-induced calcium release is primarily responsible for the contractions in older rats, thus aging-related decline in carbachol contractions may result from decreased calcium-induced calcium release rather than carbachol-induced calcium sensitisation [123]. The use oxidative stressors has shown that mechanisms

possible related to the TRPM8 (cold sensing TRP melastatin 8) ion channel may compromise urothelial function in aged bladders [124]. Studies conducted with human bladder muscle strips suggested an age-related increase in carbachol-mediated contraction via Rho Kinase pathways [125], associated with lower MLCK expression [126]. Finally, studies conducted in aged mice from a systems-based perspective demonstrated that an increase in neurogenic power during filling accompanies augmented centrally mediated compliance enhancement with aging, thus suggesting the existence of a bladder control model in which brain processes related to micturition may compensate for age-associated changes [127].

2.2. Urethra

Due to their common embryological origin, the urethra undergoes age-related mucosal and stromal changes like the vagina, and urethral changes in older women can be partially inferred from examination of vaginal tissue. Because of the difficulty of obtaining non-cadaveric urethral tissue, data on urethral smooth and striated muscle changes with age are complicated by confounding factors and definitions of controls. Urethral closure pressure decreases with age [128, 129]. Based on a sample of 82 women aged 20-70, urethral closure pressure was found to decrease by 15 cmH_2O per decade [130]. A number of anatomical and physiological changes may account for this decline. Mucosal thinning and lack of proteoglycans reduce urethral wall apposition; this also may contribute to retrograde movement of perineal bacteria into the bladder causing urinary tract infections [131]. These mucosal changes may extend up to the bladder trigone, causing irritation of sensory afferent nerves, and possibly triggering DO [132]. The submucosal venous plexus in the proximal urethra loses its corkscrew shape, the number and volume of arterial vessels decrease, and vascular pulsations lessen [133]. Several studies, using different measurement techniques, have shown that urethral vascular density and blood flow decrease with age, but not vascular flow velocity [134-136]. However, age explained only 9% of the variability in vascular density in one study [134], and none of the studies controlled for vascular risk factors such as hypertension and diabetes. The relative importance of decreased vascular volume versus hypoxia on urethral functional integrity is unclear. Other alterations in the urethral stroma are increased volume of connective tissue, decreased ratio of proteoglycans to collagen, and decrease in nerve density [137, 138].

Cadaver studies suggest that the number and density of urethral striated muscle fibres decrease with age, especially in the ventral wall of the proximal urethra [139, 140]. These authors estimated that striated fibres decrease by 1% per year. Large inter-individual variations were observed, with age and parity accounting for only a small part of the variability, suggesting that other yet to be defined factors are important. These studies also found that cross-sectional striated muscle fibre area decreased while fibre diameter was preserved. Another cadaver study by the same group found that circular smooth muscle width was 25%-50% higher in younger women (aged 20-39 years) than older (aged 70-89), and that younger women had higher fibre counts [141]. Smooth muscle loss in the older women correlated with loss of striated muscle in the anterior urethra. Moreover, a recent study raised the possibility that TNF-alpha may contribute to age-related rhabdosphincter satellite cell death and muscle loss with aging [142]. Urethral sensation, measured as current perception thresholds, was significantly higher in older women in two studies (by the same authors), one comparing 48 asymptomatic women and 13 with urgency UI [143], and another in asymptomatic women [132]. The authors concluded that age-related LUT sensory neuropathy could contribute to the higher prevalence of overactive bladder (OAB) symptoms with age; however, urethral sensation thresholds were higher in women with urgency UI when controlled for age and parity [143], and the “asymptomatic” older women may have had urodynamic DO [132].

With age, the urethral meatus generally moves toward the vaginal introitus, and may be difficult to see if there is considerable introital stenosis. Caruncles - benign violaceous soft swellings-often appear at the meatus, and are not problematic unless they cause discomfort or obstruction. Urethral diverticula can be a diagnostic challenge, especially in older women, because the symptoms (dysuria, pain, UI, frequency, urgency, dyspareunia) may be attributed to postmenopausal changes, age, OAB, or urgency UI [144]. Diverticula should be considered in women who have repeatedly failed “conventional” UI treatment. Diagnosis requires imaging by voiding cystourethrography, ultrasound, or magnetic resonance scans. Urethral obstruction is relatively uncommon in older women, and is nearly always secondary to other LUT dysfunction (e.g., pelvic organ prolapse) or is iatrogenic (from LUT/pelvic surgery or radiation. In men, age-related decrease in striated sphincter muscle cell density occurs as well, [145, 146] and has been associated with increased muscle cell apoptosis [145]. While some investigations describe an increase in resting prostatic urethral pressure with age, [147] others note the increase occurs only to the sixth decade then subsequently decreases, along with a shortening of sphincteric urethral length [148]. These discrepancies may reflect differences in prostate volume and morphology.

2.3. Pelvic floor

Pelvic floor changes in normal older men have not been well studied. In women, the effect of age on pelvic floor structure and function is difficult to differentiate from the effects of hormonal status and parity [149]. A number of studies are cross sectional rather than longitudinal, and focus on symptomatic women. For example, a questionnaire study of over 4,000 community women aged 25-84 found no association between age and stress UI (SUI), OAB, or anal UI,

after adjustment for obesity, birth history, menopause, and hormone use [150]. Similarly, in a random sample of 343 Austrian women aged 18-79 years, impaired pelvic muscle contraction (graded by the Modified Oxford Scale) was weakly associated with parity and body mass index but not age [151]. In contrast, a study combining an interview, physical exam and transperineal ultrasound identified age as a weak (r = -0.25) but statistically significant predictor of pelvic muscle weakness and levator ani morphometry even after controlling for obvious confounders [152]. A recent MRI study was able to distinguish distinct patterns of change in pelvic support in women with stress as opposed to mixed urinary incontinence[153]. Evidence of denervation and changes in pelvic striated muscle fibre number, type, and diameter have been found in asymptomatic and nulliparous women (see Committee 2, Cell Biology). For example, in a sample of 82 nulliparous women, neither levator function (measured by resting vaginal closure force and augmentation of vaginal closure force) nor pelvic organ support (on pelvic exam) showed an association with age [154]. A histomorphometric study, using levator ani muscle from 94 female cadavers (aged 15-58), 10 male cadavers (aged 23-35), and 24 women undergoing pelvic surgery, found that myogenic cell damage was associated with both parity and age (</> age 35), but there was no difference between nulliparous women, men, and women with pelvic organ prolapse and/or UI [155]. Total collagen content in pelvic muscle and fascia declines with age, with increased cross-linking and decreased elasticity, [156] but this association does not imply a direct causative effect of "ageing." Constipation may independently contribute to pelvic floor dysfunction in older women [157, 158].

2.4. Vagina

The prevalence of age-related changes in the vagina varies with hormonal status, coexistent vascular disease, and the continuation or lack of sexual activity [159]. The postmenopausal decrease in oestrogen plays a part in many age-associated vaginal changes. Oestrogen is trophic for much of the LUT in women, with oestrogen receptors found in the vagina, vestibule, distal urethra, bladder trigone, pelvic muscles, and ligamentum rotundum [160]. Yet, as the Women's Health Initiative trial has shown, one cannot assume that the association between low oestrogen levels and physiological changes implies that hormone replacement will reverse these changes, restore function, or reduce symptoms [161, 162]. Moreover, the data are equivocal whether and how LUT oestrogen receptors change in number, density, or function with age [133].

Following menopause, the vaginal epithelium loses the majority of its superficial and intermediate layers. Mucosal thinning may be associated with inflammation, evident as erythema, telangiectasia, petechiae, friability, and erosions. This may be responsible for urgency and frequency in some frail elderly women. In addition, there is loss of epithelial glycogen and lubrication, and mucosal pH increases from 4.5-5.5 to 7.0-7.4 [163]. These changes can lead to loss of normal adherent flora (lactobacillus), colonisation with pathogenic organisms such as E. coli and enterococci, and the observed increase in bacteriuria and recurrent symptomatic urinary tract infections (UTIs) in older women [164].

Vaginal blood flow, which is important for mucosal integrity and submucosal fullness, decreases with age. Whether this is oestrogen-related, and/or due to concomitant vascular disease is not known. Collagen and lipofuscin deposition in the stroma increases, and may be accompanied by invasion by lymphocytes and plasma cells [164]. The combined epithelial and stromal changes are associated with vaginal wall thinning and flattening of rugae [160]. The vaginal vault may shorten and narrow, and the introital opening decrease (and in severe cases become stenotic), which may make vaginal examination, intercourse, and use of pessaries difficult. However, it is not clear that vaginal shortening is clinically relevant: in one case series of over 3,000 women attending a general clinic, total vaginal length decreased by only 0.08 cm every 10 years [165]. Vaginal shape also may be altered by POP. Because of the multiple potential confounding factors discussed above, a causal relationship between urogenital atrophy and urogenital symptoms/LUTS should not be automatically assumed. Very few randomised trials of oestrogen (oral or topical) for urogenital symptoms include women over age 75, use patient-defined outcomes in addition to physiological measures, or evaluate quality of life outcomes [166]. There are insufficient data to provide an evidence-based approach to symptomatic urogenital atrophy in older women. Oral oestrogen should not be used, but expert opinion supports topical oestrogen treatment (cream, intravaginal tablets, or oestrogen-impregnated pessary-like ring). The validation of vaginal self-swab collection specimen collection offers new opportunities for extending relevant questions to epidemiological studies of older women living in the community [167]. Nevertheless, despite all reported biological changes, aging did not interfere with the ability of fibroblasts obtained from older women with prolapse to be successfully reprogrammed [168].

2.5. Prostate

Histological benign prostatic hyperplasia (BPH) is strongly age-related [169], and may lead to prostate enlargement (BPE) and outlet obstruction (BOO). While many LUT changes in women are associated with lower oestrogen levels, BPH results from the development of an oestrogen-predominant hormonal milieu in the prostate. The trophic prostatic androgen, dihydrotestosterone, is formed by the 5-α reduction of testosterone. Dihydrotesterone levels decrease with age, while oestradiol concentrations increase in the prostate stroma and remain constant in epithelial tissues, leading to an increase in the oestradiol/dihydrotesterone ratio and promoting stromal proliferation [170, 171]. Epithelial hyperplasia in turn is mediated by an array of stromal factors [172].

Histological BPH occurs in nearly 80% of men by age eighty [169]. Mean prostate volume increases with age but is very variable; its strongest predictor is prostate specific antigen level of >1.4-2 ng/mL [173]. LUTS in men increase linearly over time, with the fastest increase during the seventh decade, such that by age 80 approximately one-third of men have received treatment for moderate to severe LUTS [174]. Natural history studies and randomized intervention trials, however, consistently demonstrate that symptomatic progression of benign prostate disease is not inevitable. LUTS remit in about one-third of symptomatic men without treatment [175]. Approximately one-third to one-half of affected men develops DO. Thus, even in the presence of demonstrable BPE and/or BOO, the aetiology of LUTS is multifactorial, making prostate-related LUTS in older men a diagnosis of exclusion. Nevertheless, age-stratified normative values for prostate volume, PSA level, as well as indicators of clinical symptoms, quality of life measures and urodynamic parameters may help in such decisions [176].

Although most patients are asymptomatic at the time of prostate cancer diagnosis, this is another possible cause of LUTS, including urgency UI, in older men. However, evaluation for prostate cancer in frail elderly men is rarely if ever indicated, given the high likelihood of limited remaining life expectancy.

The evidence as to whether prostatic inflammation, either acute or chronic, contributes to urinary retention and LUTS in frail older men is contradictory. In a single institution case series of 374 men undergoing TURP for acute urinary retention (AUR) or LUTS, pathological evidence of acute inflammation was significantly more common men presenting with AUR than LUTS (70% vs. 45%) [177]. However, in a much smaller case series of 70 men presenting with AUR, there was no association between inflammation from prostate infarction and AUR [178]. Nevertheless, a recent study demonstrated phenotypic changes and an increased differential expression of a variety of genes involved in inflammation and oxidative stress within glandular adjacent stroma microdissected from young and aged mouse prostates [179]. Such changes may play a role in promoting the development of BPH, BPE and cancer in aged prostates [180]. However, recent studies conducted using both human tissues and animal models support the hypothesis that senescence-associated inflammatory pathways contribute to the pathogenesis of BPH [181].

2.6. Other changes

The role of various neurotransmitters in the central and peripheral nervous system in UI is under active investigation (see Committee 2, Cell Biology). Nevertheless, age-related changes in the actions of these neurotransmitters, their receptors, or the cellular events they stimulate may contribute to the development of UI in frail older persons.

The prevalence of both asymptomatic bacteriuria and UTIs increase with age [182], and the two are often found together in frail older persons. Age-related changes in immune function, vaginal epithelium, faecal incontinence, and insufficient hygiene related to disability, cognitive impairment, and/or lack of caretakers may predispose the frail elderly to bacteriuria and recurrent UTIs. However, the role of otherwise asymptomatic bacteriuria (often found in association with pyuria) [183], in the aetiology of UI in frail elderly people remains unclear [184]. Treating otherwise asymptomatic bacteriuria in frail elderly patients with chronic, stable UI does not, in general, reduce UI severity [185]. UTI symptoms may be subtle and nonspecific in this population, and include worsening of UI, delirium in patients with dementia, or a minor but important decline in functional ability [185]. At the same time, current consensus criteria for UTI are poorly sensitive and only moderately specific for UTI in frail elderly. In a prospective cohort of 340 nursing home residents, in which UTI was defined as pyuria (>10 white cells) with >100,000 colony forming units on culture, the McGeer, Loeb, and revised Loeb UTI criteria had sensitivities of only 19-30% and specificities of 79-89% [186].

2.7. Role of biological aging mechanisms in ageing and disease-related alterations in lower urinary tract function.

In recent years, there has been a tremendous growth in our knowledge in the basic biological mechanisms that drive aging processes at the level of organisms, systems, organs and individual cells [187-189]. This has led to the emergence of two major concepts within the recently-established field of Geroscience [187-189]. First, it has been proposed that interventions designed to target multiple mechanisms which are known to contribute to biological aging, would have the capacity to prevent or slow the impact of aging on clinically-relevant physiological mechanisms. To that end, the recent observation that dietary restriction in rats reduces aging-related declines in LUT function together with increases in inflammatory mechanisms, suggests that such interventions could represent a promising direction for future research. Conversely, a number of aging changes involving the LUT appear to be augmented in a mouse model of accelerated senescence [190].

Second, the concept of Geroscience suggests that since aging represents the predominant risk factor for many chronic diseases such as atherosclerosis, cancer, dementia and others, such chronic diseases are also likely to share common mechanisms with both aging and each other; and therefore strategies designed to target such pathways would have the potential to delay the onset of such chronic diseases, thus enhancing function, independence and health span in older adults [187-189]. Although there is growing evidence that atherosclerosis and other forms of aging-related cardiovascular dysfunction [191, 192], contribute to declines in LUT function and

symptoms in old age, from the perspective of mechanisms this hypothesis remains to be explored in the context of genitourinary aging.

3. FACTORS OUTSIDE THE LOWER URINARY TRACT CAUSING OR CONTRIBUTING TO URINARY INCONTINENCE

A hallmark of UI in the frail elderly population is the wide variety of factors and conditions outside the lower urinary tract that can cause or contribute to leakage **(Table 2).**

Table 2. Comorbid conditions that can cause or contribute to UI in frail elderly persons

Conditions	Comments	Implications for Management
Comorbid medical illnesses Diabetes mellitus	Poor control can cause polyuria and precipitate or exacerbate incontinence; also associated with increased likelihood of urgency incontinence and diabetic neuropathic bladder	Better control of diabetes can reduce osmotic diuresis and associated polyuria, and improve incontinence
Degenerative joint disease	Can impair mobility and precipitate urgency UI	Optimal pharmacological and non-pharmacological pain management can improve mobility and toileting ability Cough suppression can reduce stress incontinence and cough-induced urgency UI
Chronic pulmonary disease	Associated cough can worsen stress UI	
Congestive heart failure Lower extremity venous insufficiency	Increased night-time urine production at night can contribute to nocturia and UI	optimising pharmacological management of congestive heart failure, sodium restriction, support stockings, leg elevation, and a late afternoon dose of a rapid acting diuretic may reduce nocturnal polyuria and associated nocturia and night-time UI
Sleep apnoea	May increase night-time urine production by increasing production of atrial natriuretic peptide	Diagnosis and treatment of sleep apnoea, usually with continuous positive airway pressure devices, may improve the condition and reduce nocturnal polyuria and associated nocturia and UI
Severe constipation and faecal impaction	Associated with “double” incontinence (urine and faecal)	Appropriate use of stool softeners Adequate fluid intake and exercise Disimpaction if necessary
Neurological and psychiatric conditions Stroke	Can precipitate urgency UI and less often urinary retention; also impairs mobility	UI after an acute stroke often resolves with rehabilitation; persistent UI should be further evaluated Regular toileting assistance essential for those with persistent mobility impairment Optimising management may improve mobility and improve UI
Parkinson’s disease	Associated with urgency UI; also causes impaired mobility and cognition in late stages	Regular toileting assistance essential for those with mobility and cognitive impairment in late stages Patients presenting with all three symptoms should be considered for brain imaging to rule out this condition, as it may improve a ventricular-peritoneal shunt
Normal pressure hydrocephalus	Presents with UI, along with gait and cognitive impairments	Regular toileting assistance essential for those with mobility and cognitive impairment in late stages

Conditions	Comments	Implications for Management
Dementia (Alzheimer's, multi- infarct, others) Depression	Associated with urgency UI; impaired cognition and apraxia interferes with toileting and hygiene May impair motivation to be continent; may also be a consequence of incontinence	Optimising and phamacological management of depression may improve UI
Medications	See Table 3	Discontinuation or modification of drug regimen
Functional impairments Impaired mobility Impaired cognition	Impaired cognition and/or mobility due to a variety of conditions listed above and others can interfere with the ability to toilet independently and precipitate UI	Regular toileting assistance essential for those with severe mobility and/or cognitive impairment
Environmental factors Inaccessible toilets Unsafe toilet facilities Unavailable caregivers for toileting assistance	Frail, functionally impaired persons require accessible, safe toilet facilities, and in many cases human assistance in order to be continent	Environmental alterations may be helpful; supportive measures such as pads may be necessary if caregiver assistance is not regularly available

UI = urinary incontinence

3.1. Medications

The risk of difficulty controlling urination in community dwelling older women taking medications with LUT effects was about 30% higher compared to those who did not take such medications (OR 1.31 CI 1.05-1.21). This did not occur in men [193]. Overall 20.5% of these women reported incident incontinence at Year 4(3 years from baseline). Several studies have implicated alpha blockers as causing urinary incontinence in women with an adjusted OR of 4.98 [194, 195] and increasing to OR 8.81 in conjunction with loop diuretics [196]. Oestrogens have been shown to increase risk of incontinence in women OR 1.6 to 2.0. [195, 197] A wide range of medications have been implicated in causing urinary incontinence with varying degrees of evidence [198]. There has even been a case report of hydroxychloroquine causing urinary incontinence [199]. A retrospective analysis of drug dispensing data in a Japanese cohort found that polypharmacy was associated with the use of medications known to contribute to urgency [200]. Similarly, a Canadian cross-sectional study identified a strong association (OR 4.9, 95%CI 3.1-7.9) between polypharmacy, defined as 5 or more medications, and the prescription of a medication known to cause LUTS [201]. However, there is little evidence that polypharmacy in the absence of drugs that cause incontinence has an impact on the lower urinary tract, and it is likely that the association between polypharmacy and urgency relates to the fact that the more drugs an individual is prescribed, the higher the odds that one of them will be a drug known to induce urgency. Elderly patients commenced on new treatments should be monitored for changes in urinary symptoms. Many classes of medications commonly prescribed for the frail elderly can cause or contribute to the development of UI **(Table 3).**

Table 3. Medications that can cause or contribute to UI in frail elderly persons

Medications	Effects on Continence
Alpha adrenergic agonists	Increase smooth muscle tone in urethra and prostatic capsule and may precipitate obstruction, urinary retention, and related symptoms
Alpha adrenergic antagonists	Decrease smooth muscle tone in the urethra and may precipitate stress urinary incontinence in women
Angiotensin converting enzyme inhibitors	Cause cough that can exacerbate UI

Medications	Effects on Continence
Anticholinergics	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause cognitive impairment and reduce effective toileting ability.
Calcium channel blockers	May cause impaired emptying, urinary retention, and constipation that can contribute to UI. May cause dependent oedema which can contribute to nocturnal polyuria
Cholinesterase inhibitors	Increase bladder contractility and may precipitate urgency UI
Diuretics	Cause diuresis and precipitate UI
Lithium	Polyuria due to diabetes insipidus
Opioid analgesics	May cause urinary retention, constipation, confusion, and immobility, all of which can contribute to UI
Psychotropic drugs Sedatives Hypnotics Antipsychotics Histamine$_1$ receptor antagonists	May cause confusion and impaired mobility and precipitate UI Anticholinergic effects Confusion
Selective serotonin re-uptake inhibitors	Increase cholinergic transmission and may lead to urinary UI
sodium-glucose cotransporter 2 (SGLT2) inhibitor	Glycosuria and polyuria, increased propensity to urinary tract infection
Others Gabapentin Glitazones Non-steroidal anti-inflammatory agents	Can cause ooedema, which can lead to nocturnal polyuria and cause nocturia and night-time UI

UI = urinary incontinence

3.2. Comorbid conditions and functional impairment

Urinary incontinence is more prevalent in the frail elderly, is associated with cognitive impairment, decreased mobility and decreased levels of physical activity and reduced quality of life.

In a group of subjects with Medigap insurance Advancing age has been associated with an increase in the prevalence of urinary incontinence (37.5% in 5530 subjects). Comorbidities associated with urinary incontinence including arthritis of the hip or knee (Relative Risk Ratio (RRR) = 1.21, P\0.001), arthritis of the hand or wrist (RRR = 1.15, P = 0.001), stroke (RRR = 1.18, P = 0.078), other heart conditions (RRR = 1.19, P\ 0.001), and having any cancer (RRR = 1.13, P = 0.0020). Obesity and being overweight increased the likelihood of having UI (RRR = 1.32, P\=0.001 and RRR = 1.14, P = 0.0013, respectively), compared with being at normal weight. Incontinence remained a significant predictor of lower quality of life [202].

The prevalence of urinary incontinence (UI) is increased in the presence of frailty. The elderly are prone to frailty and commonly have co-morbid medical illnesses. In a large population-based observation study UI (defined as use of pads) was independently associated with one or more other geriatric conditions (cognitive impairment, injurious falls, dizziness, vision impairment, hearing impairment) in 60%, two or more conditions in 29% and three or more in 13% [203]. Elderly subjects with urinary incontinence had a 2.9 fold greater chance of becoming more frail over a 12 month period than those without incontinence (p=0.007) [204].

In a sample of 572 older Latinos participating in a programme to increase walking, medical comorbidity was independently associated with higher rates of UI (OR 1.66). More physical activity was independently associated with lower UI (Odds Ratio (OR) 0.77). Hypertension, congestive heart failure, arthritis, depression and anxiety were associated with a higher prevalence of UI. A linear correlation was found between prevalence of UI and the number of comorbid conditions. (correlation coefficient =0.81) [205].

In an observational study of 6,361 community dwelling women, aged 65 and older, participating in the

study of Osteoporotic Fractures, after adjusting for confounders, women with recent physical function decline (a worsening of 1 standard deviation from baseline) were more likely to report weekly incontinence (OR 1.3) for decline in walking speed over 6 meters and (OR 1.4) for decline to stand from sitting [206]. The Nurses' Health Study found that moderate-intensity low impact physical activity including walking resulted in a 20-25% reduction in the risk of developing UI in older women particularly stress rather urge incontinence [207]. Factors associated with persistent UI were similar to those associated with increasing incidence including lower physical activity levels. The strongest factors for

persistent UI were older age, white race and obesity [208]. Likewise, impaired cognition is associated with an increased likelihood of UI. For example in a UK cross-sectional survey of over 15,051 subjects, persons with cognitive impairment (Mini Mental State Exam score <= 23, prevalence 18%) were significantly more likely to have UI (adjusted OR 1.3), impaired hearing (OR 1.7), poor vision (OR 1.7) have had at least two falls in the previous six months (OR 1.4), and report poorer health (OR 1.9) [209].

The Jerusalem Cohort Longitudinal study assessed the same community dwelling subjects at age 70, 78 and age 85. Urinary incontinence increased from 14.1% to 31.3% and to 42.5% at age 85. This was associated with an increase in comorbidity and Charlson's disability index of 7.3, 11.7 and 21.7 respectively and increase in geriatric syndromes [210].

A study of 6903 participants (mean age 82.2) in Europe and Ontario receiving home care services identified an increase in Geriatric syndromes (GS) in the presence of associated diseases. Participants presented with an average of 2.6 diseases and 2 GS. Urinary incontinence was present in 47% [211]. A study of 270 subjects aged 65 to 89 reported 26.3% moderate or severe urinary incontinence in the preceding 12 months in 3 groups: frailty (7.4%), pre-frail (45.9%) and non-frail (46.7%) . In a second sample of 300 frail subjects aged 90 to 107, 37.4% reported moderate or severe incontinence. Incontinent subjects were 6.5 times more likely to be in the frail group and 2.3 times in the pre-frail with respect to continent subjects. The authors concluded that UI was a marker of frailty [212]. In a cross sectional study of 521 community Brazilian elderly > 60 years were assessed for the association between frailty and geriatric syndromes. Subjects were classified as frail, (>= 3 criteria) pre-frail (1 or 2 criteria) or robust elderly. Urinary/faecal incontinence occurred in 23.7%,12.8% and 9.2% respectively. The commonest Geriatric syndrome was cognitive impairment. In this study there was no association between incontinence and frailty [213]. A study of 447 community dwelling nursing home eligible elderly with diabetes found a prevalence of urinary incontinence of 44%. Older age, dependence on others for ambulation or transferring and cognitive impairment were associated with UI [214].

Comorbid conditions can affect incontinence through multiple mechanisms e.g. diabetes mellitus, present in approximately 15-20% of frail elderly may cause UI by diabetes associated LUT dysfunction (DO, OAB, cystopathy and incomplete bladder emptying) or by poor diabetic control (hyperglycaemia causing osmotic diuresis and polyuria). The Nurses Health Studies, NHS and NHS II [215] showed an increase in weekly urgency incontinence (OR 1.4) in women with type 2 diabetes compared to those without. Findings from the NHANES 2001-2002 Survey showed that prevalence of UI was significantly higher in women with impaired fasting glucose and diabetes mellitus compared to those with normal fasting glucose. Two microvascular complications caused by diabetes, peripheral neuropathic pain and macroalbuminuria, were positively but not statistically significantly associated with weekly UI [216]. In diabetic women, peripheral neuropathy have been significantly associated with LUTS and metabolic syndrome has been associated with OAB [217]. In a younger population of mean age 59 years, the Diabetes and Aging Study found the prevalence of occasional urinary incontinence to be over 65%. HbA_1C level was not associated with the presence or absence of urinary incontinence. Women with HbA_1C .=> 9% had more limitations in daily activity due to incontinence, defined as self-reported "quite a bit" or "extremely" in the preceding 12 months compared to women with HBA1C < 6% [218]. Higher glycated haemoglobin levels have been associated with increased symptoms of OAB [219].

Incontinence impairs quality of life (QOL) in the elderly [220]. In a cross sectional study of 1124 subjects over 70, (mean age 79.5 years) urinary incontinence prevalence was 18% and the severity of UI increased with age. UI was more common in women, and was associated with worse self-reported health. Incontinent subjects were more likely to require assistance with ADLs, had more depressive symptoms and worse physical performance. Increasing severity of incontinence was negatively associated with QOL as measured by the Short Form-36 [221].

3.3. Neurological & psychiatric disorders

3.3.1 Neurological disorders

A more detailed summary of neurological disorders and their impact on UI is covered in the Chapter on Specific Neurological Diseases. Neurological and psychiatric disorders are highly prevalent in frail older people. Neurological conditions in the elderly commonly associated with urinary incontinence include stroke, Alzheimer's dementia (AD), multi-infarct dementia or mixed AD and vascular dementia, Diffuse Lewy Body (DLB) disease and Parkinson's disease. Less common conditions include Normal Pressure Hydrocephalus (NPH), Progressive Supranuclear Palsy (PSP) and Multiple System Atrophy (MSA). Each of these conditions are associated with the development of brain lesions that can interfere with the micturition pathway and interfere with the normal ability to inhibit voiding as well as affecting cognition. These conditions are associated with impaired mobility and can interfere with the ability to toilet independently.

In Alzheimer's disease, UI is often associated with severe cognitive decline whereas in DLB it usually precedes severe cognitive impairment. Occurrence of UI was significantly earlier 3.2y in DLB compared with 5.9y in AD [222]. NPH should be a diagnostic consideration in any frail older patient who presents with new onset of UI in association with gait disturbance and cognitive impairment. A subset of these patients benefits from surgical implantation of a cerebrospinal fluid shunt [223].

LUTS, UI and urodynamic DO are common in older persons with Parkinson's disease. A logistic regression analysis of 3414 Parkinson's disease patients found a significant correlation of orthostatic hypotension and urinary incontinence with age and duration of the disease. The presence of UI in persons with Parkinson's may in turn increase their risk for disability: in one series of patients with Parkinson's UI increased the risk of falling by nearly six-fold. Urinary symptoms often non-responsive to L Dopa therapy [224]. MSA presents with a combination of impaired autonomic function, parkinsonism (MSA-P) or cerebellar ataxia (MSA-C) or both [225]. It frequently begins with bladder dysfunction and erectile dysfunction in males and is associated with bladder symptoms of DO, often progressing to incomplete emptying. High PVR may help in pointing to a diagnosis of MSA-P rather than Parkinson's disease [226].

With the introduction of magnetic resonance brain imaging into routine clinical practice, radiology reports in older patients have increasingly emphasised the presence of structural abnormalities involving the white matter [227]. Terminology has also undergone a great change, moving away from subcortical atherosclerotic encephalopathy (Binswanger's disease, a specific and relatively rare form of dementia), towards leukoaraiosis [228] and, most recently, to the concept of white matter signal abnormalities (WMSA) [227, 229]. Brain MRI identified subjects with leukoaraiosis as more likely to have urinary dysfunction which may precede cognitive impairment particularly in grade 1 disease [230]. White matter hyperintensities (WMH) have been linked to severity of incontinence rather than to its presence [231]. The disorder of bladder control resulting from white matter disease (WMD) has been termed vascular incontinence [232]. WMH load appears to progress in association with ageing and the amount of frontal WMH are predictive of urinary incontinence in amnestic mild cognitive impairment and AD [233].

White matter lesions were found to be a more significant contributor to OAB and incontinence than AD in the elderly [234].

3.3.2 Depression

As in younger persons, frail older persons with UI have a higher risk of depression, a finding that has been replicated across cultures. Depression in older persons with UI may be under-diagnosed and undertreated: in one study of homebound adults with UI and severe depression, only 35% carried a previous diagnosis of depression and only 34% had been prescribed an antidepressant [235]. UI may add to the burden of depression by decreasing life satisfaction [236] and self-rated health, [237] and by its association in frail elders with comorbidity [238].

Studies of the association of depression and UI in older persons are consistent across several depression measures. The validated Center for Epidemiologic Studies-Depression was used in two U.S. studies: a cross-sectional analysis of nearly 10,000 community-based persons found an adjusted risk ratio for depression with UI 1.39 [95% CI 1.24, 1.55]), [239]. A large community-based study of older Mexican Americans reported adjusted OR for depression 1.94 [95% CI 1.46-2.59]) [240]. The emotional disturbances and social isolation subscales of the Nottingham Health Profile Questionnaire was associated with urgency but not stress incontinence [241] and have included studies in Asia [242]. Although no association between UI and depression was found in a Korean study of 135 community living elderly aged greater than 85 years, it used a higher cut-off (>7) on the Geriatric Depression Scale and, unlike many other studies, found no association between UI and mobility [243]. Self-report of depression or sadness has [244],[245] and has not been associated with UI [246].

3.3.3 Psychological distress and quality of life

Psychological distress, assessed by the General Health Questionnaire, was associated with UI in African Americans (adjusted OR 5.60 [95% CI 1.88–16.67]), but not in whites, in a cross-sectional study of community based older persons with mean age 67y. However, a longitudinal analysis of the same population over 13 years found that persons with UI and psychological distress were more likely to report UI-specific functional impairment (e.g., avoidance of social activities, shopping, and physical activities) (adjusted OR 6.55 [95% CI 1.94-22.12]). Additionally, persons with UI and condition-specific functional loss were more likely to develop psychological distress (OR 3.66 [95% CI 1.61–8.33]) [247, 248].

The EpiLUTs a large cross-sectional internet study showed significant impairments in mental health and HRQOL when different urinary symptoms were combined [249, 250]. The US sample of the EpiLUTS study involving 2485 men and 2877 women aged 65 and older found OAB was associated with significant impairment in HRQOL. Rates of Anxiety of >7 on HADS-A were 16.4% for men and 23.6% for women with OAB compared to 3.3% and 8.6% with minimal or no symptoms. Similarly rates for depression on the HADS-D were 17.3% and 15.7% for OAB compared to 4% and 6.4% in those with no or minimal symptoms [251].

A case controlled study of 100 elderly men attending a Urology outpatients matched with 100 age matched controls from the community and Geriatric outpatient clinics found those with moderate to severe LUTS had worse HRQOL. This was evident in a number of ageing male symptoms including depression, decline in feelings of general well-being, decreased sexual performance, decreased muscle strength [252].

The direction of the causal relationship between UI and depression in frail persons is unclear, as nearly all studies were cross-sectional. The results of the one longitudinal study suggested that it is not UI itself but UI-specific functional loss (e.g., avoidance of social activities, attending church, etc.) that is most

closely associated with psychological distress, even after controlling for important covariates [235].

3.3.4 Falls

Urinary urgency and urinary incontinence, urinary frequency, and nocturia have been identified repeatedly as risk factors for falls among community-dwelling older adults [253-259]. Mixed incontinence (a combination of urgency and stress incontinence) has also been associated with falls risk in women 70 years and older [260]. Brown and colleagues [259] performed a secondary analysis of data from an osteoporosis cohort study, examining a group of 6049 community-dwelling older women using regular self-completed questionnaires sent to all participants every four months. In this cohort, followed for an average of three years, those with at least one weekly UUI episode were more likely to fall (OR 1.26, 95%CI 1.14-1.40) than those without. Weekly UUI was also associated with higher odds of sustaining a non-spinal fracture (hazard ratio 1.34 95%CI 1.06-1.69). In this study, stress incontinence was not associated with higher odds of falling (Odds ratio (OR) 1.06, CI 0.95-1.19) or sustaining a fracture (relative hazard 0.98, CI 0.75-1.28).

Analysis of the Concord Health and Ageing in Men Project, a longitudinal study of community-dwelling men in Australia followed 1090 men over a period of 2 years. Here, the presence of urgency incontinence, defined as weekly episodes of UUI, was associated with a higher incidence of falls (OR 2.57 95%CI 1.51 – 4.3) and men with a higher International Prostate Symptom Score storage sub-score, defined as a score of 19 and above, had a higher incident rate of falls (incident rate ratio 1.72 (95%CI 1.24-2.38) [261]. A Japanese study of patients with Parkinson's disease found that increased micturition frequency either by day or night was not associated with falls, but that the presence of urinary urgency was strongly associated with a large increase in the odds of falling (OR 5.14 95%CI 1.51-17.48). Only 14% of the falls reported in this study occurred on the way to or from the toilet [262].

A recent systematic review of the association between falls and LUTS in community-dwelling men aged 60 years and over identified six cross-sectional studies and three prospective cohort studies. The identified data were only suitable for qualitative synthesis but urinary incontinence and storage LUTS were consistently shown to have a weak to moderate association with an increased likelihood of falls. None of the identified studies examined potential causes for these associations; the categorisation of continence or not and degree of accounting for confounding variables was inconsistent across the included studies [263]. A small cross-sectional analysis of community dwelling women aged 65 and over in the US examined the association between nocturia, nocturnal enuresis and falls. Neither severity of UI nor severity of nocturia was associated with an increased risk of falls, but there was a statistically significant association between nocturnal enuresis and impairment of physical function and the presence of frailty. However, in the multivariable regression model, which included age, physical function, and the frequency of nocturnal enuresis episodes, only physical function remained as significant risk factor for falls [264]. One study, a prospective cohort study of older men in the USA, identified a statistically significant association between straining to void and falls, with a 60% increase in falls risk for those reporting the need to push or strain to initiate urination at least half the time [265]. In hospital, urinary incontinence is associated with an increased propensity to fall in older inpatients [266, 267]. Urinary incontinence is also associated with falls in institutionalised older persons [268, 269]. The underlying reason for the association is not yet clear, although several and multiple mechanisms are most likely. A UK case control study in older community dwelling women presenting to an urban Emergency Department found that only 6% of those with a fall attributed this to their LUTS[270]

3.3.5 Stroke

Conservative interventions (e.g. bladder training, pelvic floor muscle training and prompted voiding) have been shown to have some effect in Cochrane systematic reviews, but have not had their effectiveness demonstrated with stroke patients. UI may have worse prognostic implications after stroke, being associated with greater mortality, a poorer functional recovery and an increased likelihood of institutionalisation than those following strokes who regain continence [271]. Of 1,187 patients aged 60–96 with stroke, those with low bladder maintenance scores (more dysfunction) fared worse with rehabilitation than those with higher scores [272]. There has been little advance in care since the 5th International Consultation. A survey of stroke unit practice in Australia showed that less than half had a formal plan for continence care and in the UK, as part of the national sentinel audits of stroke, there was little advance in continence care [273, 274]. A comparative study of stroke nursing found a dearth of evidence and treatment focused on containment and social conti- nence, highlighting the need for systematic assessment and management [275]. The burden on caregivers of those with incontinence following stroke has been acknowledged [276].

Recommendations for research

Further research is required to:

- Examine the effect of treatment for UI in older people with Parkinson's disease
- Examine the temporal association and mechanism underlying falls and LUTS/UI in frail older persons
- Examine the effect of structured treatment for UI in older people following stroke.

- Examine the impact of interventions comorbid disease on the experience and outcomes of urinary incontinence in frail older persons

Recommendations for practice

Clinicians need to assess and manage coexisting comorbid conditions which are known to have an impact on continence status or the ability to successfully toilet.

4. ENVIRONMENTAL FACTORS

This section addresses those factors unrelated to underlying pathophysiology which affect continence status in frail older persons.

4.1 The physical environment
4.2 Processes and quality of care
4.3 Lack of assessment
4.4 Lack of knowledge about incontinence
4.5 Practices that reduce/restrict mobility and functional status
4.6 Limited or inconsistent access to toileting assistance
4.7 A lack of toileting privacy
4.8 Reduced staffing levels in long-term aged care homes
4.9 The overuse and misuse of continence products
4.10 Community / home care / primary care
4.11 Acute care / hospital/ Secondary care
4.12 Long-term aged care homes
4.13 Dignity in care

In this section, we define processes of care as the instrumental procedures involved in the assessment and management of incontinence relating to frail older persons.

4.1. The physical environment

Although the physical environment is considered a risk factor for incontinence in frail older adults, there is limited research on this topic. We located seven publications with evaluative data on this topic: two of these studies were conducted over 40 years ago [277, 278] prior to the establishment of internationally agreed standards for reporting trial data. Three were published from a series of projects conducted in the USA to examine the impact of the physical environment on specific problems of people with Alzheimer's disease and related disorders [279-281]. One qualitative study was identified that employed an ethnographic design [282]. Each of these studies involved individuals in long-term care homes. One study evaluated the prevalence and risk factors for incontinence in a sample of 5,418 community- dwelling frail older adults who were receiving home care services [283]. Environmental barriers as well as the use of physical restraints, along with UTIs were the most common reversible risk factors for urinary incontinence: increasing the risk of urinary incontinence by over 50% [283]. In this study, environmental hazards included a lack of access to the toilet, unavailability of grab rails, inappropriate toilet seat height, inadequate lighting, and inadequate toileting substitutes such as commodes or urinals.

Attempts to evaluate the effects of enhancing the physical environment on rates of incontinence in long-term aged care homes were reported by Chanfreau-Rona [277, 278]. In both studies, the intervention involved enhancing visual access to the toilet by painting toilet doors in bright colours and strategically locating pictorial signs and other visual cues. In addition, staff were asked to accompany residents to the toilet at predetermined 'peak times' and to employ operant conditioning techniques to reinforce residents' appropriate toileting behaviour. In the first of these trials, 24 elderly female residents, most of whom had cognitive impairment, were purposively assigned to either the intervention, or to usual care for seven weeks [277]. The same procedures were repeated in a subsequent trial [278]. Although reductions in incontinence were noted for residents in the experimental groups compared to the control groups, the extent to which these reductions were related to the intervention is difficult to determine as both studies lacked power and did not control for confounding factors. Nonetheless, these studies represent an early, multifaceted intervention that involved evaluating the effect of changes to the physical environment to reduce incontinence among frail older adults in long-term care.

According to the first of a series of projects conducted by Namazi and colleagues, the overall physical environment has a considerable impact on the well-being and quality of life of individuals with Alzheimer's' Disease (AD), affecting their ability to function in the face of incontinence, distraction and disorientation [280]. One of the projects focused on the clinical utility of using environmental cues (i.e. signage, colour differentiation and images) in a dementia-specific unit to assist compensate for resident' visuo-perceptual deficits [279]. The most effective environmental cue in terms of orienting individuals with AD to the toilet was a combination of using a sign with the word "toilet", together with "wayfinding" arrows on the floor. No single strategy was suitable for all individuals with AD due to the variability in the ability of individuals with AD to perform all of the tasks associated with successful toileting. The researchers therefore recommended "to maximize the remaining strengths of those who are afflicted with AD, each component of the morphology which creates difficulties for AD patients must be identified and treated individually". In essence, individuals with AD may need individually targeted cues that address identified specific deficits.

In a second project, Namazi and colleagues [281] systematically examined toilet use in a dementia-specific unit under two conditions: with the toilet

highly visible to residents, and with the toilet concealed. The frequency of toilet use increased when toilets were visually accessible during the 45 hours of observation. Visibility and accessibility of toilets may be an important factor in supporting individuals to maintain continence.

Toilet accessibility also featured highly in a qualitative study conducted by Sacco-Peterson and Borell [282]. Using ethnographic methods, the researchers collected over 200 hours of field observational data and conducted in-depth interviews with nine residents in a long-term aged care home. They reported that different aspects of the facility's physical and socio-cultural environment influenced residents' abilities to maintain autonomy in self-care. For example, there was an inadequate number of toilets, inadequate privacy for toileting, inappropriate toilet heights, excessive distances to the toilet, and a lack of call light, toilet paper, soap, paper towels, lighting and commodes. Despite the challenges of negotiating this 'defeating ward geography', many residents attempted to participate autonomously in toileting, whilst others were deterred because of a fear of falling.

4.2. Processes & quality of care

In a systematic review of the prevalence and risk factors for urinary incontinence in long-term aged care homes, Offerman and colleagues [284] identified 46 risk factors for urinary incontinence. These factors were grouped into 1) locomotion, 2) cognitive function and 3) drugs. However, in addition to these risk factors, the reviewers stated "differences in the care process and quality of care can also influence urinary incontinence prevalence; reasons for a less-than-optimal approach in long-term care homes may include, for example, inadequate knowledge of and skills for urinary incontinence in general, inability to use guidelines for urinary incontinence care, insufficient staff and poor communication among healthcare professionals" (p. 291). They recommended that risk factors related to care processes be further investigated.

Two studies offer qualitative data on how processes of care in nursing homes may represent a risk factor for incontinence. For example, descriptive information derived from semi-structured interviews with six elderly women from two nursing homes in Canada, suggests that some residents experience an environment characterised by rituals and routines, , limited assistance with pad changing, restrictions on the number and type of continence products available, set times for toileting and pad changes, ageism, and a lack of recognition of attempts to maintain continence [285]. Sacco-Peterson and Borell [2004] also found that 'toileting assistance was provided at set times, and 'if residents required more assistance other than at set times, pads were used'. Pad use also correlated with residents' mobility level, rather than their cognitive or continence status. Additionally, night-time use of pads often started following a fall at night. Residents did not divulge their difficulties to staff, and were reluctant to ask for help and thus staff members were unaware of residents 'difficulties and efforts. Residents valued the capacity to exercise some power and autonomy with regard to self-care, and didn't want to be 'a bother to the nurse'. Thus, their attempts to maintain continence may be undermined by care processes that unintentionally diminish an individual's independent toileting [282].

More recent research reinforces the finding that processes of care in organisational settings are not designed to promote therapeutic continence care for care-dependent older people. For example, in an analysis of data for 46,044 residents in 162 nursing homes in New York State, for June 2006–July 2007, and survey responses from 7,418 workers in the same facilities, Temkin-Greener et al. [286] reported an association between incontinence and nursing home work environment attributes such as teams, consistent assignment and staff cohesion. After adjusting for other factors, they found residents in facilities with stronger staff cohesion to have significantly lower odds of incontinence (OR = 0.924; $p < .001$). A one standard deviation (0.23) increase in the staff cohesion score resulted in 7.6 percent lower odds of incontinence. Likewise, in a longitudinal correlational study, Yoon et al. [287] examined the impact of organizational factors on the quality of UI care (i.e. defined as improvement in UI status or maintenance of continence post admission to Korean long-term care hospitals. After controlling for other factors, they found higher Registered Nurse to patient ratios was significantly associated with better resident UI outcomes.

Thomas et al. [288] conducted a mixed-methods study which explored the organisational context for embedding a systematic voiding programme for patients with UI after stroke in secondary care settings. The researchers concluded there was a focus on containment of UI that was not conducive to therapeutic continence management. In a prospective cohort study of 282 hospitalised older adults, Zisberg et al. [289] found the quality of continence care was one of three factors that directly related to functional decline at discharge. Thus, there are organisational processes beyond individual risk factors that account for potentially modifiable causes of incontinence in care-dependent older persons.

Ostaszkiewicz [290-292] conducted a Grounded theory study to describe and explain the context that affects continence care in long-term aged care homes. The findings suggest a basic social problem that is characterised by multiple constraints to residents' overall care. Factors that contribute to this problem include: (i) a highly regulated work environment; (ii) ethically challenging care; (iii) highly dependent residents; and (iv) a devalued role. Staff responses to this problem include accommodating strategies such as acquiescing, concealing, protecting, adapting, prioritising, normalising, compromising, and ritualising, as well as self-protective distancing strategies such as blanking out, using distancing language, and reframing care. The researcher called for a comprehensive

multifaceted research-based strategy that addresses the social, regulatory, organisational, and personal constraints to evidence-based, ethical, resident-centred care, including continence care. There is a need to counter the pervasive belief that quality continence care for frail older adults is a function of cleaning and containing incontinence. In countries that rely on education about incontinence from the continence product manufacturing industry, the strategy should also counter the dominance of industry-based education. Although independent quality performance standards have been developed for disposable absorbent products there is an absence of standards to promote ethical relationships between healthcare consumers and the continence product manufacturing industry [293].

4.3. Lack of assessment

A comprehensive assessment to determine type and causes of incontinence is an essential precursor to appropriate management. However, many older people with incontinence do not have access to this assessment, and are therefore at risk of remaining incontinent (Table 4). This finding is consistent for older adults across different countries and settings.

4.4. Lack of knowledge about incontinence

A lack of knowledge about incontinence and its management may operate as an antecedent to care processes that inadvertently promote incontinence. Specifically, a lack of knowledge that incontinence is a symptom of a potentially treatable condition, may have the unintended effect of hindering access to diagnosis and treatment.

A number of studies reveal gaps in nurses' and nursing aides' knowledge about and attitudes toward older people with incontinence in long-term aged care [294-313], as well as acute care [310, 314-318]. Other research highlights gaps in medical practitioners' knowledge about incontinence [319-323]. For example, a survey of general practitioners (GPs) knowledge of investigation modalities and treatment options for individuals with faecal incontinence in the UK, found that only 32% were aware of at least one investigation, and 32% were aware of at least one form of surgical treatment [323]. In a cross-sectional national survey to determine knowledge, attitudes, and management of urinary incontinence among family physicians in Canada, less than half (46.0%, 284/617) indicated that they had a clear understanding of incontinence and just 37.9% (232/612) had an organized plan for incontinence problems [322]. Similarly, Teunissen et al [324] reported three main themes from focus groups with 13 GPs in Holland: (i) therapeutic nihilism of GPs and low motivation of patients, (ii): GPs experienced lack of time because of difficulties in explaining the therapy and because of impaired mobility of older patients, (iii) reluctance to treat UI because of the complexity of the problem and co-morbidity.

Knowledge about incontinence and its management in the general community is also lacking, especially amongst men, those aged 85 and older, and those with lower levels of education [325]. For instance, a nation-wide consumer survey conducted in the USA in 2000, found four in ten people (41%) thought that loss of bladder control was a disease and a similar percentage (38%) believed it was a natural part of ageing [326].

Improvements in knowledge about incontinence in older people are possible. Szonyi and Millard [320] reported a significant improvement in GPs knowledge about incontinence following receipt of an education package. Likewise, Mathis et al. [327] and Ehlman et al. [328] demonstrated improvements in knowledge among nursing home staff following an educational intervention.

Table 4. Evaluative studies on assessment of incontinence in frail older adults

Study	Objective	Sample	Method	Findings
[943] Du Moulin et al., 2009	To assess the prevalence of UI and gain insights into care issues	2866 patients (mean age 80 ± 7.2yrs) living at home receiving home care in Holland	Survey + audit of medical records	Type of UI was diagnosed in 49% of patients. Management did not differ for patients with and without a diagnosis of UI type
[614] Georgiou et al., 2001	To evaluate the recommended outcome measures in clinical practice	1125 residents in 17 residential homes, 14 nursing homes and 5 long-stay wards in UK.	Analysis of data on the UI section of the Royal College of Physicians Continuous Assessment Review and Evaluation Scheme audit tool	Rates of full clinical assessment were 48% for people in residential homes 24% for people in nursing homes 36% for people in long- stay wards
[254] Rodriguez et al., 2007	To explore continence prevalence, knowledge and care	66 care homes in Birmingham, UK	Survey completed by managers or other senior staff	Only two respondents gave information indicative of a full assessment. Most respondents had difficulty identifying the process of assessment.
[257] Pringle-Specht et al., 2002	To determine patterns and treatment of urinary incontinence	145 residents with dementia (mean age 83.3yrs) from 13 special care units in long-term care facilities in USA	Retrospective audit of residents' medical histories using 'Incontinence Patterns Tool' (IPT)	55% of residents with UI and dementia had a documented care plan for treatment of UI 2.1% (n=3) had a current medical diagnosis of bladder incontinence
[245] Wagg et al., 2008	To assess the quality of continence care for older people	Patients from 138 primary care trusts, 195 secondary care trusts, and 27 care homes in UK	Audit of patients' clinical records	Poorly documented aspects of a clinical assessment across all settings: rectal examinations and post-void residual urine volumes. In secondary care trusts, 919/3509 (25%) of histories had documentation of an assessment to determine UI type or cause
[944] Watson et al., 2003	To assess the use of the Agency for Healthcare Policy and Research Guideline for managing UI in nursing homes	200 residents with new UI or newly admitted with UI from 52 nursing homes in upstate New York, USA	Retrospective chart review and Nursing Assistance screening interviews	4 new cases of UI per 100 beds over 12 weeks UI Guideline standards met 20% of cases (0-45%). Aspects of assessment rarely performed rectal examination (15%) digital examination of prostate (15%) pelvic examination (2%)

4.5. Practices that reduce/restrict mobility and functional status

Impaired mobility and ability to perform activities of daily living (ADLs), such a toileting ability, can cause or contribute to incontinence in frail older persons in any setting. Urinary incontinence is associated with severe impairment in ADLs in long-term aged care homes [329, 330]. In a cross-sectional analysis of data from the 2010 National Survey of Residential Care Facilities, Talley et al. [331] found the prevalence of toileting disability was 15% and was highly associated with ADL impairments. Hence, greater emphasis should be given to interventions that reduce the risk of functional decline that may subsequently prevent or delay the onset of incontinence. Two recent trials reveal reductions in the frequency and severity of incontinence from exercise programmes that aim to improve frail older person's functional status [332, 333].

Practices that restrict or minimise a person's mobility and ability to function hinder their ability to reach and use the toilet autonomously. The use of physical restraints is one such practice. Although restraint-free care has been recommended as standard, restraints remain widely used in long-term aged care homes, ranging from 12-47% internationally [334]. In a multivariate analysis of data from 2,014 residents from 270 USA Medicaid-certified nursing homes, Brandeis and colleagues [329] identified that urinary incontinence was independently associated with a number of factors, including the use of restraints of the trunk (OR = 1.7; CI = 1.5,2.0), restrained to a chair (OR = 1.4; CI = 1.2,1.6), and bedrails (OR = 1.3; CI = 1.1,1.5). Similarly, in a community–based sample of frail older adults, the use of physical restraints was identified as a key reversible risk factor for urinary incontinence [283].

4.6. Limited or inconsistent access to toileting assistance

An obvious, yet often overlooked risk factor for incontinence is a lack of toileting opportunities and assistance for individuals who are care-dependent. Research from USA shows that the frequency of toileting assistance provided in long-term aged care homes is too low to maintain continence [78]. In recent years, the UK media has drawn attention to the fact that many people in hospital do not receive timely assistance to use the toilet: a situation that contributed to the establishment of the "Dignity in Care Campaign" – launched in 2006. In response to concerns about neglect in aspects of personal and healthcare, the British Geriatrics Society proposed that the ability to use the toilet in private was in fact, a marker of human rights, and developed a "Behind Closed Doors Campaign". The aim of the campaign was to empower, educate and influence providers and policy makers to adopt a more pro- active stance to demand better continence care. A more recent campaign, again led by the British Geriatrics Society, titled "Do not forget the person" was launched in March, 2010. The extent to which such awareness raising activities affect day-to-day care processes in the absence of structural change and resources requires evaluation.

Structured toileting programmes require a staff to patient ratio of 1:5. A lack of staffing or institutional understaffing represents a key risk factor for incontinence among individuals who are dependent on another person to use the toilet. There is a need to identify the best methods to implement and sustain toileting assistance programmes, especially when caring for cognitively impaired care-dependent individuals who may be unable to communicate their need for assistance, and when caring takes place in an organisational care setting such as a long-term aged care home [335].

4.7. Lack of toileting privacy

Privacy to void or defaecate are important social factors unrelated to underlying pathophysiology which may affect the continence status of frail older persons. It is possible a lack of toileting privacy to may cause a person to defer or ignore the urge to void or defaecate. According to the findings of a cross sectional survey of 120 adults with FI aged 65 and over and living in either their own homes, a nursing home, or an acute or rehabilitation, privacy to defaecate is usually attainable in one's home, but not in a nursing home. Privacy to defaecate was reported by 23% of respondents in a nursing home, 53% of those in rehabilitation wards, and 50% of those in acute wards [336]. Further research is required to explore the relationship between a lack of toileting privacy and incontinence in frail older adults.

4.8. Reduced staffing levels in long term care

Estimating and achieving the optimal level and skill mix of any workforce is a challenge. In long-term aged care homes where residents' have chronic health problems and complex health needs, maintaining sufficient staffing levels is exacerbated by a high staff turnover. Nurses consistently cite inadequate staffing levels as a major barrier to providing optimal continence care [337-341]. The extent to which patients and residents' continence care needs are considered in formulas designed to establish the right staffing level and skill mix is unclear. The time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management to prevent and/or manage incontinent episodes require consideration in service planning.

4.9. The overuse and misuse of continence products

For many people, continence products represent a means by which they can achieve effective and discrete containment of incontinence, minimise physical discomfort and optimise psychological and social function [342]. At the same time, their overuse and misuse may represent a risk factor for incontinence

and, for pads, urinary tract infection. Although continence products have an important place in the control of incontinence, their use in the general community, in hospital settings, and in long-term aged care homes is widespread (Table 5). For example, in the largest and widest audit of continence care conducted in the UK and involving over 6,000 patients across primary and secondary care trusts, and care homes, containment strategies (i.e. the use of continence products) far exceeded all other forms of documented continence management [343].

Table 5: Evaluative studies on the use of continence products (pads and briefs)

Community / home care / primary care				
Study	**Objective**	**Sample**	**Method**	**Results**
[943] Du Moulin et al., 2009	To assess the prevalence of UI and gain insights into care issues	2866 patients (mean age 80 ± 7.2yrs) living at home and receiving home care in Holland	Survey + audit of medical records	Pads were used by 59.2% of patients with diagnosis of UI type and by 55.8% of patients with no diagnosis of UI type
[945] Samuelsson et al., 2001	To study age- and sex specific use and costs of freely available incontinence aids in Sweden	2542 women & 1292 men living in their homes (including special accommodation) in a county of Sweden who were using incontinence aids	Audit of incontinence aid prescriptions – data extrapolated to general population	Incontinence aid use 367000 (3.7%) of all people in Sweden 6.4%-women /2.4%-men in the county 765000 (66%) in special accommodation Costs 925 million SK 50% of cost attributable to those aged 80 yrs or >
[247] Sorbye et al., 2008	To determine prevalence and characteristics associated with UI	4010 randomly selected older persons (mean age 82.3 ± 7.3 yrs) living at home in one of 11 European countries and using home care agencies	Cross sectional survey using the International Resident Assessment Instrument for Home Care (RAI-HC)	39% used pads (highest usage in France -52% / lowest usage in Norway and Czech Republic – 29%) Pad use correlated with need for toileting assistance (p<0.001)
[245] Wagg et al., 2008	To assess the quality of continence care for older people	2717 patients from 138 primary care trusts in UK	Audit of patients' clinical records	Containment strategies were used by 1294/2717 (48%) of patients
Acute care / hospital / secondary care				
Study	**Objective**	**Sample**	**Method**	**Results**
[250] Kadir, 2004	To determine the incidence and appropriateness of incontinence aid use	333 elderly patients in an acute hospital (Singapore)	Survey – patient self report	200/333 (60%) - using some form of aid 101 (50.1%) could have been managed with alternatives
[249] Palese et al., 2007	To evaluate the incidence of pad use and explore appropriateness and reasons for use	396 patients (mean age 76.8 ± 11.8yrs) admitted to medical units in 2 acute care units in Italy	Survey – interview + clinical assessment 3 x day each day during hospitalization	Inpatient use of pads – 218/396 (55.1%). Of this cohort, 120/396 (30.3%) had incontinence prior to admission Rationale for pad use: urinary incontinence associated with acute confusion or dementia
[251]	To determine the prevalence of UI & FI +	447 inpatients (mean age 70 ± 18.7yrs) admitted to 3	Point prevalence survey + an audit of medical	266/446 (60%)- using a continence product/ device

Ostaszkiewicz, et al., 2008	pad use + documentation of incontinence	acute and 1 subacute care hospitals in Australia	records	50/121 (41%) of patients using pads had no UI or FI in the preceding 24 hrs. 18/113 (16%) patient with UI or FI in preceding 24 hrs had no continence product/device
[245] Wagg et al., 2008	To assess the quality of continence care for older people	3683 patients from 195 secondary care trusts (hospitals) in UK	Audit of patients' clinical records	2070/3683 (56%) patients used containment strategies
[253] Zisberg 2011	To determine incidence of incontinence brief [pad] use	465 older patients (mean age 78.6 ± 5.8 yrs) who were not using incontinence briefs prior to admission to medical acute care units in a 900 bed teaching hospital in Israel	Admission interview and then every day after first 48 hrs	65/465(14%) used incontinence briefs during most of their hospitalisation. Brief use was associated with low mobility
Long-term care / nursing homes / skilled nursing facilities / residential aged care / care homes				
Study	**Objective**	**Sample**	**Method**	**Results**
[255] Brandeis et al., 1997	To describe the frequency and correlates of potentially treatable causes of urinary incontinence	2014 residents (mean age 84.3 ± 8.7) from 270 Medicaide-certified nursing homes in USA	Review of MDS data / Interview with the nursing home staff, and interaction and observation of residents	990/2014 (49%) of residents were incontinent. Of these, 84.0% were managed by pads/briefs. More than one-third (n = 350) of the incontinent residents were managed with two modalities
[258] Omi et al., 2010	To determine daily pad usage & association with UTI, and fluid intake	153 residents (mean age 83 ± 8.2 yrs) from 6 nursing homes in Norway	Number and weight of pads per/resident calculated over 2 days	118/153 (77%) used pads 36/48(75%) men 82/105(78%) women Average number of pad changes p/day-2.7 UTI correlated with pad use but not fluid intake or number of pad changes
[254] Roderiguez et al., 2007	To explore incontinence prevalence, knowledge and care	66 care homes in Birmingham, UK	Questionnaire to care home managers	Several methods to manage incontinence were cited however briefs and pads accounted for over 50% of responses

Community / home care / primary care

Extrapolating data from users of absorbent pads in one area in Sweden, Samuelsson and colleagues [344] found 6.4% of all women and 2.4% of all men in the country, used continence products: equating to 3.7% of the total population. Most of these users were aged over 75 years of age and 21% lived in special accommodation. Other studies have examined use of continence products in targeted populations. For example, among individuals receiving home care services in European countries, rates of continence product use vary from 29-52% (mean 39%) [345] to 57% [346]. And across primary care trusts in the UK, containment strategies are used by 48% of patients [347].

Acute care / hospital/ Secondary care

Rates of continence product use in elderly patients in acute care across several countries are similar and range from 55.1% in Italy [348], 56% in the UK [347] to 60% in Singapore [349] and Australia [350]. Not only are they widely used but they are often used indiscriminately. One of the earliest studies to draw attention to an overreliance on continence products was conducted by Starer and Libow [351] who found more residents using pads than those with incontinence. More recently, Ostaszkiewicz and colleagues found that in the inpatient care setting, pads were inappropriately used for some patients, and were underused for others [350]. Of 121 patients who were using pads at the times of the survey, 50(41%) reported no UI or FI in the preceding 24-hours. However, 18% of patients who had no pad did report such an episode. This mismatch between incontinence and pad use has been noted in other research [348, 352].

Long-term aged care homes

We located six studies that provided data on the use of continence products in long term aged care homes. These were conducted in the UK [347, 353], the USA [329, 354, 355], and in Norway [356]. Wagg and colleagues reported that of 488 residents from 27 care homes included in the national audit of continence care in the UK, 307 (63%) used a containment strategy to manage their incontinence [343]. Roderiguez and colleagues reported similar rates based on interview data from managers of 66 care homes in Birmingham [353].

In the USA, Brandeis and colleagues reported a higher rate of pad use (84%) in their sample of 2,014 residents from 270 Medicaid-certified nursing homes [329]. Eighty-four percent were managed with pads/briefs, and more than one third of incontinent patients were managed with two modalities. A recent evaluation of the use of urinary collection devices by 57,302 residents from skilled nursing facilities found that pad use remained relatively stable over a 12 month period [354]. Pad use among a sample of 11,549 newly admitted 75-84 year old residents was 58.7% at admission and 61.1% twelve months later. This rate was higher for residents aged 85 years of age and older (i.e. 60.3% at admission and 62.6% one year later). In a survey of patterns and treatments of urinary incontinence in 13 special care units in the USA, Pringle-Specht and colleagues (2002) reported that 72% (n=105) of residents used a continence product: the most common type of product being a continence brief or pad (n=93) [355].

According to Omli and colleagues who estimated the daily pad usage of 153 elderly residents from six nursing homes in Norway, 77% of residents use pads [356]. Omli and colleagues also found that residents' pads were changed infrequently (i.e. an average of 2.3 times a day (range 0.5-8.0) for female residents and 3.1 times a day for male residents (range 1.0-9.0). Moreover, urinary tract infections were associated with pad use (41 vs. 11%; P= 0.001): but not with fluid intake or number of pad changes. Residents pad usage did not correlate well with the volume of their incontinence:

As inappropriate use of continence products may con tribute to onset, or continuation of, incontinence, it is important that clinicians who advocate or authorise their use, are familiar with evidence-based guidelines that advocate an active approach to diagnosing, preventing and treating incontinence.

Dignity in care

Protecting the dignity of the people who are care-dependent and helping them to maintain optimal continence are key concerns for older persons and their caregivers. However, peoples' opinions on continence care practices that dignify a care-dependent person sometimes differ, resulting in considerable angst [357]. A new conceptual approach to providing continence care titled *The Dignity in Continence Care Framework* developed by Ostaszkiewicz (3), aims to improve choice, physiological autonomy, and dignity for people who require assistance to maintain continence or manage incontinence. The biopsychosocial framework represents an integration of contemporary biomedical understandings about incontinence with theoretical concepts from the disciplines of nursing, psychology, and sociology. It is underpinned by two core concepts: *'dignity'* and *'care'*, and is characterised by a focus on: empathic continence care; acknowledgement of personhood; therapeutic communication; authentic partnership in continence care; acknowledgement of stigma, social taboos, and courtesy stigma; and the need for a foundational continence assessment. The framework can be adapted to suit the needs of individual organisations, and guide the implementation and evaluation of education for formal caregivers. Although the framework is conceptually sound, further research is required to evaluate its effect on continence care practices and patient outcomes.

Recommendations for practice

1. Environmental cues such as toilet visibility, signage, colour differentiation and images should

be used to compensate for visuo-perceptual deficits in frail older adults with cognitive impairment.

2. As remaining physical strength and dexterity varies in individuals with cognitive impairment, each component of the toileting process which creates difficulty for such patients should be identified and treated individually.
3. Awareness raising activities should be conducted to enhance day-to-day continence care processes in healthcare settings.
4. Ensure that the time, resources, knowledge and skill required to conduct an assessment, and offer active, effective management and manage UI episodes are considered in service planning.
5. Continue to address gaps in healthcare practitioners' knowledge about preventing and managing incontinence in frail older persons.
6. As inappropriate use of continence products may contribute to onset or continuation of UI, clinicians who advocate or authorise their use, should be familiar with evidence-based guidelines that advocate an active approach to prevention, diagnosis and treatment.

Recommendations for research

Further research is required to:

- Explore the physical environment as a risk factor for UI in frail older adults, and to evaluate the effect of modifying the physical environment.
- Embed processes of care in health care systems to promote frail older adults' autonomy and continence.
- Translate findings about the benefits of exercise programmes to minimise the risks of functional decline, falling, and UI in frail older persons.
- Explore the association between a lack of toileting privacy and UI in frail older adults.
- Identify the best methods to implement and sustain toileting assistance programmes.
- Identify the optimum staffing levels and skill mix required to optimise continence in care-dependent frail older adults.
- Explore the association between the misuse/overuse of continence products and UI.
- Addresses the social, regulatory, organisational, and personal constraints to evidence-based, ethical, resident-centred continence care in long-term aged care homes.
- Counter ageist perspectives that hinder frail older people from access to a comprehensive assessment to prevent, minimise or treat UI
- Explore the influence of the continence product manufacturing industry on how continence care is framed for frail older adults.

5. ASSESSMENT OF THE FRAIL OLDER PERSON WITH URINARY INCONTINENCE

Recommendations for the basic assessment of frail elderly persons with UI are summarised in the algorithm (see Summary Document). Because UI in the frail older person is almost always multifactorial, it is essential to conduct a comprehensive assessment with the goal of identifying all potential contributing factors. Collaboration among primary care physicians, geriatricians, surgical specialists, nurses, other health professionals and caregivers, both formal and informal, may be necessary for optimal assessment and management.

The number of guidelines in the area of urinary incontinence have proliferated since the 5th consultation the majority of these are consistent in their approach. For example, since the last Consultation, the European Association of Urology has developed its published guidelines on UI which bear relevance for frail older men and women. These remain largely based on the findings of the 4th ICI but now include consideration of anticholinergic load when prescribing for older people. Other than this guideline, the impact of comorbidity lying without the lower urinary tract is seldom considered; there remains a need for consideration of this area in both robust and frail multimorbid older persons.

Two groups, the US Assessing Care of Vulnerable Elders (ACOVE) project and the UK Clinical Effectiveness and Evaluation Unit, have developed quality performance measures for UI care in frailer older persons, using structured literature review and expert panel review and have published results based upon surveys of concordance with these guidelines [347, 358-362]. These measures are variably based on the prevailing applicable guidelines of the time. Although both groups have demonstrated using their measures that UI assessment and care by practitioners in the US and the UK is of a poorer standard than that afforded to younger adults, there is evidence that integrated services are more likely to provide a higher standard of UI care [363]. Thus, there is an urgent need to re-establish the fundamentals of UI assessment and management for all health care providers who care for frail older persons with UI and ensure that there is adequate service provision.

a) Identification of frail older persons. Health care providers can case find in older patients with UI for frailty using the Vulnerable Elders Survey, which can be administered in person or by phone [364], Persons with a score of 3 or greater have four-

fold increase in the risk of death and functional decline compared with persons with lower scores. A patient self-reported scale in which those people classified as either frail or pre-frail had higher frequency of hospitalisation, a higher probability of co-morbidity and higher mortality than those classified as non- frail has also been reported [365]. There has also been increasing interest in the detection of frailty in patients undergoing surgery (see later), as its presence predicts poorer outcomes from hospitalisation and surgery. However, caution still needs to be exercised when classifying an older individual as frail as there is considerable heterogeneity within this group [366]. There may also be a clear distinction between cognitive and physical frailty.

b) Primary care assessment. Physician education using a modified version of the ACOVE model to reach a large group of primary care physicians resulted in between 80% and 92% of them planning to make a change in their practice behaviour [367], although no formal assessment of carry through was undertaken. Geriatricians' and primary care physicians' (PCPs) UI assessments were compared in a randomised multicentre study involving 364 subjects, 42% of whom self-reported UI to the investigators. Geriatricians were significantly more likely to detect UI (59% of cases vs. 16%), regardless of the severity of UI, and were more likely to refer to Continence Programmes (25%); all referrals by PCPs were to urologists [368]. An assessment strategy based on clinical evaluation, simple cystometry, and several criteria for referral was compared with urodynamic diagnosis. Approximately 25% of patients met criteria for referral, half of patients accepted urodynamic evaluation, yet urodynamics changed the treatment plan in only 12% of the patients who did not met the a priori criteria for referral [369].

Practice patterns and adherence to US UI guidelines were evaluated by retrospective chart review of 300 consecutive patients aged >65y, seen by either an internist or geriatrician for UI at a tertiary care centre. Geriatricians ordered more testing, such as urodynamics, before referring patients to a surgical specialist [370]. Over- all, primary care practitioners rarely follow the US Agency for Healthcare Research and Quality UI guidelines, [371] and nursing home practitioners rarely follow the Federal guidance for UI care regarding recommended physical examination, PVR testing, urinalysis, and identification of potentially reversible causes [372]. Okamura and colleagues investigated the diagnosis and treatment of lower urinary tract symptoms (LUTS) by general practitioners (GPs) according to the "Practical manual for LUTS evaluation and treatment in the elderly For GPs (Japanese)" and found adherence to the manual, reinforced by educational and promotional activities resulted better treatment outcomes [373, 374]. A randomised trial of an electronic screening tool was useful in improving conversations about urinary incontinence in older women (not frail) [375].

A systematic review of articles identified only 5 studies meeting eligibility criteria, and all were in women. None of studies found sufficient diagnostic evidence (for different types of UI. The best was a general population study reporting the utility of history and examination for the diagnosis of SUI (positive and negative likelihood ratios 3.23 and 0.40, respectively) [376]. Adding a nurse practitioner to general practitioner care for adult patients with UI can reduce the impact of UI and has been proposed as a cost effective model using the Netherlands as an example[377, 378].

c) Cough stress test. We have found no additional evidence on the utility of the cough stress test since the 4th consultation. Utility of the cough stress test was studied in 97 incontinent female long-term care residents using blinded comparison with single channel cystometry. Of the 77% in whom single channel cystometry diagnosis was congruent with the stress test (i.e., urodynamic DO with negative cough test, no DO and positive cough test), all were correctly classified. No woman with SUI was missed nor were any with DO misclassified [379]. An analysis of 200 older women with UI found that provocative full-bladder cough test was as effective as radiographic or urodynamic pressure measurement in detecting SUI. Clinical diagnosis incorporating the cough test with leakage symptoms was 78% accurate, with only 6% false negatives for SUI, but was only 44% accurate with 45% false negatives for urgency UI [380].

d) Postvoid residual measurement. We identified no studies evaluating the impact of PVR measurement on clinical diagnosis and treatment outcomes. The frail elderly may have a higher prevalence of elevated PVR, especially in association with DHIC. One study of 100 patients consecutively admitted to a geriatric ward found that 34% had PVR > 50 mL; these patients tended to have more UI (57% vs. 38%, p >.05), greater functional dependency, and a higher mortality rate (36% vs. 9%) [381]. A study of the residual urine in a randomly selected community dwelling sample of men and women aged 75 years of age found more than 10 ml of residual urine in 91 of the 92 men (median 90 ml; range 10-1502 ml), and in 44 of the 48 women (median 45 ml; range 0-180 ml). The significance of this single measurement could not be estimated [382]. There is considerable variability from test to test. The algorithm for UI suggests situations in which PVR measurement may be warranted, but this is not routinely required as part of the initial assessment in the absence of voiding symptoms.

e) Urodynamic testing. Urodynamic testing is feasible and safe, even in frail nursing home residents [62]. There is no evidence, however, that urodynamic diagnosis changes the outcome of treatment. Expert guidelines have recommended urodynamic testing before surgical or minimally invasive UI treatment in women, but there remains debate about the utility of this approach in men.

f) Ultrasound estimation of bladder weight (UEBW). A single study of men attending a uroflow clinic of mean age 65 (range 23 – 90) detected no statistically significant differences in ultrasound estimated bladder weight between men with Qmax <10mL/ min versus those with >15mL/min [383]. In a study of asymptomatic men, UEBW is most closely associated with height; there appears to be little diagnostic utility of this measure [384].

Summary of evidence

- Active case finding and screening for UI in older persons because many do not spontaneously report their symptoms. (Level 1).
- Screening for frailty is possible with short screening instruments (Level 1).
- Current quality of primary care assessment of UI in frail elders is poor (Level 2).
- Cough stress test has moderate accuracy in frail institutionalised women (Level 2).
- No recommendation is possible on the utility of PVR testing in the assessment of UI in frail elderly (Level 4).
- Urodynamic testing is feasible in frail older people (Level 1) but it is unlikely to change management or outcomes except, perhaps, in those considered for surgical treatment of UI (Level 4).

Recommendations for evaluation

The essential first step is to actively case find in the frail elderly, as both UI and FI are generally underreported.

The second is to identify treatable, potentially reversible conditions and other factors (medications, environment) that can cause or contribute to incontinence. Although UI associated with such factors has been commonly called "transient UI," this is erroneous, as for most frail older persons incontinence is a chronic and often progressive condition. It is important to evaluate for such contributing factors because their amelioration may improve UI directly, make UI more amenable to other interventions, and overall improve the patient's (and caregiver's) quality of life [385]

The common, treatable, potentially reversible conditions that can contribute to UI in frail older people can be defined by the mnemonic DIPPERS ((Delirium, Infection [urinary tract), Pharmaceuticals, Psycho- logical, Excess fluid (in/out), Restricted mobility, and Stool impaction [and constipation]). This is a useful aid to teach and remember these conditions [386]. Cognisance must be made of the potential to overtreat asymptomatic bacteriuria as apparent infection because of the risk of adverse outcome [387].

6. FACTORS IN MANAGEMENT OF THE FRAIL OLDER PERSON WITH URINARY INCONTINENCE

6.1. Background

This section highlights the issues that distinguish management of incontinence in frail older people from that of healthier older adults. These include preferences for care, goals of care, determination of costs and benefit special issues in drug treatment, and issues unique to frail elderly men. They incorporate knowledge of physiological, psychological, sociological, and economic changes associated with frailty and advanced age, and reflect the importance of patient-centred goals and the role and burden of caregivers in this population. These factors provide the context of continence care and should be incorporated into the management of all incontinent frail persons, regardless of the choice of specific treatment.

6.2. Role of comorbidity in management decisions

Many frail older people will have coexisting disability and comorbidity, both of which can influence the clinical presentation and assessment of UI, as well as responsiveness to interventions. Frail older people are not only at higher risk for unintended ad- verse effects from treatment (e.g., fulminant *Clostridium difficule* colitis from antibiotics used to treat otherwise asymtomatic bacteriuria), but also may realise additive benefit in domains other than UI [385] For example, UI treatment that is aimed at underlying comorbidity and impairment (e.g., topical oestrogen for irritating urogenital atrophy reduces recurrent UTIs); and a nursing home exercise programme done in the course of toileting improves both physical function and UI [333]). Likewise, management of chronic cough from obstructive pulmonary disease may benefit stress urinary incontinence but, aside from the evidence for weight loss [388] and obstructive sleep apnoea [389] (both not in frail older adults), the is little published evidence. The role of dementia is discussed above.

6.3. Defining outcomes from treatment

Outcome measures must be fundamentally different from those used in healthy older persons, because of the heterogeneity of this frail population regarding comorbidity, remaining life expectancy (RLE), patient perceptions, personal values, and the involvement of caretakers and proxy decision makers. Unfortunately, intervention studies in the frail elderly remain focused on objective disease related variables and seldom, if at all, take account of these factors. Subjective outcome goals and measures are would be preferable study outcomes in this patient group. Additionally, comorbidity is frequently used as an exclusion criterion in therapeutic trials. A review of care home residents' views on continence showed that they valued having independent bowel and bladder function, but

believed incontinence to be inevitable and intractable. Residents often had low expectations, and declined further evaluation and treatment [390]. There are few data on older or frail peoples' expectations from specific treatments.

Although quality of life (QoL) is a key concern for UI in all persons (see Committee 5, Initial Assessment Including Quality of Life), and has special relevance in frail elderly with limited RLE, there are few validated QoL outcome measures applicable to this population. Only one validated UI- related QoL measure is derived specifically from patient-based data among persons older than 65, and these subjects were community-dwelling and relatively healthy [391]. None of the ICI-endorsed UI-related QoL measures have been validated in oldest-old or cognitively and/or functionally impaired persons. Traditional UI QoL domains—e.g., impact on IADLs, travel, sexual relations—are often not relevant to frail older persons, and there could be significant effects" for social and role function domains. One alternative QoL domain for frail elderly is social interaction, especially for nursing home residents; [392] an analysis of cross sectional and longitudinal data from over 100,000 US nursing home residents found that prevalent and especially incident UI had negative impact on social interactions, particularly among persons with moderate ADL impairment [392]. An analysis of older Medicare benefit over 65 years of age, and including those over 85, found significant impairment of QoL, in accordance with that found in younger people [393].

The profound question when considering UI outcomes in frail older persons is, "Is complete cure ever possible?" In short, this depends on patient factors, specific treatment(s), and the target out- come. While no geriatrician endorses "ageism" and therapeutic nihilism, research evidence suggests that complete dryness is unlikely for certain frail patients, particularly frail institutionalised persons with severe cognitive and functional impairment. Even "intractable" UI is amenable to interventions that may improve the patient's urinary and bowel function and quality of life The Committee of the Third ICI introduced an alternative continence paradigm for frail elderly (Figure 3), which subsequently was generalised for all persons with UI [394]. In this paradigm, people with "dependent continence" are dry due to ongoing assistance, behavioural treatment, and/or medications. UI would return if the interventions ceased, a situation analogous to chronic disease models [395] such as "controlled hypertension" or "controlled diabetes." Persons with "independent continence" are cured without need for ongoing treatment (e.g., dry after successful anti-incontinence surgery). For patients who are unable to achieve independent or dependent continence, "contained incontinence" should be possible by use of appropriate products such pads, catheters, and appliances (See Chapter 20, Management Using Continence Products), thus providing "social continence" or "accepted incontinence."[396]. The balance between the degrees of continence achieved may vary as UI severity changes, and are dependent upon patient and caregiver preferences. These continence outcomes encompass a common need: to be both realistic and hopeful about UI in frail elders while avoiding nihilism and neglect; maintaining comfort and dignity and preventing avoidable complications of UI. The other consideration is that any comorbidities associated with frailty, e.g. dementia and Parkinsonism, are progressive conditions so that treatment goals may need to be re-evaluated as time progresses. Although the ICS standardisation document on outcomes in older patients is now over 15 years old, little progress has been made and many of the identified needs still pertain (see Recommendations for Research).

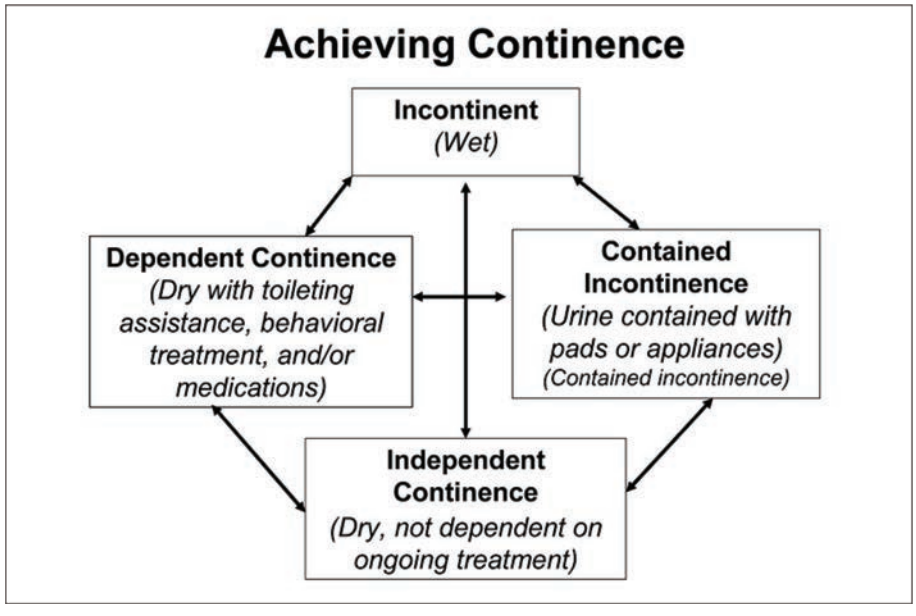

Figure 3. A paradigm for continence

6.4. Role of remaining life expectancy in treatment decisions

Remaining life expectancy (RLE) is a key yet often misunderstood concept in treatment decisions for frail older people. RLE is not uniformly short in this population; moreover, there is a demographic trend of increasing RLE, with a smaller proportion of persons spending their remaining years living with disability [397]. Evidence shows that many health care professionals will underestimate life expectancy [398]. Reference to actuarial tables produced for insurance purposes is often enlightening. Incorporation of RLE into treatment decisions in urology and gynaecology has been studied only in relation to cancer treatment. Two studies, both in prostate cancer, examined specialists' ability to estimate RLE. Canadian urologists were more accurate in estimating longer RLE: using scenarios based on actual patient data, 31% were accurate within 1 year, 67% within 3 years, and 82% in estimating greater than or less than 10 years in 82% of responses [399]. Comprehensive Geriatric Assessment can help estimate remaining life expectancy and can help predict treatment-related morbidity and mortality in older men with prostate cancer [400].

Walter and Covinsky [401] developed a graphical tool for estimating quintiles of RLE by age. Medical conditions most closely associated with shorter RLE are class III/IV congestive heart failure, end-stage renal disease, and oxygen-dependent chronic obstructive pulmonary disease. Estimates of RLE are significantly affected by frailty and cognitive impairment [402]. Functional status has a dramatic impact on life expectancy. For example, 75-year-old men and women without limitations have life expectancies 5 years longer than those with ADL limitation and more than 1 year longer than those limited in mobility [403]. Alzheimer's dementia decreases RLE profoundly (by nearly 75%) among older persons who otherwise would be in the top quintile of RLE [404]. Compared to older persons with at most one IADL deficit, persons with more deficits have significantly higher 5-year mortality (with two deficit, adjusted RR 1.46 [95% CI 1.20 – 1.78] ; with three or more deficits, adjusted RR 1.64 [1.26 – 2.14]) [401].

6.5. Preferences for care

Because there are multiple treatment options available for frail older adults with UI, and individualised care should be emphasised, obtaining patients' and caregivers' opinions regarding preferences and goals for care is essential for quality care planning. It should not be assumed that persons with cognitive impairment are unable to make their care preferences known or participate in treatment decisions and all reasonable efforts to help them to do so should be made. The spectrum of cognitive impairment is large and the wishes of the patient should be paramount. Preferences for toileting and changing were studied in 111 nursing home residents with UI; residents preferred an average of 2 pad changes, 1.5 toilet assists, and 2 walking assists more than they actually received, yet even these levels were lower than guidelines recommend, suggesting that residents may have reduced expectations based on their experience [405]. In a second, residents of board and care facilities and two nursing homes, their family members, and facility nursing staff were given definitions of and information about UI treatment options (indwelling catheter, prompted voiding, adult diapers [sic], electrical stimulation, and medications) [406]. Respondents were asked their preferences between pairs of

treatment options (e.g., "diapers" versus prompted voiding). Most of the board-and-care respondents were continent, although some were undergoing UI treatment at an outpatient clinic. Patients and family members were evenly divided between "definitely" and "probably" preferring prompted voiding versus diapers. Almost 80% of nursing staff, however, preferred prompted voiding to diapers. Families perceived staff members as unwilling to perform prompted voiding, and some thought prompted voiding was degrading to the resident and that it was bothersome to be asked to go to the toilet frequently. Using a similar method, a German study with 117 geriatric hospital patients (mean age 85; 43% with UI), 72 staff members, and 71 family members, found that most patients preferred diapers (79%), medications (78%), and scheduled toileting (79%) over urinary catheters, and 64% preferred scheduled toileting [407]. When choosing between diapers and medication, equal proportions preferred each option. Patients with greater functional dependence were more likely to prefer catheters, and those with experience with diapers were more likely to prefer medications and toileting. Notably, spouses showed moderate to al- most perfect agreement with patient preferences, but those of other family proxies had only slight to fair agreement. In a qualitative study of 25 women with pelvic floor dysfunction living in residential facilities, residents expressed a desire to live with their problem rather than undergo assessment and management, emphasizing the need to include the patient in management decisions at the outset [408].

6.6. Cost and benefits of treatment of UI in frail older persons

An overall discussion regarding UI-related costs is covered by Committee 22, Economics of Incontinence. The following discusses UI cost issues specific to the frail elderly.

a) Estimating Costs. For the majority of developed countries, the greatest increase in population is occurring in the oldest old, those > age 85. This group has the highest prevalence of UI, and accordingly the increased prevalence of lower urinary tract symptoms will result in higher UI care costs. Such an increase has already been observed between 1992 and 1998 amongst US women aged > 65 [409]. The costs of care for older persons has been estimated at double that for people under 65, but care for those older persons living in institutions was less than for community dwelling individuals [410]. Likewise, the cost of OAB in five European countries is estimated to rise by one billion Euros between 2000 and 2020 [411] and in the US it has been estimated that by 2030 the greatest increase in demand for UI care (81%) will be in older women aged 60-89 with OAB symptoms [412]. In one US study using of a community managed care population, the presence of OAB and comorbidity doubled the associated costs of UI care [413]. In South Korea, the estimated cost of treating overactive bladder was 117 billion Korean Won (KRW) in 2006 and 145 billion in 2007. The estimated total cost in treating stress urinary incontinence was 122 billion KRW in 2006 and 59 billion in 2007 [414].

Costs can be expressed as direct costs, indirect costs, and intangible costs [413]. Previous estimates have focused on diagnostic costs, treatment (including routine care and pads), and consequence costs (skin irritation, urinary tract infection, falls, fractures, additional nursing home and hospital admissions, longer hospital length of stay). Direct healthcare costs are most often estimated but there is a lack of meaningful research into indirect costs and those related to comorbidity in the frail elderly. Intangible costs have not been considered in these estimates because of their subjective nature and the methodological difficulty of collection and estimation. Much of the evidence for the cost of UI in older persons has been gathered from either epidemiological surveys or analyses of claims from insurance databases; these have often involved many assumptions or complicated formulae to calculate financial costs. There is a consistent theme that the cost of caring for older adults with UI will increase, but the estimated magnitude of this increase is variable.

For the frail elderly, especially those in long term care, cost calculation is especially complex. The greatest costs for UI care in nursing homes are by far nursing labour costs [415]. Extrapolated costs for nursing home admission due to UI was $6 billion (2000 US dollars), with institutional costs of UI management and consequences of $5 billion (2000 U.S. dollars) [416]. In one small 6-month study, the mean daily cost of UI care, including direct nursing care, indirect nursing overhead, and supplies, was $9.09 (+/- $ 0.52) per resident (2003 U.S. dollars) [417]. The costs for UI pads alone in Dutch long-term care have been estimated at 160 million Euros [418]. In an Australian sub- acute care setting, the costs of daily UI care was AU $49, with most spent on staff wages [419]. In Canada, researchers found that 1% increase in UI prevalence was associated with an 11-12% increase in costs [420]. The extra nursing time needed to maintain toileting programmes contributes to high costs [421]. Routine garment and laundry costs may be lower than estimated because in practice residents are not changed as often as needed. In addition, for prompted voiding to remain effective, such things as regular refresher education programmes for staff or wet sensors may be necessary, and thus are rarely considered in cost estimates. Moreover, the time over which the costs and benefit are calculated needs to be explicit because both benefit and costs will change, and patient morbidity and mortality need to be considered. The costs of correcting functional and medical causes of UI are rarely considered. Also, the potential differential in costs across the span of cognitive and functional impairment has seldom been assessed, [422] despite evidence that UI care costs are closely related to the degree of functional impairment [423]. Some surveys suggest that the costs of care for younger community dwelling adults outweighs that

associated with the elderly, but there are wide variations of estimates depending upon the population studies [424].

Costs related to caregivers of frail persons with UI living in the community include lost wages, de- creased productivity (both within and outside of the home), the additional number of caretaking hours when a frail person develops UI, [425] and the cumulative effect of increased strain and burden, along with any resultant illness. Overall, there are still limited data on costs of UI treatment in other residential (such as assisted living or rest homes) and acute care settings [426], costs may vary by access to care. Because so many frail elderly are homebound or live in institutions, they often do not have the same access to the UI therapies as other populations. Their health care providers may be limited to primary care physicians, community nurses, and care assistants or aides with little to no expertise in UI management. Specialist consultation may be minimally available in home or long term care settings, leading to a focus solely on behavioural management and/or containment products. An assessment of a multi-component intervention based upon absorbent products, a structured skin care regimen, and nursing advice on incontinence associated dermatitis revealed that incontinent residents used an average of 5.19 absorbent products, at a mean cost of € 1.79 per day. Following introduction of the intervention, the mean number of absorbent products consumed per day was 2.02 per incontinent patient, at a mean cost of € 0.97 per day [427].

Cost relates strongly to reimbursement, which varies considerably from country to country, depending not only on structure of the health system but special programmes for the aged and persons with UI. Within countries, there may be further variation based on insurance, co-insurance, drug versus procedure coverage and incentives, access to care, programmes for vulnerable populations, and urban/rural differences.

b) Benefits and effectiveness of treatment. The ability to define the benefit of UI treatment in frail older people is highly dependent on the individual, their caregivers, and the health care system. Outcomes research indicates that patients value quality of life, which encompasses many domains beside reduction in UI (See Committees 5A Initial Assessment of Urinary Incontinence in Adult Male and Female Patients and 5B Patient-reported Outcome Assessment). Even cognitively impaired people can still express treatment preferences [407, 428], so it is also possible to evaluate domains of quality of life (e.g., social interaction) [392] and assess treatment satisfaction directly or behaviourally. At the same time, we found no data on the value or utilities frail elderly or their caregivers assign to varying degrees of UI (with or with- out treatment intervention) versus “dryness.” Standard outcomes such as quality adjusted life years (QALYs) may overestimate effectiveness in older people, [429] not just because of potentially different utilities, but because of the altered importance of “years of life saved” in a population with variable and limited remaining life expectancy.

The need for novel and specific outcomes for use in both trials of UI interventions and clinical care of incontinent frail elderly people continues. Outcomes measured by single item tools of perceived benefit or satisfaction with treatment are unlikely to be generalisable across the heterogeneous older population. It should not be assumed that perceived benefit of treatment can be measured with the same tools across cultures and health systems, unless such tools are sensitive to differences in such things as reimbursement and provision of continence services and supplies. The association between expectations, preferences, and outcomes needs to be prospectively studied in relevant ad representative populations. New approaches and tools to assess UI-specific quality of life in cognitively-impaired frail elderly are needed, as well as better understanding of the interaction between functional impairment and the impact of UI [392]. When QALYs are included as an outcome in UI treatment trials in older persons, they should be specifically analysed by age and also possibly health status.

7. ISSUES IN DRUG TREATMENT

7.1. Age-related changes in pharmacology

Specific age-related changes in pharmacokinetics, alteration in drug absorption, distribution, metabolism and clearance, and their potential effect on UI drugs, are shown in Table 6. Age-related pharmacokinetic changes are rarely considered in planning the duration of time off previous UI medications, placebo-run in periods, and wash-out periods in UI drug trials in older persons. Typically, a two-week washout from other drugs, three weeks for solifenacin and mirabegron, is planned, regardless of age. The numerous factors potentially affecting drug clearance in older, frail patients, as well as previous and/or cross-over compounds, may confound observed drug effects. Age-related changes in pharmacodynamics have been described for benzodiazepines, beta-adrenergic agents, and opiates [430, 431] but there are few available data concerning change, even in these, other than for limited numbers of community dwelling older people, often with median age of around 65 years old.

Availability of low dose agents: One effect of the underrepresentation (if not exclusion) of frail older persons in UI drug studies is a lack of knowledge regarding minimal effective drug doses for this population. The age-related changes in pharmacology noted above suggest that some UI drugs may be effective at lower than standard doses in frail older persons with concomitant decreased adverse effects [432]. This issue is especially relevant for extended release preparations, which cannot be divided into smaller doses. There are some data supporting the effective use of low dose oxybutynin in older persons [433,

434]. Since the last consultation, a single study has assessed low standard doses of trospium chloride and solifenacin in combination in older persons (not frail) average age 69. 4 years in comparison to higher doses showing higher efficacy of combination lower dose therapy [435]

P**olypharmacy:** Approximately 60% of people over age 65 take at least one prescribed medication, and about one-third take more than five prescribed drugs. In a Swedish analysis of 3 cohorts of older persons examining the trends in medication taking over the years 1987-2007, the prevalence of medication use and polypharmacy increased in the age group 78 years from 2.8 drugs in 1987 to 5.8 drugs in 2007, and for the age group 96+ years from 3.6 to 7.7 [436]. There is evidence from some jurisdictions which suggests a reduction in potentially inappropriate medication exposure in older persons [437]. Similar results have been reported from other countries [438].

In addition, many older persons take over-the-counter, naturopathic or herbal agents and dietary supplements, with the rate of use varying across countries and cultures. In a US analysis of a longitudinal, nationally representative sample of community-dwelling older adults, 62 - 85 years old interviewed twice, initially in 2005-2006 and again in 2010-2011, concurrent use of at least 5 prescription medications increased from 30.6% to 35.8%. The use of over-the-counter medications declined from 44.4% to 37.9%, while the use of dietary supplements increased from 51.8% to 63.7% (P < .001 for both). In 2010-2011, approximately 15.1% of older adults were at risk for a potential major drug-drug interaction compared with an estimated 8.4% in 2005-2006 (P < .001) [439].The likelihood of adverse drug reactions (ADEs) and drug interactions rises exponentially as the number of medications increases. This has led to the recommendation in geriatric prescribing to "subtract before adding," to consider whether target symptoms might be due to medications before adding another drug targeting those symptoms. This approach is relevant in geriatric UI, as UI may have been precipitated and/or worsened by medications (see Table 3). Changes to existing drug regimens should be considered in the management of UI in all frail older people. The national audit of continence care in the United Kingdom reported that of older adults, mean age 80 years, only 27.5% (2082/7572) had documented evidence of a medication review [440].

Adverse drug effects (ADE): ADEs are extremely common in older persons, [441] with rates up to 35% among community-dwelling persons aged > 65 in the US [341], and up to two-thirds of long term care residents [342]. Although the prevalence of drug – drug and drug disease interactions in older persons is high, there are limited data on important clinical outcomes, largely due to the varying nature of the reporting of events[442]. In a recent review of prevalence and contributing factors in developed and developing countries, of the median prevalence of ADR-related hospitalisation was 6.3 % (interquartile range (IQR) 3.3-11.0) and 5.5 % (IQR 1.1-16.9), respectively. The median proportions of preventable ADEs were 71.7 % (62.3-80.0) and 59.6 % (51.5-79.6). Factors associated with increased risk of hospitalisation were older age, female sex, number of medications, renal impairment and heart failure [443]. In a UK series, 59% of ADEs requiring hospital admission involved patients aged > 60 [444]. Factors associated with higher ADEs in older persons are higher drug doses, age-related pharmacological changes, polypharmacy, comorbid conditions and the interactions between them, and female sex [445, 446]. Older people are at higher risk of ADEs

Table 6. Pharmacokinetic changes in older persons

Parameter	Age-associated Changes	UI Drugs Potentially affected
Absorption	Minimal quantitative change despite ↓ gastric motility, yet little known regarding effect on slow-release agents	Extended release preparations
	↓ Skin thickness	Transdermal preparations
Distribution	Decrease in lean body mass leads to ↓ Vd /↓T½ for hydrophilic drugs and ↑Vd/↑T½ for lipophilic agents	Lipophilic agents, tricyclic antidepressants
	Decreased protein binding in frail patients with low albumin, leading to higher concentration of free drug	Tolterodine
Hepatic metabolism	↓ Phase I reactions (oxidation/ reduction)	Tricyclic antidepressants
	No change in Phase II reactions (glycosylation)	

Parameter	Age-associated Changes	UI Drugs Potentially affected
	↓ Hepatic blood flow and ↓ hepatic mass, leading to reduced clearance for agents with first-pass metabolism	Oxybutynin Tolterodine Solifenacin Darifenacin
	Stereoselective selectivity in metabolism (hypothetical)	Enantiomers
	Cytochrome P450	Oxybutynin TolterodineSolifenacin Darifenacin Mirabegron 5HMT, clearance only)
Clearance	Decrease in renal clearance	Tolterodine Fesoterodine (5-HMT)

from antimuscarinics because of age, and comorbidity-related changes in muscarinic receptor number and distribution, blood-brain barrier transport, and drug metabolism [447] . Whereas antimuscarinic ADEs in younger persons are bothersome, in the frail elderly they can result in serious morbidity such as sedation, heat intolerance, prolongation of delirium, and falls.

Xerostomia is common in older people [448]. A study of 175 acutely hospitalised community dwelling older people (mean (SD) 82 (5.7) years) and 252 outpatients (mean (SD) 77 (5.7) years) found that 63% of the hospitalised elderly and 57% of out- patients complained of dry mouth. Dry mouth was more common amongst those on multiple medications [449]. In general, older people, women and those taking multiple medications are more likely to report the symptom. Antimuscarinics may exacerbate this condition, leading to concerns about deteriorating dental health and a 2011 warning to the Food and Drug Administration from the American Dental Association (no longer online). meta-analyses of bladder antimuscarinics show minor variations in the incidence of dry mouth from clinical trials, with oxybutynin associated with the highest prevalence [450, 451]. A subcut analysis of a Canadian randomised controlled trial of solifenacin, 5mg/day, versus oxybutynin 5mg tid, examined the tolerability of both drugs in subjects under and over the age of 65 years, the study found that dry mouth was no more common amongst those over the age of 65 but was more common and more severe with oxybutynin [452]. In those over 75 years of age treated with 8mg versus 4mg of fesoterodine from a pooled analysis of data from registration trials, dry mouth was more common in the older sample; this finding was duplicated in a prospective trial of fesoterodine in older patients [453, 454].

Another antimuscarinic ADE to which the frail elderly may be predisposed is decreased visual accommodation, yet this has been specifically evaluated only in young healthy volunteers, [455] and a single prospective cohort including patients up to the age of 60 years [456]. Drug trials typically report only “blurred vision,” without further characterisation.

The incidence of increased post void residual volume (PVR) as an ADE is reported in clinical trials of antimuscarinics for UI or OAB as urinary retention, typically defined of a retained volume above 200mL. Patients with a PVR ≥ 200mL are usually excluded from trials at the outset. When it has been reported, the magnitude of increase is seldom of clinical significant at usual therapeutic doses.

The incidence of acute urinary retention with antimuscarinics in general is low [457] but has not been evaluated in frail older persons. In a trial of fesoterodine in “vulnerable elderly” patients (see specific drugs, below), urinary retention occurred in 9/281 fesoterodine exposed patients over 12 weeks and none exposed to placebo [458]. There is no consensus, other than that used in clinical trials, as to what constitutes a sufficiently high PVR to preclude antimuscarinic treatment or to require dose adjustment of an already prescribed agent. If urinary frequency or UI worsens after an antimuscarinic is started or increased, then PVR should be checked because an increased PVR will lower functional bladder capacity and worsen UI. PVR should be monitored in frail older men treated with antimuscarinics who may not reliably report change in LUTS or voiding difficulty. The majority of men with clinically relevant outlet obstruction are excluded from treatment trials and the results of these should be viewed in that light.

7.2. Anticholinergic medication and cognitive impairment

A major antimuscarinic ADE of concern in frail adults is cognitive decline. There has, since the last consultation been a number of associative reports linking anticholinergic medication to cognitive impairment, an increase in incident dementia diagnosis and a possible increase in mortality [66, 459, 460]. Medications with anticholinergic properties are commonly used by older persons. For example, in a US retrospective, cross-sectional study of adults aged 65 years and older using 2012 American Geriatrics Society Beers Criteria, 9.56% (7.51 million) older adults used potentially inappropriate anticholinergic medications in 2009-2010; those aged 75-84 or ≥ 85 years did, however, have a decreased likelihood of receiving them [461]. Of 964 older persons attending an Australian memory clinic, potentially inappropriate medications affecting cognition were used by 206 (21.4%) patients. Anticholinergics and sedatives were the most common. One hundred and thirteen (11.7%) patients had a clinically significant anticholinergic burden score (≥3) [462]. As much as there is a reported increase in overall medication prescribing for older persons, temporal trends also reveal an increase in anticholinergic medication prescribing for older persons [463]. Due to the nature of the cohorts of persons studied, data on medications used for overactive bladder and urgency incontinence are limited to identifying immediate release oxybutynin as a consistent significant factor in exposure. In the study of Gray [67], over 10 years, those with the highest cumulative burden of oxybutynin exposure had a significant association with cognitive impairment.

Cognitive effects may be under-detected because they are clinically subtle, neither asked about nor reported by the patient, or mistaken for age-related diseases and ageing [464, 465]. A 2014 systematic review of the effect of medications with anti-cholinergic properties on cognitive function, delirium, physical function and mortality examined 46 studies including 60,944 participants; 77% of included studies evaluating cognitive function (n = 33) reported a significant decline in cognitive ability with increasing anti-cholinergic load. Four of five included studies reported no association with delirium and increasing anti-cholinergic drug load ($P > 0.05$). Five of the eight included studies reported a decline in physical function in users of anticholinergics ($P < 0.05$) [466]. A recent study investigating the association between anticholinergic medication use and neuroimaging biomarkers of brain metabolism and atrophy in 52 cognitively normal adults, mean [SD] age, 73.3 [6.6] years in the Alzheimer's Disease Neuroimaging Initiative and the Indiana Memory and Aging Study found showed lower mean scores on Weschler Memory Scale-Revised Logical Memory Immediate Recall, Trail Making Test Part B and a lower executive function composite score in participants taking anticholinergic medications compared to those participants not taking such medications. Reduced total cortical volume, temporal lobe cortical thickness and greater lateral ventricle and inferior lateral ventricle volumes were also seen in the participants taking anticholinergic medications compared to those not taking such medications [467]. It is clear that duration of exposure and extent of exposure to medications with anticholinergic properties are significant factors in the observed associations with cognition. Many scales exist which purport to measure anticholinergic burden, each varies in its utility in identifying anticholinergic load. The clinical results in studies using these scales are different depending on the scale used dependent upon the different methods used in their development [468]. Persons with pre-existing cognitive impairment (especially from conditions known to affect central cholinergic pathways) may be at greater risk for cognitive impairment although there are also some data to suggest that those with established dementia may not experience cognitive decline following therapy with anticholinergic agents [68]. Additionally, a recent meta-analysis examined the relationship between serum anticholinergic activity and decline in cognitive performance, delirium, and functional impairment. The review included 4 RCTs, 5 prospective cohort studies, 3 longitudinal cohort studies, 17 cross-sectional studies, and 4 case-control studies. Twenty-four of the retrieved studies examined an association between SAA and cognitive outcomes, 2 studies examined an association with SAA and functional outcomes and 8 studies examined associations between SAA and both cognitive, and functional outcomes. The meta-analysis on 4 RCTs showed no association with higher SAA and cognitive performance however, the pooled data from 4 observational studies showed elevated SAA was associated with reduced cognitive performance ($I2 = 0.00\%$, $H2 = 3.37$ and p-value = 0.34) [469].

Whereas the beta-3-agonist, mirabegron, is associated with similar rates of adverse events to the anticholinergic drugs, there are obvious differences, the most obvious being a relative absence of adverse events such as dry mouth and constipation. In a single pooled analysis of mirabegron studies in patients 65 years, the three most common TEAEs in patients randomised to mirabegron 50 mg were hypertension, nasopharyngitis and UTI (9.9, 4.1 and 3.1%, respectively. In the ≥65-year subgroup, over 12 weeks, the incidence of the most common TEAEs was similar for both doses of mirabegron and placebo, except for hypertension, UTI and dizziness, which occurred with a higher incidence in the mirabegron 25 mg group than the placebo or mirabegron 50 mg groups. Hypertension has been a common concern with mirabegron therapy, but in the same pooled analysis, over 12 weeks, in the ≥75-year subgroup, the incidence of hypertension with tolterodine ER 4 mg (comparator) was seen to be higher (21.6%) than with either dose of mirabegron (18.8 and 13.6% for the 25 and 50 mg doses, respectively) or placebo (9.6%). The incidence of hypertension in the oldest patients was also higher with tolterodine (14.5%) than mirabegron 50 mg (9.3%) over a 1-year period [470].

7.3. Drug interactions

Because frail older people take higher numbers of drugs and usually have several comorbid conditions, drug interactions are more common [471]. All antimuscarinic agents for UI will have additive side effects when combined with other anticholinergic agents. Antimuscarinics could potentially alter the absorption of other drugs by slowing gastrointestinal motility.

Drug-drug interactions for oxybutynin, solifenacin, darifenacin, and tolterodine include potent CYP3A4 inhibitors (azole antifungals, macrolide antibiotics, cyclosporin, and vinblastine). Fesoterodine, a pro- drug that is converted to tolterodine by non-specific esterases, is also dependent upon CY3A4 for its excretion. There is one case report of interaction between tolterodine and warfarin in 2 older patients, which [472] has not been seen in healthy volunteers. Naturopathic/herbal preparations should also be considered for potential interactions, especially in areas where these agents are frequently used. Potential drug-drug interactions with mirabegron, a beta-3-agonist for the treatment of overactive bladder have been evaluated in younger healthy subjects, between mirabegron and metformin, warfarin, digoxin, or a combination oral contraceptive. Changes in maximum concentration of metformin and digoxin were observed, but no dose adjustment of either drug is required when mirabegron is administered concomitantly with metformin, warfarin or the oral contraceptive. The authors suggested that patients receiving mirabegron with digoxin may require additional monitoring of digoxin concentrations with dose adjustments where needed [473].

Evidence regarding the co-prescription of bladder antimuscarinic agents and cholinesterase inhibitors (CEIs) used for dementia are of poor to moderate quality. There is evidence CEIs can cause or worsen UI from a case report [474] and also a case series of 216 consecutive patients with probable Alzheimer's disease attending a memory treatment centre [475], but this finding has not been replicated in a large Dutch dataset analysis [476]. In the case series, CEI treatment was overall associated with 7% risk of new UI: the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Further evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [477]. Residents with dementia, newly treated with cholinesterase inhibitors, were more likely to then be prescribed a bladder antimuscarinic than those residents with dementia not given a cholinesterase inhibitor, an example of a geriatric "prescribing cascade" [478]. In a cross sectional survey to determine the proportion of nursing home residents with overactive bladder or urinary incontinence with potential contraindications to antimuscarinic treatment because of concomitant anticholinergic medications or acetylcholinesterase inhibitors (AChEIs) 71.3% received at least one anticholinergic medication. CEIs and antimuscarinic treatment were prescribed concurrently in 24% [479]. Concomitant use of antimuscarinics (extended release oxybutynin and tolterodine) and cholinesterase inhibitors in nursing home residents was associated with a decline in ADL function in the most functionally able residents but there was no worsening of cognition, probably because the cognitive measure (MDS-COG) was inadequately sensitive. More importantly, there was no case of delirium observed [480]. In a study in which the primary objective was to assess the cognitive impact of trospium chloride in older people with dementia treated with galantamine over a six-month period, 46 subjects with UI and dementia were enrolled, 10 withdrew from the study. No effect on cognition or activities of daily living was detected over the duration of the study. A within group analysis demonstrated an improvement in nocturia and reduction in pad use in this combination group [481]. A small study reported some positive effect of the treatment of UI with propiverine in subjects with probable AD taking cholinesterase inhibitors [482]. The practice appears to be common in Finland [483]. Although intuitively illogical, given the opposing pharmacological actions, there seems to be no reason not to use bladder antimuscarinics for older people with dementia, ensuring that the cholinesterase inhibitor is warranted and effective, that the incontinence is sufficiently bothersome to warrant treatment and that the patient (where possible) and the caregiver are fully informed. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living.

7.4. Potentially inappropriate drugs for older persons

Efforts at quality improvement for older populations have led to the development in several countries of expert consensus guidelines regarding inappropriate drugs for older persons, although the continuing relevance of these guidelines has been questioned and alternative systems suggested. A revised Beers criteria was introduced in 2015 [484]. These guidelines focus on drugs with lower risk-benefit ratios and higher potential for drug-drug and drug-disease interactions, and are used for nursing home regulation and quality performance measurement. The concerns regarding oxybutynin and tolterodine in causing urinary retention have been removed. All bladder antimuscarinics are included with respect to their anticholinergic properties. More recently, a system for prescribing appropriate medications for older persons, the Fit fOr The Aged (FORTA) criteria have been published with respect to drugs for lower urinary tract symptoms [485]. These guidelines systematically review available evidence for the use of medications in the population studied (in this case adults >65y with multimorbidity) and assign levels of appropriateness according to the available data. A Delphi process is used to assign drugs into A, Absolutely, B, Beneficial, C, Caution and

D, Don't criteria. Of all lower urinary tract drugs, fesoterodine achieved a Beneficial grade. Most drugs were placed into the Caution category, reflecting either deficiencies in, or absence of, available data.

8. SPECIAL ISSUES IN FRAIL OLDER MEN

Although their ranks thin into the ninth decade, men still comprise a significant portion of frail older persons. The prevalence of UI increases in men after age 80, going from about one-third of the rate in women to become equivalent. Over the past ten years, the prevalence of UI in US male nursing home residents aged 65-74 has increased to a greater extent than in female residents (from 39% to 60%, compared with 45% to 59%) (http://www.cdc.gov/nchs/data/series/sr_03/sr03_036.pdf) At the same time, frail older men are underrepresented in UI treatment trials, whether behavioural, pharmacological, or surgical (see also Committee 13: Surgery for Urinary Incontinence in Men). Since the time of the 5th ICI, the European Association of Urology has summarized their recommendations (2015) for Urinary incontinence in frail/older men and women [486]. One prospective study of overactive bladder in older patients included 50% of men, but their results were not separately reported [454].

This under representation is unfortunate, because results from treatment trials in frail women cannot be directly extrapolated to men for several reasons:

- **Differences in comorbidity:** frail older women have higher rates of functional impairment and chronic disease and geriatric syndromes [487] which may mean that frail men may be more likely to respond to behavioural intervention. For older adults who become incontinent, a composite measure of physical performance (rising from a chair, walking, balance) is a better predictor of UI incidence in men than in women [488].
- **Differences in caregivers:** more older men have living spouses who can provide care, with a potential impact on the risk and type of caregiver burden associated with UI management.
- **Prostate cancer:** nearly all men in their ninth decade have histological evidence of prostate cancer. However, it is not clear that frail elderly men have an increased risk of prostate cancer-specific mortality, especially given that their remaining life expectancy (RLE) is primarily affected by comorbid conditions. The need to screen for and treat prostate cancer diminishes with functional status, comorbidity, and RLE [489]. At the same time, more men are living with the sequelae of prostate cancer treatment, particularly stress UI after radical surgery.
- **Benign prostate disease:** the prevalence of histological BPH, BPE, and BOO increase with age, and is associated with LUTS, UI, and DO. In a urodynamic study of older persons, 29% of men had BOO and 59% had DO as the predominant cause of UI, versus 4% BOO and 61% DO in women [62] .
- **Risk of urinary retention:** because of age-related decrease in detrusor contractile function and increased likelihood of BPE and BOO, it is often assumed that frail elderly men have a higher prevalence and risk of urinary retention. However, this has never been demonstrated. Among NH residents with UI, the prevalence of underactive detrusor was similar in women and men (38% and 41%, respectively), despite the higher prevalence of BOO in men [62, 102].
- **Differences in device usage:** A nationally representative survey of adults in the US showed that older men were nearly three times less likely than older women to use pads to contain leakage (15% vs. 45%) [490]. Data from Scandinavia, where some countries provide absorptive pads as part of the health care benefit, showed that this gap might be narrowing (22% vs. 48%), and that increased functional impairment was associated with greater pad usage [345]. In a survey of patients recruited from family practice clinics in the Netherlands, the gender difference for pad usage by older adults with UI was even higher, with 4 out of 5 women using pads versus 1 of 9 men using pads [491]. Men are also more likely to be users of indwelling catheters, both in the long-term care setting [354] and in the community [492].
- **Differences in medical treatments:** there are medications that might be used by only one sex, or might have distinct side effect profiles. For example, alpha-adrenergic antagonists in particular should be cautiously considered in men due to their potential side effect of causing orthostatic hypotension. (Grade C) [486]. The interactions of UI and other conditions with regards to orthostatic hypotension and risk of falls merits attention. In a German registry of 3,414 patients with Parkinson's disease, for those with urinary incontinence (716; 21%), orthostatic hypotension was reported for 14% of the men, yet only 9% of the women [493]. On the other hand, for women and men who had strokes and urinary incontinence, both were equally more likely to sustain a fall after stroke, though women were more likely to sustain an injury (OR 1.5) than were men [494].
- **Differences in surgical treatments**: there are gender-specific devices and surgical approaches that do require active management on the part of the patient. In particular, certain frail older men might not be appropriate for placement of an artificial urinary sphincter due to co-morbidity, medications and cognitive and/or functional impairment would not allow for the individual to manage the device on his own (Grade C) [486].

Despite these issues, evaluation and management of UI in most frail older men follows the same roadmap as for women (see Algorithm).

9. SUMMARY OF THE EVIDENCE

Age-related changes in pharmacokinetics affect antimuscarinic drugs for UI and should be incorporated into treatment planning. (Level 1-2)

Drugs may be effective at lower doses in frailer compared with healthier older persons (Level 3)

Polypharmacy increases the chance of adverse reactions to drug therapy. (Level 1)

Adverse drug events are more common in the frail elderly. (Level 2)

Drug-drug and drug-disease interactions are common in frail older persons (Level 1-3).

Antimuscarinics for treatment of overactive bladder remain as potentially inappropriate medications for frail older people according to the Beer's criteria (Level 3-4)

Specific guidance for drugs for LUTS in older people exists, this may, with caveats, guide practice (Level 3).

10. TREATMENT OF URINARY INCONTINENCE IN FRAIL OLDER PERSONS

10.1. Lifestyle interventions

Several treatable lifestyle risk factors are associated with UI. Modifications in fluid intake, avoidance of caffeine and other bladder irritants, weight loss, smoking cessation, constipation prevention, and physical activity are commonly recommended by health care professionals [416, 495-497] and included in clinical practice guidelines to prevent or reduce UI [498]. We were unable to identify lifestyle interventions, alone or in combination, that have been rigorously evaluated in frail older adults. Those studies available were conducted in healthier younger and older women, with some studies on weight loss interventions conducted in overweight women and men with impaired glucose intolerance or type 2 diabetes mellitus (See Committee 12, Conservative Management). Some interventions may be inappropriate for or impractical to use in frail older adults, for example, weight loss. However, advanced age alone should not preclude use of lifestyle interventions if assessment warrants this. Caution should be exercised in recommending fluid restrictions as inadequate fluid intake and dehydration are common in long-term care residents [499] and newly admitted frail older hospitalized patients [500]. Dehydration may actually increase the risk of UI and its severity in frail older adults because of its significant association with constipation and delirium, both known risk factors for UI [501, 502].

Quality of the data

Since the 5th ICI we identified two systematic reviews on lifestyle intervention: a review of multiple types of lifestyle interventions in adults [503] and a review focused on volume of daily intake in adults with overactive bladder [504]. These reviews confirmed our earlier findings that there was insufficient evidence on the effect of lifestyle interventions on UI in the frail elderly. There was some evidence that fluid reduction did decrease the severity of overactive bladder symptoms; however, studies in this review were limited as they did not exclude known bladder irritants (e.g., caffeine) from the fluids measured nor did they establish baseline hydration status prior to any fluid modification. Although the authors recommended a 25% reduction in fluid intake could be effective, they cautioned that using a fluid reduction could have serious consequences in the elderly. There was some evidence in small trials [505-507] that raised the possibility that increased hydration for incontinent frail elderly may actually decrease UI. In this review, we located one article reporting on a small cross-over RCT examining the effect of caffeine versus decaffeinated fluids on symptoms of overactive bladder, including UI in women, but were unable to identify the number of oldest-old participants, few, if any appeared frail, and results were not stratified by age [508].

Recommendations (Table 7)

No recommendations are possible regarding lifestyle interventions for UI in the frail elderly (Level 4).

10.2. Behavioural interventions

Behavioural interventions have been a mainstay of UI treatment in the frail elderly, and include two major types: voiding programmes, including use of strategies to suppress urgency and delay voiding, and pelvic floor muscle training (PFMT). More recently, functional training with exercise targeted at improving mobility and toileting skills has been recommended for frail older adults, especially those in long-term care settings, who are at risk for functional decline and UI because of difficulty reaching and accessing the toilet in a timely manner [502]. Behavioural interventions may be especially beneficial for the frail elderly because they have few, if any, side effects.

Voiding Programmes. Voiding programmes are used predominantly with frail older persons, some which require active caregiver participation [509]. These interventions evolved from classical behavioural change theory, using antecedent and/or consequent conditioning to shape the desired behaviour [510]. Voiding programmes can be used for frail older people with cognitive and physical impairments who have difficulty learning new behaviours or difficulty actively participating in self-care activities, as well as

with frail older adults without these impairments. They include:

- ***Prompted voiding*****,** involving prompts to toilet with contingent social approval, is designed to increase patient requests for toileting and self-initiated toileting, and decrease the number of UI episodes. It was first used in the late 1980s for incontinent nursing home residents [386] but has also has limited testing in a homebound older population [511].
- ***Habit training*** requires the identification of the incontinent person's individual toileting pattern, including UI episodes, usually by means of a bladder diary. A toileting schedule is then devised to pre-empt UI episodes. There is no attempt in habit retraining to alter an individual's voiding pattern [512].
- ***Timed voiding*** involves toileting an individual at fixed intervals, such as every 2-3 hours. This is considered a passive toileting programme; no attempts are made at patient education or reinforcement of behaviours, or to re-establish a voiding pattern. Other terms used to describe timed voiding are scheduled toileting, routine toileting, and fixed toileting [513].
- ***Bladder training (or bladder retraining)*** involves a progressive voiding schedule in combination with patient education that incorporates teaching of strategies for suppressing urgency and delaying voiding. This intervention is used in individuals who do not have cognitive or physical impairments [514].

A prior systematic review and metastudy of bladder training, prompted voiding, habit retraining, and timed voiding [515] found limited evidence on the effectiveness of voiding programmes, with the majority of trials not determining the type of UI or sufficiently describing whether comorbidity that possibly contributed to UI was evaluated or treated. Randomised trials in long-term care settings have overwhelmingly depended on research personnel to supervise or conduct the interventions. Studies repeatedly show that, once a trial ends, the long-term care staff rarely maintains the intervention at the same level, if at all. Outcome evaluation is usually limited to "wet checks" (percentage of times the patient is found to be wet on a set schedule) and not UI, and no studies report cure or patient-based outcomes, such as satisfaction and quality of life impact, or staff-based outcomes such as burden.

The context in which care is provided has been implicated in the provision of quality continence care [516], with staff knowledge about UI and UI care an important aspect in continence care delivery [517]. Staff or family caregiver buy-in for the intervention is considered an important component to behavioural interventions [518], Consideration of organisational and social factors and interplay among older adults, by the health care team, was also identified as important in the implementation of evidence-based practices [311]. Staffs' beliefs and experience with regulatory policy may also have an unintended, negative effect on provision of continence care in long-term care facilities [292, 519].

Functional Training and Exercise. Functional training involves exercises focused on improving skills involved with toileting and other activities of daily living (ADL). Functional training has also been used in conjunction with prompted voiding, and is referred to as functional incidental training (FIT). In some studies, FIT may be implemented by nursing home care aides (nursing assistants) [8, 520]. Functional training for UI has also been delivered by an occupational or physical therapist [521]. Functional training, with and without prompted voiding significantly reduced UI (measured in wet checks) in two long-term care populations [8, 520]. However, these interventions involve extra staff effort which may limit their feasibility in practice.

Pelvic Floor Muscle Training (PFMT). Although PFMT has been extensively studied in adults and some older people, primarily women and men undergoing prostatectomy, it has had limited study in frail older persons. An early study evaluated the effect of biofeedback-assisted PFMT in homebound older adults and found evidence that it significantly improved UI [522]. Age and frailty alone should not preclude the use of PFMT in appropriate patients with sufficient cognition to participate [523].

Multicomponent Behavioural Interventions. Studies have examined the effectiveness of multicomponent behavioural interventions involving PFMT in combination with bladder training for treatment of UI in women and non-frail older women [524, 525]. A multicomponent behavioural intervention involving pelvic floor muscle exercises, bladder training, and information about lifestyle modifications has also been studied in prevention of UI in community-dwelling older women aged 55 to 80 years [526], 2004); this intervention might be effective in some frail older women.

Quality of the data and results **(Table 7)**

Since the 5th International Consultation a systematic review on management of incontinence and promotion of continence in older people in care homes [527], and an umbrella review of other systematic reviews using behavioural interventions for the promotion and management of UI [528] were published. These reviews confirm our findings that voiding programs are conducted primarily with frail older women (age > 80 years) in long-term care settings, with prompted voiding the most common intervention. Both reviews found evidence of the effectiveness of prompted voiding in reducing wetness rates and improving appropriate toileting in the short-term in both long-term care and homebound populations. Bladder training was effective in reducing UI frequency in

older women; however, there was no evidence regarding the effectiveness of timed voiding and habit retraining.

We also located two systematic reviews on conservative interventions for UI in frail older adults. One review examined treatments conducted in frail community-dwelling older populations [529]. The other review with meta-synthesis assessed conservative treatments in older adults and frail older adults in both community and long-term care setting [530]. This review concluded that there is some evidence that conservative treatments can reduce UI and improve quality of life. However, the quality of the evidence varied from low to moderate. These reviews confirm our previous observation on the limited number of studies on behavioural interventions in the oldest-old adults. A limitation identified by both reviews was the lack of an operational definition for frailty which made it difficult to distinguish older from frail older persons, along with incomplete descriptions of the study population in terms of comorbidity and ADL capacity.

Since the 5th ICI, we were unable to locate new articles on prompted voiding, timed voiding, habit training, or bladder training that incorporated randomized controlled trial (RCT) or quasi-experimental designs. However, we did locate two non-randomised studies evaluating the feasibility and effect of an ultrasound-assisted prompted voiding programme for management of UI in hospitalised Japanese older adults [531] and nursing home residents [532]. In a 4-week period evaluating ultrasound-assisted prompted voiding in 88 older hospitalised patients, there were statistically significant –post-test improvements in absorbent pad use (62.5% decreased their use and 26.3% no longer required use, with 37% unchanged) and reduction in caregiver stress [531]. In a 12-week study involving 77 nursing home residents, absorbent pad cost was decreased in 51.9% of participants, overall costs decreased by 11.8%, and quality of life for care workers in subscales of role emotional and mental health were significantly improved [532]. These promising results warrant larger scale testing using more a more rigorous design.

We were unable to locate any studies that reported on prevention of UI in frail older adults. We located five articles reporting on multicomponent behavioural interventions [332, 333, 533-535] (Table 7). Three studies were located that evaluated interventions in community-dwelling older adults. These included a RCT of fitness exercises and PFMT [536] in older women, a secondary analysis of a RCT involving biofeedback-assisted PFMT and stress UI and urgency suppression techniques in homebound and non-homebound older adults [535] and a RCT evaluating fitness exercises and PFMT with and without the use of a heat and steam sheet placed on the back for 30 minutes daily) in older women with stress, urge, and mixed UI [534]. Two studies were located that evaluated multicomponent behavioural interventions in long-term care populations: a RCT of a group-based education, bladder training and PFMT programme in care home residents, and a RCT of physical activity and activities of daily living (ADL) training in nursing home residents [333].

There continues to be limited evidence on the use of behavioural interventions in the frail elderly. The majority of studies have been conducted with frail older adults in long-term care settings; few interventions studies have been conducted in hospitalised or homebound older adults. In the previous ICI review we noted limitations in most studies including: small samples with low power to detect significant differences; varied terminology, operational definitions, and measures of UI making comparisons across studies difficult; inconsistent definitions of frailty; limited racial or ethnic diversity or men in samples; little focus on night time UI; little consideration to the psychosocial impact of voiding programmes on frail older adults and caregivers; and no long-term follow-up. Most studies excluded frail older adults with terminal illness. Ethical concerns for human subjects prohibit withholding treatment; thus, true “control” conditions were nearly impossible to create. Prompted voiding protocols varied across studies, with prompted voiding conducted every two hours over 12-hour, 14-hour, and 24-hour schedules. Cost data on voiding programmes was either dated (> 16 years) or was not available.

Table 7. Behavioural interventions

Intervention	Authors	Study Design	Sample	Methods	Results
Systematic Reviews					
Conservative treatments	Talley et al., 2011	Systematic review of conservative treatments in community-dwelling, frail older populations	7 studies (N=683; 75% women)	Literature review according to protocol including quality assessment	Multicomponent behavioural interventions (PFMT and bladder training) effective in reducing UI but low level of evidence Habit training and timed voiding led to modest reductions in UI but not considered clinically significant
Conservative interventions	Flanagan et al., 2012	Systematic review of care interventions for UI and faecal incontinence	33 studies, with 26 studies on UI only (N=1111; majority > 80 years, predominantly female); 7 studies on UI and/or fecal incontinence	Literature searched according to protocol; no quality assessment	Prompted voiding effective Combined prompted voiding and exercise was effective in improving endurance, strength, and continence but no evidence for exercise alone
	Roe et al., 2015	Systematic review of systematic reviews on management of UI and promotion of continence using behavioral interventions	5 systematic reviews; 3 specific to intervention studies (N= and two reviewed descriptive studies	Literature searched according to protocol (all systematic reviews); two reviewers evaluated reviews for methodological quality	Toileting programmes, particularly prompted voiding, is effective in the short term, reliant on staff adherence and resources
Conservative treatments	Stenzelius et al., 2015	Systematic review with metasynthesis on conservative treatments for UI and/or faecal incontinence in frail older populations	23 studies, with 9 moderate to high quality studies (N=895) included in metasynthesis	Literature searched according to protocol with quality assessment	PFMT in combination with physical training was effective in reducing UI and improving quality of life Prompted voiding and toileting assistance with functional exercise reduced UI Nighttime prompted voiding and waking routine had no effect on UI reduction Education had no effect on UI on quality of life
Functional Training and Exercise					
Physical activity and ADL training	Vinsnes et al, 2012	2-arm RCT	98 residents (mean age 84.3 years) in a Norwegian nursing home	3 month treatment of physical activity and individualised functional training by physiotherapist or occupational therapist; control group received usual care	After adjusting for age, sex, and functional status, the treatment group had significantly less urine leakage than the control group which increased their leakage

Multicomponent Behavioral Interventions					
PFMT and functional training	Kim et al., 2011	2-arm RCT	127 community-dwelling Japanese older women (mean age 75.9) with stress, urge, and mixed UI	60-minute exercise class with PFMT and fitness exercises, twice a week for 3 month; followed for 7 months post-treatment	Treatment group had significant cure rates after treatment and follow-up
Physical exercise, PFMT, and heat and steam sheet	Kim et al., 2011	4-arm RCT	147 community-dwelling Japanese older women (Mean age 76) with stress, urge, and mixed UI	3-month group exercise class with PFMT and fitness exercises twice weekly, with or without 30 minutes use of a heat and steam sheet applied to back daily or heat and steam sheet only; control group received general education once monthly for 3 months	Intervention groups significantly improved muscle strength and walking speed compared to control Exercise and use of heat and steam sheet led to significantly greater reductions in UI cure rates than exercise or heat and steam sheet alone Exercise and use of heat and steam sheet led to higher cure rates in women with stress UI than those with urge or mixed UI
Education, PFMT, bladder training, and functional training	Tak et al., 2012	Group RCT	192 residents (mean age 84.6) in 20 participating Dutch care homes	22 week intervention involving weekly group-based classes with education, PFMT, bladder training; control group received usual care	No statistically significant improvement in UI or quality of life Significant improvement in physical performance
PFMT and stress and urge suppression techniques	Engberg et al., 2016	Secondary analysis of RCT	279 homebound and non-homebound American adults aged 60 years and over	3-month intervention with PFMT, 6 weekly electromyography-guided biofeedback, and stress and urge suppression strategies; intervention conducted in homes by registered nurse	UI episodes were significantly decreased in the homebound group with UI

Efficacy

Findings from the 5th ICI and several recent systematic reviews [527-530] indicate that **prompted voiding** is more effective, in the short-term, than no intervention for improving daytime dryness in nursing home residents and some home care clients **(Level of Evidence 1)**. Our prior review identified predictors of treatment response using a three-day trial of prompted voiding which included: appropriate toileting rate (the number of times the resident voided into the toilet divided by the total number of voids) greater than 66%, a wet check rate (number of times the resident was wet when physically checked) less than 20%, ability to pass a simple cognitive screening procedure of a one-step command, and the ability to transfer without human assistance [75]. Individuals who meet these indicators should continue on prompted voiding, and all other residents should be managed by "check and change." This approach allows prompted voiding to be targeted to those nursing home residents who are eligible for and respond to prompted voiding (approximately 40%), and should help decrease the considerable time and labour costs now used for inappropriate, unsuccessful toileting [415].

The large majority of prompted voiding trials have been conducted in the United States, with little evidence of adoption in other countries. There is limited data on the effects of prompted voiding on caregivers, and no data are available on its long-term effects.

There continues to be insufficient evidence to determine if **timed voiding or habit training** improves continence in frail older adults **(Level of Evidence 4)** [537]. **Bladder training** appears to be effective in reducing UI in older women, some of whom may be frail.

Studies on functional training with other behavioural interventions (prompted voiding, PFMT, bladder training) report on improvements in endurance, strength, and walking ability, and subsequently reductions in UI in frail older adults in community-dwelling and long-term care settings. However, functional training alone did not appear effective in reducing UI.

There is some evidence that multicomponent behavioural interventions lead to improvements in UI in frail elderly, although this depends on the specific interventions and the population. There is some evidence that interventions including PFMT with and without functional training may be effective in improving UI in community-dwelling older women. Overall, there is insufficient evidence of effectiveness of functional training in combination with other behavioural interventions such as PFMT and bladder training. There is a need for high quality studies of multicomponent behavioural interventions in frail older adults in all settings, with evidence on their effectiveness in reducing UI, improving quality of life, impact on caregivers, and long-term benefit.

Recommendations for practice

1. Prompted voiding is effective in the short-term treatment of daytime UI in nursing home residents and home-care clients when caregivers comply with the protocol **(Level of Evidence 1).**
2. Prompted voiding is ineffective and should not be used for people who need the assistance of more than one person to transfer, cannot follow a one-step command, have less than a 20% reduction in wet checks or less than a 66% appropriate toileting rate after a three-day trial; these people should be managed with "check and change" **(Level of Evidence 1).**
3. Interventions combining toileting and functional training decrease urine loss and improve endurance in nursing home residents **(Level of Evidence 1)**.
4. It is uncertain whether habit retraining reduces UI in frail older persons **(Level of Evidence 4)**.
5. It is uncertain whether timed voiding reduces UI in frail older persons **(Level of Evidence 4).**
6. It is uncertain whether bladder training reduces UI in frail older persons **(Level of Evidence 4).**
7. Biofeedback-assisted PFMT in combination with bladder training reduces UI in homebound older adults **(Level of Evidence 2)**.
8. Functional training in combination with PFMT reduces UI and improves walking time in frail older women **(Level of Evidence 2).**
9. There are no proven interventions to reduce the incidence of UI in hospitalised frail older persons **(Level of Evidence 4).**

10.3. Interventions with long term care staff and caregivers

Many frail older adults rely on family, caregivers, or residential and/or nursing staff for toileting assistance and personal care. These carers may not be available as frequently as necessary for the frail elderly to maintain continence, and even if available may not be able or willing to provide the needed assistance. Research has shown that the frequency of toileting assistance actually provided in US nursing homes is too low to maintain continence [77, 78]. There is dissonance between nursing home surveyors, nursing staff, and nursing home administrators' knowledge and beliefs about UI and its management, which may be an important barrier to UI care [299]. Several studies suggest that nurses across all care settings (home care, acute care, and long-term care) settings continue to provide urine containment interventions rather than promoting continence [318, 343, 346, 348, 350, 352, 353, 538]. Moreover, nursing staff preferences for UI management (toileting) often conflict

with those of residents and their families' patient treatment preferences (medications and garments) [406, 408]. Acute care patients' preferences for UI treatment also differ from hospital staff preferences [407]. For example, nurses and physicians preferred scheduled toileting over diapers more than did the patients [407].

Management of UI in long-term care settings is complex, time-intensive, and requires staff training and cost-efficient systems for care delivery [417, 527]. Consistent findings from studies conducted in several countries suggest that lack of knowledge about UI, attitudes toward the elderly and incontinence, and the lack of formal preparation and continuing education influence continence care practices in long-term care settings [307, 539, 540].

Several researchers have recommended a two-pronged behavioural intervention to UI care: one geared towards the nursing home resident and the other geared toward staff members [541-543]. Nursing assistants provide a majority of the direct care in nursing homes and play a key role in the success of behavioral programs; yet they receive the least amount of formal education on UI. Organisational schemes involving use of incentives for nursing assistants to keep residents' continent has been recommended [544].

Several approaches have been studied in an attempt to promote continence and improve the management of incontinence in long term care. One approach involved a specialty practice exemplar model, with a nursing faculty member with expertise in the assessment and treatment of UI having a clinical practice in the nursing home. Assessment and treatment skills ultimately were transferred to the facility nursing staff through several mechanisms, including staff education and improved continence care systems [545]. Quality assurance programmes using incontinence quality indicators have also been proposed [358]. A clinical leadership model involving staff empowerment and mentorship in a subacute setting in Australia was successful in implementing practice-based changes for continence care that were sustainable 2 years after their introduction [546]. This model incorporated unit-based continence care resource nurses to implement evidenced-based strategies in continence care delivery. The effectiveness of clinical leaders may depend on several factors including, but not limited to their educational preparation for the role; the extent to which they feel supported; and the maintenance of the role (i.e., succession planning).

Quality of data

The challenges reported in conducting research in long-term care settings. Factors such as staffing ratios, staff turnover, changes in administrative and regulatory policies, and fiscal issues are beyond researchers' control. In addition, investigators report on issues with staff compliance in implementing research protocols involving toileting programmes and attendance at staff training was not optimal. We were unable to locate recent articles reporting on staff intervention research to improve continence care in older persons in acute and long-term care settings.

We located one article reporting on the use of an innovative staff training programme of distance learning and coaching for motivating nursing home staff to adopt a best practice toileting programme [547]. This programme involved a series of webinars to nursing home supervisors and staff designed as nursing home champions in 10 states in the US. Although one-third of nursing homes dropped out prior to or soon after the training was initiated, the results supported distance learning and coaching as an effective method of staff training and dissemination of a best practice protocol. Participants' knowledge of incontinence care practices was significantly increased, and there was evidence for the implementation of the toileting programme. The majority of participants preferred this method of training over a traditional 1-2 day conference. Course delivery costs including per facility courses were substantially less than traditional methods of staff training [548]

Results

Interventions with Long-term Care Staff

A recent systematic review on the promotion and management of incontinence in older people in care homes concluded that use of incontinence pads and toileting programmes comprised the most common management strategies, and assessment processes were inconsistently used [528]. Assessment protocols are a key first step in the process of identifying residents' individual continence care needs. Several assessment tools have been developed for this purpose. They include, but are not limited to:

- The Resident Assessment Instrument/Minimum Data Set (RAI/MDS) used in US and other countries' nursing homes
- The 'Continence History, Assessment, Medications, Mobility, Plan' (CHAMMP tool, developed to support the use of the RAI/MDS [549].
- The 'Capital Health Authority (CHA) Screening Tool 'for use within community and clinical settings in Canada [550].
- The 'Continence Assessment Tools for Residential Aged Care' for use within Australian long-term care settings [551].

Toileting assistance programmes also play a central role in optimising continence for frail older adults in long term care settings. One study examined the effect of a scheduled toileting programme and addition of a mechanical lift for patient transfers on the incidence of nursing home staff injury, using a quasi-experimental design [552]. Regular toileting significantly increased, and there were no increase in staff injuries following the programme. Staff also noted less resident agitation. Another study investigating a

multifactorial programme that included toileting assessment in Japanese nursing home residents also reported improvements in residents' continence status. Managerial support was key to the success of the intervention, as was the involvement of a clinical leader on each unit to oversee the protocol [553].

While toileting programmes are effective in reducing incontinence rates when implemented [554], and in-service classes on UI may change staff knowledge and attitudes about UI, in-service classes alone do not improve resident toileting [347]. In one study, only 70% of toileting assists were completed after staff training [541].

In response to nursing staff's knowledge deficits, some researchers have developed and trialled education and awareness-raising strategies, designed to enhance knowledge that would subsequently lead to practice improvements, and in turn, enhance the quality of continence care in long-term care. For example, a number of countries have established postgraduate and continuing education courses that prepare nurses and physiotherapists to address the broad spectrum of continence issues. However, most of this research was conducted prior to 2010 [295, 297, 302, 304, 305, 311, 555], other than a study involving a distance learning with coaching strategy for nurses in long-term care settings [547, 548].

However, the association between improved knowledge and improved practice is not straightforward. Some researchers reported improvements in knowledge that did not translate into improvements in practice [295, 301, 304]. Cognisant of this dilemma, Henderson and Kashka [301], examined the association between knowledge, beliefs, attitudes, and practice about incontinence in US nurses from hospital, home health, and long-term care settings using a tool titled "the Urinary Incontinence Scales". Using a multiple regression analysis, they found that although participants' knowledge and beliefs were positively associated with their self-reported practice, attitude alone had a direct effect on self-rated practice, thus, highlighting the need for educational strategies that address the effective behaviours associated with caring for incontinent persons.

Given the longstanding challenges surrounding the uptake of evidence into practice, results from qualitative studies may be informative in identifying factors that are useful in the adoption of evidence-based practice, particularly in long-term care settings. In one study [556], managerial support was ranked as the most important factor, followed by sufficient resources to implement new learning; the learner's belief in the practicality of training; integration of the learning into ongoing practice; staff feeling valued; on-the-job reinforcement of learning; knowing change of practice is supported; seeing benefits of new approaches; and attitudes toward elderly people. Whilst all of the above mentioned resource factors are important to optimise evidence-based continence care practice, several researchers draw attention to the need for theory to inform improvements in the quality of care [510, 557, 558]. However, models for translation of research into practice for long term care rely on the belief that usual care staff are able to implement better care if they know what to do and are properly motivated [559]. However, one of the key steps in the process of translating evidence-based knowledge into practice is to identify potential barriers to change.

Research literature on UI in homecare and nursing home settings identify extensive barriers to UI care [346, 372, 559, 560]. In the 5th ICI, barriers to implementing voiding programmes such as prompted voiding in nursing homes included: poor communication, inadequate staffing, staff work load, turnover, absenteeism, and lack of education programmes. Other barriers include the belief by nursing assistants that UI is a normal part of aging and that nothing could be done for it [372] or that use of incontinence pads protect and dignify residents [292]. A further challenge to UI care in long-term care was identified as the differences may exist between documented care, reported care, and actual care [77], and the need for ongoing monitoring.

Another approach to translating evidence-based protocols into practice in long-term care involves the use of quality management programmes. In an early study, Schnelle and colleagues [77] tested a computerised quality management programme for prompted voiding and found the programme was effective in improving dryness for six months while the research staff monitored the database, but only one facility continued the programme after the research ended.

The 5th ICI identified the need for changes at resource and policy levels to address the disincentive inherent with toileting assistance programmes that require significantly more staff time than the practice of checking and changing residents' pads [552] and for maintaining a resident's functional ability to walk to the toilet [520]. For example, in an analysis of the cost and time involved in changing nursing home residents' pads, compared with implementing prompted voiding, or a functional incidental training programme (FIT), researchers found that changing residents' pads averaged 5.5 minutes, compared to 7.7 minutes for prompted voiding, and 13.7 minutes for FIT [520]. Although FIT resulted in significantly better outcomes for residents in terms of their strength, mobility, and continence, it relied on a staff to resident ratio of one aide to five residents [559].

As reduced mobility is a major risk factor for incontinence, further attention should be directed toward developing, implementing, and evaluating interventions that can increase residents' functional skills, or at the very least, minimise their functional decline. Several studies have reported that frail elderly people participating in functional training programmes to improve mobility and toileting skills [75, 333, 521] are able to significantly reduce their UI.

Interventions for continence care in frail older adults should also minimise the incidence of incontinence-associated dermatitis (IAD). Palese and Carniel [427] described a three-phased multi-intervention incontinence care programme in a long-term care facility in Northern Italy that reduced the incidence of IAD, and the number and cost of absorbent products. The intervention consisted of an assessment process, the introduction of new absorbent continence aids, a structured skin care regimen, and advice and education from a Continence Nurse Advisor.

10.4. Interventions to manage night time incontinence in long term care.

Night-time sleep in long-term care residents is often fragmented and disrupted, and much of this sleep disruption is caused by noise, light, and incontinence care routines [561-564]. There is some evidence to suggest residents may spend long periods of time in bed overnight (returning to bed after dinner about 6:30 pm and waking between 0600-0700 hrs), and staff conduct pre-scheduled rounds to reposition residents and change their pads [565]. In one study, although senior staff stated that such rounds were conducted every two hours during the night; the number of observed rounds was 0.3-4.5 per resident [565].

Interventions that have been trialled in an attempt to enhance the quality and duration of sleep for residents with incontinence include:

- A daytime physical activity programme [566]
- A daytime physical activity programme combined with a night staff behaviour programme aimed at reducing noise, light, and sleep-disruptive care practices [566]
- A two to four hourly incontinence care schedule based on an individualised assessment of each resident's skin health [543]
- An individualised incontinence care routine combined with feedback to usual care staff about methods to reduce noise levels [567]
- A two or four hourly prompted voiding schedule based on an individualised assessment of each resident's skin health [568]
- A four or eight hourly pad changing regime based on an individualised assessment of each resident's skin health [569]

The combined findings of these trials along with a recent qualitative study of nursing staff in Australian residential care facilities [570] suggest that continence care at night in long-term care settings can, and should be individualised based on an assessment of residents' skin health; their ability to spontaneously move in bed; their sleep/wake status, and the frequency, severity, and type of the residents' incontinence. It should also be based on an assessment of residents' preferences. One of the main reasons for residents' sleep disruption is due to the time-honoured practice of waking residents to check their continence status and reposition them in order to minimize the risk of pressure ulcers. In an early RCT, 81 older adults from UK residential homes were randomized to either a four or an eight hourly night time pad changing regime [569]. Investigators found no evidence that the less frequent changing regimen had an effect on skin erythema or on skin pH. However, residents on the less frequent pad changing regime had significantly wetter skin, and five residents developed grade 2 pressure ulcers. Advances in the design and absorbency of pads and of pressure relieving devices may mitigate the number of times residents' need such care. Whilst toileting assistance should be available to residents during the night as well as day, one study suggest that prompted voiding is not effective or well tolerated at night [568]. Further research to guide practice on residents' preferences for night-time continence care, as well as the frequency of night time pad changing regimes and their impact on skin health is needed.

10.5. Interventions with caregivers

Family caregivers of frail older persons with UI report a high level of physical and psychological exhaustion, burden, embarrassment, and social isolation [571, 572]. This is particularly so for family caregivers of individuals with UI and dementia, especially if the care recipients have challenging behaviours [573, 574]. We noted that toileting is a complex event, and as a task it is unaesthetic and unpleasant for caregivers and care recipients. Individuals with dementia have variable responses, with some retaining the ability to toilet appropriately, and in others, toileting can trigger a severe emotional response. Prior research indicates the need by caregivers for information on resources [571]. Some caregivers at home report that the requirements of implementing a behavioural protocol may be more than they could manage [573]. However, in contrast to long-term care staff, family caregivers have higher adherence rates with prompted voiding, and a higher proportion is either somewhat or completely satisfied with the decrease in UI [511].

There has been limited intervention research with family caregivers of frail older adults with UI. Few studies address the caregivers' needs for education and information on continence management, nor are outcome variables included related to caregiver burden and satisfaction. This represents an important gap in the evidence base for UI, and is an opportunity for future research.

Recommendations for practice

- Family caregivers or residential and/or nursing staff dealing with different levels of UI (mild, moderate, severe, catheter managed) have different educational needs and require different levels of support.
- Interventions to support family caregivers of individuals with UI may need to be adapted to suit

formal caregivers or staff in long-term care so that they accommodate the organisational context.
