- An individualised approach is recommended to meet the needs and preferences of older people in long-term care.
- Interventions or approaches to caring for an individual with UI and cognitive impairment need to be tailored to the person's unique abilities and disabilities.
- Interventions for UI should be theory-based, multicomponent, interdisciplinary, and person-centred.

11. PHARMACOLOGICAL TREATMENT

11.1. Background

This section deals with the management of frail older persons. The pharmacological management of UI in robust older men and women is discussed in Chapter 8, Pharmacology. Specific treatments for bladder outlet obstruction and associated LUTS in frail elderly men are outside the scope of this chapter; special matters relevant to the care of frail older men with UI are discussed above. For frail older men and women in nursing homes, urinary incontinence and overactive bladder appears to be associated with an excess of concomitant co-morbid conditions compared to continent residents [575] thus frail persons with UI should undergo a comprehensive evaluation of remediable causative factors and, if practical, have had a trial of behavioural and lifestyle interventions prior to initiating pharmacological therapy. Drug treatment should not generally be used for persons who make no attempt to toilet when aided, become agitated with toileting, or are so functionally and cognitively impaired that there is no prospect of meaningful benefit. Even so, a recent study of US nursing home residents suggested that only a small proportion of incontinent residents potentially suitable for drug therapy ever received it [576, 577]. A more recent study identified the high prevalence of potential reasons why treatment with antimuscarinics might not be suitable [479].

11.2. Quality of data

Since the last ICI we located further randomised placebo controlled trials (RCTs) of medication, involving subjects over the age of 80. As before, the majority of studies addressing UI in frail older people are of only modest quality, reflecting their vintage. There have been two large prospective studies of older people, one in Europe and one in the US; the latter targeted at medically complex older people identified by the VES-13 [578]. A systematic review of pharmacological therapy in old and frail older persons as part of the formulation of the Swedish national guidelines has also been published [579]. There has also been a number of *post hoc* pooled analyses of patients over 65 years of age, and reports of sub-groups of patients ≥75 years of age taking part in registration studies of medications for overactive bladder. For most studies it remains impossible to identify whether included subjects might be defined as frail, even though the spread of co-morbid condition and co-existing medication suggests a representative sample of medically complex community dwelling older people, except where the study was performed in an institutional environment, in which it is reasonable to assume a high prevalence of functional and cognitive dependence.

The methods of blinding and randomisation in RCTs were seldom specified Other than those conducted by the pharmaceutical industry, most studies were generally small and potentially under-powered, and others lost power because of high dropout rates due to illness and death (inevitable in trials with frail elderly persons). Because of these issues, many RCTs provide only Level 2 evidence. Some studies in older persons without clear frailty are included here, to recognise an increasing emphasis on including older persons in drug trials.

Precise descriptions of the target population - including the definition of "frail persons" and a comprehensive description of the degree of cognitive and functional impairment were usually absent. Some investigators included information on patients' comorbid conditions and concomitant medication load at baseline; these descriptions are largely descriptive, with no outcomes analyses based upon either factors. Explicit, concurrent behavioural therapy was used in most nursing home studies, yet may have occurred in many others although these are usually specifically prohibited in trials managed by the pharmaceutical industry. Combination therapy, coexistent medications and comorbidity could alter differences between drug and placebo, and therefore make it difficult to compare results directly with results from studies in robust older and younger persons. Outcomes in care home studies were universally assessed by disease related outcomes (largely incontinence episodes, measured by pad-weighing, bladder diaries, and wet-checks), and none report quality of life outcomes. In fact, there is a dearth of understanding about what might be a meaningful outcome measure of continence care to frail older nursing home residents.

In at least six studies, investigators treated subjects with "urinary tract infection" (usually defined as pyuria and bacteriuria in the presence of UI) before initiating antimuscarinic therapy, and one study excluded such subjects. In another, investigators treated urogenital atrophy with oestrogen prior to antimuscarinic therapy, possibly leading to an additional amelioration of symptoms. However, no other reversible or remediable causes were addressed prior to entry or randomisation in most studies.

The generally low quality of trials other than those conducted by the pharmaceutical industry reflect not just study design, but the larger issue of the difficulty of doing large, prospective intervention trials in frail

populations. Moreover, UI in the frail older person is universally a multifactorial problem involving a large number of factors beyond the bladder. Thus, the expectation that drug therapy targeted solely at underlying OAB, DO or SUI would markedly improve/cure UI in this population is unlikely to be realised.

Additionally, the reporting of adverse events relevant to managing frail older people is deficient with a concentration on those which might matter only recently being reported. A meta-analysis examining the measurement and reporting of CNS outcomes showed that, 77% (242/314) of eligible trials identified neither measured nor reported CNS outcomes. Of the remaining 23%, it was difficult to ascertain whether CNS adverse events were systematically measured or spontaneously reported. Only one of 72 trials objectively measured changes in cognitive performance. Age-stratified analyses of CNS outcomes from trials in adults aged 65 and older with overactive bladder were found in only eight publications [580].

Results

Results from randomised trials are summarised in Table 8; the following sections discuss specific drugs in detail.

1. OxybutynIn

The majority of older studies in frail older persons used immediate-release oxybutynin (oxybutynin-IR). There are three studies of extended release oxybutynin (oxybutynin-ER), one examining cognitive effects in nursing home residents with dementia and urgency UI, [581] the other reporting on the effect in cognitively impaired nursing home residents [582] and the last involving community-dwelling women over age 65 [583]. Published trials of the efficacy of transdermal oxybutynin included subjects up to age 100 and in institutional care settings, but did not stratify results by age or comorbidity [584]. Due to concern regarding the association between anticholinergic drugs and cognition (see above) a number of articles [585, 586], national [52] and European guidelines [486] have counselled against the use of oxybutynin immediate release in frail older adults. Since the last consultation, oxybutynin gel has been introduced and its effect on cognitive function in healthy older people assessed [587] in addition to phase 3 trials of the preparation [588], which reported no data from older patients. A small study of 10 US veterans (6 with Mild Cognitive Impairment) with OAB treated with antimuscarinics aged between 60 – 85 years reported significant improvement in at least one subtest score on well-characterised instruments after 4 weeks of withdrawal from medication [589].

The pharmacokinetics of oxybutynin-IR and its active metabolite, N-desethyloxybutynin, in one study tended to show greater plasma levels and bioavailbility with increasing frailty and age [590]. Another found peak levels in 21 octogenarians similar to those reported in young normal males (12.5 ng/mL vs. 8.9 ng/mL) [591]. A study of the pharmacokinetics of transdermal oxybutynin showed no significant difference in plasma levels between young and old (up to 77 years) subjects [592].

Efficacy: Many of the early trials shown here are, perhaps now, only of historical interest. However, there have been few additional studies of newer agents in frail older persons from which to draw data. An early, small (n=15) trial of oxybutynin-IR and habit training in nursing home residents showed no effect on UI episodes [593]. However, in a subsequent and larger study in nursing home residents who had failed prompted voiding alone, the addition of titrated oxybutynin IR resulted in a significant but modest reduction versus placebo [594]. Wet-checks decreased from 27% at baseline to 20% on drug and 24% on placebo, leading the authors to conclude that the improvement was not clinically significant especially given the continuing requirement for nursing intervention. However, their a priori definition of “clinically significant improvement” (one or fewer episodes of daytime UI was achieved by 40% on drug but only 18% on placebo ($p<0.05$). The dose generally associated with improvement was 2.5 mg three times daily. In another controlled study of UI in long-term care residents (n=24), there was little effect of oxybutynin-IR 5 mg twice daily given for 8 days, but all residents were toileted 10 times daily, and the dose may have been too high and given too infrequently [595]. In a randomised two-month trial in frail community-dwelling elderly, oxybutynin-IR plus bladder training was subjectively and objectively superior to bladder training alone in improving urinary frequency (95% CI 6-27 fewer voids per 2 weeks) but not UI [596]. Insuffi information was available regarding a Japanese study in 75 “elderly” patients to assess the population and outcomes [597]. A study in 416 community dwelling older persons, including the robust elderly, found 68% reported a partial or complete symptomatic cure with 2.5 mg three times daily; 30% of subjects experienced ADEs, but only 10% withdrew because of them [433].

Two identified RCTs in frailer older people examined the efficacy of oxybutynin-ER [582, 583] The other examined the effect on cognition [581] and is discussed below. No published RCTs of transdermal oxybutynin in the frail elderly were found, a post hoc

Table 8. evaluable drug trials in frail older persons

Drug	Study	Design	Setting and pts	Results	Comments
Oxybutynin	Minassian 2007[583]	prospective randomized 12-week, open-label study to investigate the effectiveness of extended release versus immediate release oxybutynin	community-dwelling female population over the age of 65	72 women (23%) were enrolled over 34 months (33 in the immediate release group, and 39 in the extended release group). The study was stopped prematurely	
	Sand 2007[584]	randomized, open-label, assessing health-related quality-of-life (HRQoL) and safety with oxybutynin transdermal system (OXY- TDS)	community-based study of 2878 participants aged >/=18 years who had been given a diagnosis of OAB.	There were clinically meaningful and statistically significant improvements in nine of 10 domains in KHQ at the study end; the greatest improvements were in Incontinence Impact (-13.5), Symptom Severity (-12.4), and Role Limitations (- 13.3).	No age stratification, not obviously a frail element to the study sample
	Lackner 2011[582]	efficacy of oral extended-release oxybutynin for urge urinary incontinence	4 week trial in 50 older female nursing home residents with mild to severe cognitive impairment.	both groups achieved a significant median decrease in mean urinary incontinence episodes and urinary frequency at 4 weeks (P = .01-.05). Staff ratings found that more participants had improvement in urinary symptoms from baseline with oxybutynin than placebo but significant only for delaying evening voiding (P = .02).	No between group differences in any outcome
Solifenacin	Herschorn 2011[452]	randomised, multicentre, prospective, double-blind, double-dummy study to compare the incidence and severity of dry mouth and other adverse events in patients <65 years and >65	132 subjects with >1 urgency episode per 24 h, with or without urgency incontinence, and >8 micturitions per 24 h for 3 months.	incidence and severity of dry mouth and other adverse events with solifenacin were similar between younger and older patients. solifenacin 5 mg/day was associated with fewer episodes and lower severity of dry mouth, and a lower discontinuation rate	adverse events were evaluated in subgroups of patients <65 years and >65 years. No stratification otherwise
Drug	Study	Design	Setting and pts	Results	Comments

Drug	Study	Design	Setting and pts	Results	Comments
Darifenacin	Chapple 2007[598]	RCT assessing efficacy, tolerability, safety and quality of life in 400 subjects mean age 72 years	randomized (2:1) to 12 weeks of double-blind treatment with darifenacin 7.5 mg once daily for 2 weeks, then optional titration to 15 mg daily or placebo with sham titration	Mean urgency urinary incontinence episodes decreased significantly with both darifenacin (-88.6%) and placebo (-77.9%; p > 0.05), QoL assessments revealed significant improvements with darifenacin versus placebo	Unsure re “frailty” of sample
Fesoterodine	Wagg 2013 [454]	RCT, efficacy and PRO comparing fesoterodine to placebo	794 community dwelling men and women >65 (1/3 >75)	improvement in urgency episodes (-1.92 v -3.47, p<0.001), micturitions (- 0.93 v -1.91, p<0.001), nocturnal micturition (-0.27 v -0.51, p=0.003), severe urgency episodes (-1.55, -2.40, p<0.001), and incontinence pad use The response on the treatment benefit scale, OAB-S, PPBC, and UPS significantly greater in fesoterodine group	Community dwelling sample, including very elderly, no assessment of frailty, largely cognitively intact
	DuBeau 2013 [458]	12 week double blind, placebo controlled study	562 people of mean age 75 years fulfilling definition of vulnerable elderly	mean reductions in UUI episodes at week 12 versus placebo -0.65 (0.21), p<0.0018) and 24h micturition frequency -0.84 (0.23), p<0.0003)	
	Dell'Atti 2015 [599]	12 weeks prospective randomised study (open label)	108 consecutive patients diagnosed with OAB 56 patients treated with tadalafil 5 mg once daily 52 patients treated with fesoterodine 8 mg once daily	OABSS baseline 9.87 ± 2.68 12/52 6.02 ± 3.59 <0.204 Micturition/24hours baseline 11.92 ± 4.68 12/52 10.82 ± 3.86 <0.001 Urgency episodes/24hours baseline 4.53 ± 0.91 12/52 3.54 ± 1.23 <0.003 Urge incontinence baseline .73 ± 1.32 12/52 1.02 ± 1.37 <0.001	Older sample, some mention of comorbidities, unable to assess frailty

Drug	Study	Design	Setting and pts	Results	Comments
Trospium chloride	Sand 2011 [600]	Pooled analysis of all pts >75y in 2 12 week RCT and open label follow-up of 1 year	143 subjects (85 trospium ER 58 placebo; mean age 79 years and ranging up to 90 years; 73% female)	Change in mean number of weekly urgency incontinence episodes: -22.17 (69.9% reduction)	

sub-analysis of efficacy in subjects over the age of 65 and improvement in quality of life has been published, but unobtainable [598, 599]. In a small Japanese case series (n=13, mean age 75) in persons with urgency UI and cystometric DO, intravesical oxybutynin caused no significant increase in mean bladder capacity one hour after installation of 5 mg oxybutynin at pH 5.85 [600]. In four patients who continued twice daily installation, two had UI "disappear" and one "markedly decrease" (duration until effect not noted). No patient developed an "increased PVR" (not defined). A study examining the effect of an oxybutynin vaginal ring included some older women (mean age 57.1, ranging up to 85) but results for older women were not reported separately. The vaginal ring statistically significantly reduced mean urgency incontinence episode frequency and urinary frequency, but not urinary frequency. The most commonly reported treatment emergent adverse events were UTI, vaginal discharge and dry mouth [601].

Predictors of efficacy: Predictors of efficacy were examined in one study in persons with urgency UI and urodynamic DO (n=41, mean age 79) treated with 2-4 weeks of oxybutynin-IR (5-15 mg/day) [602]. Factors associated with baseline urine loss (by pad weighing) were impaired cognitive orientation (on the Cambridge Mental Disorders of the Elderly Examination), number of daily voids, and fluid intake. Persistent urine loss after treatment was associated with impaired orientation, reduced sensation of bladder filling during cystometry, and most significantly global cortical under-perfusion on single photon emission computed tomography scan, suggesting that cortical factors are the main determinant of the severity of urgency UI before and after oxybutynin. In a study of 80 older patients (mean age 74), patients with dementia (by Hasegawa dementia scale) were less likely than cognitively intact patients to report subjective improvement in UI with antimuscarinic agents, despite similar objective outcomes [603]. However, these results could reflect treatment-associated cognitive effects.

Adverse reactions: A comparative sub-analysis of oxybutynin IR versus solifenacin in subjects below or above 65 years of age (mean 71 years in >65 year age group) showed subjects receiving oxybutynin IR at a fixed dose of 15mg/day were over eight times more likely to have dry mouth than were the solifenacin treated subjects [452]. In a study which included patients up to the age of 91, but with mean age 61 (SD 12.4) years showed oxybutynin to be non inferior to trospium in terms of resolution of UI episodes, but was associated with twice the incidence of dry mouth (7.7% versus 4.1%) [604].

Cognitive side effects from oxybutynin have been reported in older persons. In one case series, four older men with Parkinson's disease and mild-severe cognitive impairment developed confusion, psychosis, hallucinations, behavioural disturbance, and/or paranoia after receiving oxybutynin-IR (5-15mg/day), which resolved when oxybutynin was stopped [605]. Of note, each patient was also on L-dopa (co-beneldopa) and selegiline, and the observed effects could reflect drug-drug interactions. However, these results are belied by a large RCT in which oxybutynin-ER 5 mg daily did not cause more delirium than placebo in NH residents with UI and dementia [581]. Other concerns regarding cognitive function are discussed above.

There are case reports of reversible peripheral neuropathy confirmed by re-exposure in a 70 year old woman taking oxybutynin-IR 5-7.5 mg/day [606] and recurrent heat stroke associated with oxybutynin in one elderly patient [607]. Few studies have addressed cardiac effects. A small study of community dwelling older persons with UI (n=20, mean age 75) found no change in resting heart rate or electrocardiographic evidence of either prolonged PR interval or QTc, or QTc dispersion after 4 weeks of oxybutynin-IR (mean daily dose 7.6 mg [range 2.5-10 mg]) [608]. Using a large administrative database, no association was found between antimuscarinics (oxybutynin, flavoxate, hyoscyamine) and ventricular arrhythmia and sudden death [609]. Post-marketing adverse events with extended release oxybutynin include tachycardia and hallucinations.

2. Tolterodine

Efficacy: Since the last ICI, we identified no further studies of tolterodine for OAB/ DO in frail older persons but tolterodine has increasingly been used as a comparator agent in studies of newer agents in registration trials. Analysis of the studies of tolterodine in "older patients", however, does not allow any conclusion to be drawn about the frailty status of any older patient. For example, "older" patients in one RCT of tolterodine-ER were all community-dwelling, able to complete a 7-day bladder diary, had a high prevalence of previous antimuscarinic treatment (53-57%), and a low prevalence of arthritis (15-18%), unlike most frail older persons [610]. Although several trials include elderly persons in their ninth and tenth decades, [610-612] the mean age (approximately 64 years) was much lower, persons with "unspecified disease which the investigator thought made the patient unsuitable" and/or "renal disease" were excluded, and results were not stratified by age. In a secondary analysis of a large, open label German trial of tolterodine- IR 2 mg twice daily, higher age was significantly associated with "less favourable efficacy" [613]. However, the absolute difference in odds was only 0.019. There was no association of tolerability with age, only mean age is described, and UI frequency was based on patient report, not bladder diaries, all of which fail to add up to a clinically meaningful difference. In a non-randomised study, tolterodine was given to 48 nursing home residents who did not respond to toileting alone; 31 of these patients had a 29% increase in dryness (versus 16% in residents on toileting alone) [614]. A recent moderate quality short term (1 month) trial of tolterodine (2mg bid) and oxybutynin (5mg tid) in 100 older Iranian women, mean (SD) age 53(12) years with detrusor overactivity showed efficacy in disease related variables with both

drugs – there was no indication of comorbid conditions allowing any conclusion regarding frailty status. Withdrawals, the majority due to dry mouth, occurred in 6% of the oxybutynin and 8% of the tolterodine group [615].

There has been some reporting of trials including older men with BPH/BPE. A trial of 1-year duration of the addition of tolterodine ER 4mg to alpha blocker or 5 ARA therapy in older men (mean age 74.9 years) resulted in a between group, statistically significant decrease in the storage symptom score on the IPSS [616]. A newer trial involving men of mean (SD) age 61 (9.1) comparing tolterodine with either doxazosin or tamsulosin in a 12-week study showed Q_{max}, IPSS, QoL, intravesical pressure (Pves), and bladder compliance (BC) in the doxazosin plus tolterodine group were all significantly better than in the tamsulosin plus tolterodine group (P=0.03, P<0.001, P<0.001, P=0.027, and P=0.044, respectively). The prevalence of orthostatic hypotension was not reported other than in a general category "headache and dizziness" [617]. A recent review confirmed the greater chance of orthostasis with doxazosin, suggesting its use in older men who are more prone to the effect, be restricted [618]. This is also in concordance with the recent LUTS-FORTA guidance [485], above.

Adverse reactions: There are no prospective systematic data on tolerability in frail older patients. There have been case reports of hallucinations (73 year old woman with dementia [619]) and worsening memory,[620] including a 65 year old cognitively intact woman [621] There is a case report of delirium when tolterodine was given with a cholinesterase inhibitor [622]. Analysis of prescription event monitoring in the UK (mean patient age 63) found a significant association between age (>74 years) and psychiatric events and tachycardia (odds ratios not given) [623]. In a similar database study, the age- and sex-adjusted risk of hallucinations with tolterodine was 4.85 (95% CI 2.72-8.66) compared with 10 other drugs (acarbose, alendronate, famotidine, 3 proton pump inhibitors, finasteride, meloxicam, misoprostol, and nizatidine) chosen for presumed lack of antimuscarinic, cardiovascular, and CNS activity, and available in the database. Important confounders such as other drugs and comorbidity were not evaluated. Similar to oxybutynin-ER, post-marketing information on tachycardia and hallucinations was added to the tolterodine-ER package insert in 2003.

3. FesoterodIne

Efficacy: There are four studies of age related pharmacokinetics in younger versus older subjects (although not frail), a pooled analysis demonstrating efficacy of fesoterodine in subjects over the age of 65, stratified into >65 and >75year age groups from all prospective registration studies and from 2 only a large prospective study which reported the efficacy of fesoterodine in subjects stratified by age (>65 and >75) years of age and a prospective study in the medically complex or vulnerable elderly [453, 624, 625]. The pharmacokinetic study found no clinically meaningful effect of 5-HMT, the active metabolite of fesoterodine pharmacokinetics or pharmacodynamics after single dose administration of fesoterodine 8 mg. The efficacy of fesoterodine has also been studied in a European trial in 794 elderly men and women with OAB [454], 47% of whom were men. Forty-six percent of subjects reported urgency incontinence episodes at baseline, and 64% had prior treatment with antimuscarinics. At week 12, the improvement from baseline in urgency episodes (-1.92 v -3.47, p<0.001), micturitions (-0.93 v -1.91, p<0.001), nocturnal micturition (-0.27 v -0.51, p=0.003), severe urgency episodes (-1.55, -2.40, p<0.001), and incontinence pad use were statistically significantly greater with fesoterodine (pooled 4 and 8mg) than with placebo. The responses on the treatment benefit scales, OAB-S, PPBC, and UPS were also significantly greater in those in the fesoterodine group versus placebo. The results of the open label extension study [626] confirmed the efficacy and tolerability of active drug over a further 12 weeks. A subcut analysis from participants in the study investigated factors associate with dose escalation and identified at baseline, body mass index (OR: 1.06, 95% CI 1.01, 1.12; P = 0.0222), and male sex (OR: 2.06, 95% CI 1.28, 3.32; P = 0.0028) and at week 4, change from baseline in urgency episodes (OR: 1.12, 95% CI 1.05, 1.20; P = 0.0008), patient perception of bladder control (PPBC) (OR: 1.44, 95% CI 1.12, 1.84; P = 0.004) as significantly affecting the likelihood of dose escalation at week four [627].The effect of fesoterodine has also been assessed in vulnerable older people as assessed by the Vulnerable Elders Survey [578], which identifies those at risk of death in the following two years. This 12 week double blind, placebo controlled study including 562 people of mean age 75 years resulted in mean reductions in UUI episodes at week 12 versus placebo (-0.65 (0.21), p<0.0018) and 24h micturition frequency (-0.84 (0.23), p<0.0003) [458]. Fesoterodine 8mg has been compared to tadalafil 5mg in a small study evaluating efficacy on OAB symptoms, impact on quality of life and sexual function of in older patients. All men were over 65 years of age and 65% of them were over 75 years of age. The most common comorbidities were hypertension 37.8% (39/103), diabetes mellitus 18.4% (19/103), heart disease 16.5% (17/103) and depression 10.6% (11/103). Fesoterodine was effective in treating OAB symptoms in this group of multimorbid older men, whilst tadalafil showed superior efficacy in improving total IPSS and sexual function scores [628].

Adverse effects: The cognitive safety of fesoterodine has been assessed in a single small study of cognitively intact older subjects, using alprazolam as an active control and placebo. There were no statistically significant changes in performance on a computer assisted battery of cognitive tests versus placebo [629].

4. Solifenacin

Efficacy: Solifenacin has been used in combination with mirabegron in a Japanese post marketing study involving patients of approximate mean age of 65 with no description of sample comorbidity or results stratified by age [630]. Otherwise, two studies in older men and women of solifenacin in addition to mirabegron and solifenacin in addition to trospium have been conducted by the same group [631, 632]. The mean (SD) ages of included older people in the solifenacin and mirabegron study was 71.2 and all patients had urodynamically diagnosed detrusor overactivity. No mention was either made of comorbidity or frailty. The included patients in the solifenacin and trospium study had an average age of 69.4 years; once again, no description of comorbid disease or frailty status was given. A sub-cut analysis from a Canadian study which reported tolerability of solifenacin versus oxybutynin in older subjects, reported above [452]. Solifenacin has been compared to imidafenacin in a 1-year open label randomised trial the treatment of The pharmacokinetics of solifenacin in older adults have been assessed in 23 older subjects (mean age 68); t_{max} was longer and there was a higher maximum plasma concentration, but the differences from results in younger patients were small and deemed by the authors to be clinically irrelevant [633]. A secondary analysis of pooled Phase III data in patients aged 65 and older (all community dwelling and fit, mean age 72) found similar efficacy to that reported for younger and middle aged persons [634]. However, direct comparison with subjects < 65 yrs from the same pooled trials was not done. Adverse effects in older frailer patients have not been specifically reported. However, data from an open-label, 12-week trial in patients treated by community urologists found that overall treatment-emergent adverse events were more likely in patients aged >80 years (OR 3.9 [95% CI 1.3-11.5]) and taking concomitant medications (OR 1.8 [95% CI 1.2-2.6]) [635]. Patients with concurrent medications were more likely to be male and on average about 12-14 years older, have comorbid disease, and be administered higher doses of solifenacin, yet had no observed increase in heart rate or blood pressure with solifenacin.

Adverse effects: The cognitive safety of a single dose of 10mg solifenacin was tested versus placebo and 10mg oxybutynin IR in an exploratory study in 12 cognitively intact older subjects. Solifenacin showed no evidence of impaired cognition or self-ratings of mood and alertness versus placebo [636]. In a 3-way crossover design, chronic dosing of 5mg solifenacin, placebo and 5mg bid of oxybutynin were compared using a similar battery of tests in 23 older subjects with mild cognitive impairment. There was no statistically significant effect on cognition of solifenacin versus placebo. Oxybutynin 5mg bid was associated with impairment in power and speed of attention in a *post hoc* analysis of pooled data at 1+2h post dose [637].

5. Darifenacin

Efficacy: There is one RCT of darifenacin for OAB in persons aged ≥65 (mean 72), in which there was no statistically significant difference between drug and placebo for the primary end point, UI frequency [638]. There were statistically significant improvements with exposure to drug for urinary frequency (-25.3% vs.-18.5% with placebo; $p < 0.01$) and quality of life, as measured by OAB-q and patient perception of bladder condition. There is also a 2- year extension study in subjects >65, showing maintenance of OAB symptom improvement over the 2-years with 44.4% patients achieving > or = 90% reduction in incontinence episodes at 2 years for the 64% (137/214) subjects remaining in the study [639]. Both studies likely recruited robust community dwelling elderly, the extent to which these individuals had multimorbidity was not reported. A study of time to effect of darifenacin conducted using data from 1,059 patients (19-88 years, 85% women) randomised to darifenacin 7.5 or 15 mg once daily or matched placebo in three double-blind 12-week studies, but with no age stratified results showed that, using electronic diary data, darifenacin achieved statistically significant improvements in all OAB symptoms (except nocturnal micturitions) for both darifenacin doses versus placebo at week 2, with further improvements over 6 and 12 weeks [640].

Adverse effects: The cognitive effects of darifenacin have been prospectively studied in a series of trials; there have been no further studies since the last consultation. The first was a 3-period cross-over RCT in 129 older subjects (mean age 71, 54% of those screened), 88% of whom had co-morbid medical conditions and 93% were on other medications [641]. Cognition was assessed using a standardised computer test battery. Darifenacin at 7.5 and 15mg doses did not adversely affect cognition compared to placebo, but results were aggregated so that patients did not serve as their own controls. A subsequent study in cognitively intact older persons (n = 49, mean age 66) using a similar computer cognitive test battery compared titrated darifenacin and oxybutynin-ER with placebo over a period of 3 weeks [642]. Oxybutynin-ER but not darifenacin or placebo adversely affected the primary endpoint, delayed recall on the Name-Face Association test. However, oxybutynin was titrated one week earlier than darifenacin, and to a final dose (20 mg daily) much higher than that most commonly used in clinical practice. Also, there were no differences between the two drugs and placebo for many other domains of the cognitive battery.

6. Trospium chloride

Efficacy: Although often promoted for use in the elderly because of the reduced likelihood that the drug crosses the blood-brain barrier, there have been only two studies which has evaluated the agent specifically in older persons, and none in the frail elderly. The study by Kosilov is discussed above [632], and is of moderate quality. The other [643] was a subgroup analysis of pooled data for subjects aged ≥ 75 years

from two randomised, double-blind, multicentre studies of subjects with OAB receiving once-daily trospium 60 mg extended release (ER) or placebo for 12 weeks, followed by 9-month open-label extension periods during which all subjects received trospium ER.

143 (85 trospium ER, 58 placebo; mean age 79 years and ranging up to 90 years; 73% female) were assessed. At week 12 of the double-blind period, trospium ER produced greater improvements from baseline than placebo in voiding diary variables, global assessment, and quality of life indices. Efficacy and tolerability persisted among subjects receiving open-label trospium ER for up to 1 year. Although not assessing frail older persons, the other trial of interest, using all patients from the same studies examined the safety and efficacy outcomes with trospium chloride 60 mg in patients with OAB who were taking 7 or more concomitant medications at baseline. Of all 1135 included patients, 427 were taking seven or more medications (placebo, n = 199; trospium XR, n = 228). Amongst these, there was no significant difference between trospium chloride XR and placebo in the proportion of subjects experiencing one or more TEAEs (64.5% vs 58.3%). The odds of experiencing a TEAE were influenced by concomitant medication use, but not by randomisation to either trospium or placebo. For those taking ≥ 7 concomitant medications, compared to those taking 1-2 concomitant medications, the adjusted odds ratio (OR) for experiencing any TEAE was 3.39 (95% CI 2.39, 4.80) [644].

Adverse effects: The effect of 60mg trospium chloride once daily over 10 days on either learning or memory was assessed in 12 cognitively intact older people (>65 – 75 years). There was no change in standardised testing. Additionally, no trospium was detectable in the CSF of the subjects at day 10 [645, 646]. The pooled analysis of trospium, above noted a 10% occurrence of both dry mouth and constipation associated with trospium exposure [643]. As part of a larger study of trospium chloride 20mg bid, 36 (26 completed). Subjects with UUI and dementia, treated with galantamine and trospium) were examined. Subjects with severe dementia were excluded in this non-randomised, open label study. There was no observable decrement in either cognition, but only measured by MMSE, or ability in terms of activities of daily living in the dually treated group [481].

7. Propiverine

Efficacy: In 46 patients with dementia (mean age 81), there was a 40% decrease in urgency UI with propiverine 20 mg/day for 2 weeks, [647] similar to two small Japanese trials [648, 649] and a German trial in 98 patients [650]. The agent's high protein binding, extensive first pass metabolism, 15-hour half life (in normal younger persons), and renal clearance [647] need to be considered if used in frail older people; this is borne out by the LUTS-FORTA classification for the drug [485].

8. Imidafenacin

There have been no pharmacokinetic studies of imidafenacin in older people [651]. However, a population pharmacokinetic analysis demonstrated that oral clearance was decreased with advancing age, increasing hepatic function parameters (AST and ALP), food intake, and itraconazole co administration [652]. The absorption rate constant was decreased with food intake [653]. The drug is metabolised by the CYP3A4 system, and it is affected by drugs which inhibit this system [651] . There appears to be no affect on digoxin pharmacokinetics in healthy volunteers [654]. There are no trial data on older patients using this agent.

9. Duloxetine

There was a statistically significant reduced rate of clearance of duloxetine in patients over age 65, based on a study in 12 fit women aged 65-77 [655]. The authors felt the differences were not clinically significant given the "similar safety profile of the drug in older and younger women. In three large RCTs in women with SUI, aged 24-83 years, n = 494 [none frail] [656] with OAB, aged 21-84 years [none frail], n = 306 [657];and with mixed UI, up to age 85 [658], duloxetine decreased UI and urinary frequency, but none stratified outcomes or adverse effects by age. A single randomised controlled study of 265 community dwelling older women, 134 treated with duloxetine, of whom 20% had mild cognitive impairment as classified by the modified mini- mental state exam [636], duloxetine treatment led to a statistically significant decrease in incontinence episode frequency (median percent change 51.6%) versus placebo (32.1%) for stress predominant mixed symptoms, but did not reach significance for stress urinary incontinence (53% v 42%) [659]. Duloxetine is neither approved by the US FDA nor recommended by the UK National Institute of Healthcare and Clinical Excellence on the grounds of cost effectiveness.

10. Mirabegron

Efficacy: There are data on the comparative pharmacokinetics of mirabegron in older people, but not specifically the frail elderly. In available studies, there were no statistically significant differences in mirabegron exposure between older volunteers aged 55 years and above and younger volunteers (18-45 years). Similar results were obtained for those aged 65 years and above. AUC was predicted to be 11% higher in a subject aged 90 years of age [660]. A pooled analysis examining the short term efficacy and longer term safety of mirabegron from patients >65 and >75 years of age included in the registration trials demonstrated a reduction in mean numbers of incontinence episodes and micturitions/24 h from baseline to final visit in patients aged ≥65 and ≥75 years. The drug was well tolerated: in both age groups. Hypertension and urinary tract infection were among the most common TEAEs over 12 weeks and 1 year. As might be expected, the incidence of dry mouth, a typical anticholinergic TEAE, was up to sixfold higher among the older patients randomised to tolterodine

than any dose of mirabegron [470]. A recent non randomised, open label study examining the effectiveness and safety of solifenacin (10mg) and mirabegron (50mg) in combination versus the single drugs over 6 weeks in 143 women and 95 men over 65 (average age: 71.2) reported a statistically significant additional effect of dual therapy versus monotherapy in terms of a reduction in incontinence episodes [631]. In an open label single centre study involving 60 patients with a mean age of 72.3 years (50-86 years) using urodynamic variables and the overactive bladder symptom score to assess efficacy. Mirabegron, 50 mg once daily over 12 weeks was associated with a reduction in mean OAB symptom score (9.4 to 6.2 points (P <.001)), a statistically significant increase in volume at first desire to void and maximum cystometric capacity and an absence in detrusor overactivity in 14 of 35 patients compared with that at baseline (P <.01). There was no change in observed voiding function variables. There was neither age stratified reporting of results nor any indication of the frailty status of older persons in this study [661].

11. oestrogen

There have been no additional studies of oestrogen in older women. Oral oestriol 3 mg/day has been compared to placebo for 12 weeks in 34 women aged 75 [131]. The group was highly self-selected; complete results were available for 11 with SUI, 12 with urgency UI, and 8 with mixed. Two-thirds of urgency UI and 75% of mixed UI patients reported improvement; there was no effect on SUI. Four patients reported metrorrhagia and mastodynia. A 10 week crossover trial comparing quinoestradol 0.25 mg four times a day compared with placebo in 18 women in long-term care (type of UI not reported) found a mean 12% decrease in UI episodes vs 22% increase with placebo [662]. The combination of conjugated oestrogen 0.625 mg/day and progesterone 2.5 mg/day was evaluated in a 6 month, placebo- controlled trial in 32 female NH residents with pre- dominantly urgency UI, who also received prompted voiding as a behavioural intervention [663]. In the 21 women who finished the trial, there was no difference in wet checks between drug and placebo despite increased serum oestrogen levels and partial oestrogen effect on vaginal cytology and pH in the women on drug. Two women on the drug developed vaginal spotting, and 10% developed breast tenderness. A similar lack of efficacy despite vaginal changes was found in a case series of 9 frail women (mean age 83) with urgency or mixed UI using an oestrogen-implanted vaginal ring (Estring ®) [664].

12. Miscellaneous medications

Readers interested in agents which are seldom used in clinical practice should refer to the 4th International Consultation on Incontinence for data relevant to frail older people for information on:

Emepronium bromide, Flavoxate Propantheline, Imipramine, Flurbiprofen, Procaine haematoporphyrin.

13. Comparative trials

We found no studies that compared antimuscarinic agents in frail older persons. Other comparative studies in community dwelling elderly, where relevant, are mentioned above.

Pharmacological therapy in cognitively impaired persons

The Committee felt that the treatment of older persons with a dementia diagnosis was an important area to consider, particularly where patients are both physically and cognitively frail, cognitively impaired or at risk of cognitive impairment. This section considers drug treatment in those with a dementia diagnosis. Some of the evidence introduced above is recapitulated here.

There is a dearth of systematically collected data upon which to base any firm recommendation for the drug management of incontinence in persons with a dementia diagnosis. There are data from nursing home residents [50, 480, 582, 593, 594], some of whom would have a dementia diagnosis, most likely in increasing proportions in the newer studies, but there are no reports which stratify results by the presence or absence of this diagnosis. Ouslander *et al*, in 1995, reported that the addition of oxybutynin to a prompted voiding programme conferred no additional benefit to the treatment of incontinence in nursing home residents, there was no reduction in overall labour involved in continence care but there was a statistically significant difference, in favour of oxybutynin over placebo, in the proportion of residents achieving their continence criterion of one or fewer incontinent episode per day [594]. The dementias, and Alzheimer's disease in particular, are characterised by a central cholinergic deficit. The loss of cholinergic function in the central nervous system contributes significantly to the cognitive decline associated with advanced age and Alzheimer's dementia [665]. The administration of anticholinergic agents to cognitively intact individuals can lead to similar changes in cognition to those seen in persons with dementia [666]. Likewise, there are epidemiological data linking exposure to anticholinergic agents to cognitive impairment and an increase in incident diagnosis of dementia over the longer term [66, 67, 460, 667-669]. There are though conflicting data on the cognitive effects of anticholinergic agents in those with established Alzheimer's disease, no effect reported over eighteen months in a single study, and in a small case series, adverse effects in some cognitive domains associated with medications for continence which reversed on cessation of the drug [68, 670].

1. Bladder antimuscarinics and cognition

In general, the rates of Central Nervous System side effects reported in clinical trials of bladder antimuscarinics are low, and reports from clinical practice also suggest that they are rare [580, 671]. However, there have been case reports of associated acute cognitive impairment in both cognitively impaired and cognitively intact patients, these effects have been reversible on cessation of the antimuscarinic agent [605,

619, 621, 672]. The specific effects of bladder antimuscarinics on cognition have been assessed in short term, small to medium sized studies in cognitively intact older people and one in those with mild cognitive impairment, but never in those with pre-existing dementia. Trials have used either oxybutynin, diphenhydramine or alprazolam as an active control. Outcome measures have largely been based upon a battery of computer assisted cognitive tests, with the exception of a single study using simulated driving ability [673] and a study using alterations in encephalographic activity as a surrogate measure [674]. The specific trials are mentioned above.

There have also been studies assessing the effects of antimuscarinics on sleep quality, showing an adverse effect of oxybutynin on sleep, with no discernible effect compared to placebo in young, healthy volunteers [675]. In those over the age of 50 years of age, a reduction in sleep quality was found with oxybutynin and tolterodine, reported as clinically insignificant, compared to placebo. No alteration versus placebo was found for trospium chloride[676]. When tolterodine metaboliser state was taken into account, intermediate and poor metabolisers had a significant reduction in REM sleep [677].

2. Bladder antimuscarinics and delirium

A cohort study in 147 hospitalised older patients which examined the association of anticholinergics and delirium found no increased likelihood of developing delirium in those with either possible (OR 0.33 (95%CI0.1 – 1.03)) or definite anticholinergic medications (OR 0.43 (95% CI = 0.11-1.63)) [678]. There is a single case report of delirium related to solifenacin treatment which resolved following a switch to darifenacin [679] and 2 reports of hallucinations associated with tolterodine treatment, both in cognitively intact patients [619, 680]. These events seem rare given the frequency of use of these medications but do reflect that they should be used with care, particularly in those who might be considered cognitively at risk. As a class, drugs with anticholinergic properties can precipitate delirium in older people, particularly when the anticholinergic load is changed [681].

3. Cholinesterase inhibitors and bladder antimuscarinics

There is evidence cholinesterase inhibitors can cause or worsen UI from a case report and a case series of 216 consecutive patients with probable Alzheimer's disease attending a memory treatment centre [474, 475]. In the latter, CEI treatment was overall associated with 7% risk of new UI: the highest risk was observed in patients with more behaviour problems, and lower risk in patients who demonstrated positive cognitive and/or behavioural response to CEI. Further evidence for an interaction between antimuscarinics and CEIs comes from a database study of nursing home residents in one US state [477]. Residents with dementia, newly treated with cholinesterase inhibitors, were more likely to then be prescribed a bladder antimuscarinic than those residents with dementia not given a cholinesterase inhibitor, an example of a geriatric "prescribing cascade" [682]. Concomitant use of antimuscarinics (extended release oxybutynin and tolterodine) and cholinesterase inhibitors in nursing home residents was associated with a decline in ADL function in the most functionally able residents but there was no worsening of cognition, probably because the cognitive measure (MDS-COG) was inadequately sensitive. More importantly, there were no cases of delirium observed [480]. A recent study in which the primary objective was to assess the cognitive impact of trospium chloride in older people with dementia treated with galantamine over a six month period hypothesised that galantamine in combination would not result in any adverse outcome. Forty six subjects with UI and dementia were enrolled, 10 withdrew from the study. No effect on cognition or activities of daily living was detected over the duration of the study. A within group analysis demonstrated an improvement in nocturia and reduction in pad use in this combination group [481]. A small study reported some positive effect of the treatment of UI with propiverine in subjects with probable AD taking cholinesterase inhibitors [482]. Although intuitively illogical, given the opposing pharmacological actions, there seems to be no reason not to use bladder antimuscarinics for older people with dementia. The current weight of evidence appears to be that a positive outcome in terms of bladder control can be achieved without a significant detriment in either cognition of activities of daily living.

4. Non - antimuscarinic agents

Although there are 12 – week efficacy and 1 year's safety data on the newer beta-3 agonist mirabegron in older persons from a pooled analysis of registration trials [683], there are no data on frail older persons or those with a dementia diagnosis. However, given the lack of data on functional beta—3 receptors in the human CNS an effect on cognitive dysfunction may be unlikely. There are large observational studies of mirabegron use which are designed to capture cognitive adverse events in progress.

A global assessment of the cognitive and "at risk" status of the patient should be undertaken. Unfortunately, the MMSE and ADAS-Cog seem to be insensitive to change in cognitive impairment due to bladder antimuscarinics [454, 480]. Patients that might be at risk of impaired cognition have been well described [684] and consist of those with mild cognitive impairment, long-standing type II diabetes, poorly controlled hypertension, alcohol misuse, dementia, Parkinson's disease and the other akinetic-rigid syndromes. Those with Parkinson's disease may be exquisitely sensitive to the cognitive adverse effects of antimuscarinics [685]. These individuals will need to be carefully assessed, both prior to, and shortly after, initiation of treatment with bladder antimuscarinics. Treatment may necessarily depend upon a global assessment of cognition during the clinical assessment and, if possible, a carer's impression of change. In addition

to the of likely benefit from drug treatment, considering the life expectancy and wishes of the patient, account should be taken of total anticholinergic load, as this clearly increases the likelihood of cognitive impairment. There is evidence of the short term cognitive safety of bladder antimuscarinics, with the exception of immediate release oxybutynin, for the most part in cognitively intact older adults, and therefore, prescribing bladder antimuscarinics as single agents is, on the whole, probably safe.

Those studies using high doses (20mg) of oxybutynin are associated with an increased likelihood of causing cognitive impairment, which may not be apparent to either the patient or the clinician. This drug should probably be avoided in the elderly at high dose, and in those at cognitive risk, in any case. The other antimuscarinics should be initiated carefully, at the lowest dose for tolerability, with dose increases where indicated for efficacy, and reviewed early.

The length of exposure to anticholinergics seems to be important, studies suggest a lack of decline in those with established dementia [68, 686] but with exposures of at least two years, there is a reported increase in mortality [66, 460]. To what extent this is explained by case mix, comorbidity or other factors is not known and will be the subject of further research. Consideration should be given to limiting the overall exposure of antimuscarinics, particularly if in combination with other drugs with anticholinergic properties.

The recent introduction of mirabegron offers an alternative mechanism for treating OAB with similar efficacy, and theoretically, little chance of cognitive impairment, although mirabegron is a weak inhibitor of the permeability glycoprotein system at high concentrations; this mechanism is responsible for active transport of drugs from the central nervous system. Beta-3-adrenoreceptor mRNA has been isolated from human brain [687] but there are no studies which locate the functional receptor and no studies on cognitive effects of the active drug.

Summary of the evidence

1. Short-term treatment with oxybutynin-IR has small to moderate efficacy in reducing urinary frequency and urgency UI when added to behavioural therapy in long term care residents. **(Level 2)**
2. Low dose oxybutynin-ER does not cause delirium in cognitively impaired nursing home residents **(Level 1)**
3. Oxybutynin-IR has been associated with cognitive adverse effects in persons with dementia and/or Parkinson's disease **(Level 3)**, although the incidence and prevalence are unknown **(Level 4)**
4. Oxybutynin has been associated with tachycardia **(Level 3)**, but not associated with QTc prolongation **(Level 3)** or ventricular arrhythmia **(Level 2)**
5. Oxybutynin is less effective in persons with impaired orientation, cerebral cortical under-perfusion, and reduced bladder sensation **(Level 2)**
6. Oxybutynin is less well tolerated, versus solifenacin, in older people **(level 2)**
7. Fesoterodine is effective in ameliorating the symptoms of OAB in robust community dwelling and medically complex older people, identified by VES-13 **(level 1).**

There is insufficient evidence to determine the efficacy, tolerability, and safety of the following agents in the frail elderly **(Level 4)**:

a) Intravesical oxybutynin

b) Transdermal oxybutynin

c) Trospium

d) Tolterodine

e) Darifenacin

f) Solifenacin

g) Mirabegron

h) Duloxetine

i) Oral and topical oestrogen

8. Tolterodine has been associated with cognitive impairment and tachycardia (Level 3), although the incidence and prevalence are unknown. (Level 4)
9. Solifenacin (5mg/day) is associated with no impairment of cognition in older persons with mild cognitive impairment versus placebo (level 2)
10. Excessive anticholinergic load is associated with cognitive impairment in frail older adults (level 3)
11. Anticholinerigc agents should be prescribed with due regard to underlying anticholinergic load in older persons (level 3)
12. The effect of cholinergic load on persons with mild dementia is uncertain (level 3)

12. SURGICAL TREATMENT IN THE FRAIL OLDER PERSON

12.1. Background

Since the 5th ICI we found for this updated chapter additional trials and 5 review articles on surgical intervention published since January 2012. In providing an evidence-based summary on this topic, we have taken advantage of a professional literature review done and additional literature found through citations found within the search. We revisited the available data and general issues regarding perioperative care

which could improve surgical outcomes in frail elderly.

Despite ongoing reports concerning the aetiology and pathophysiology of UI in older people, information on surgical management of the frail elderly is still scarce [688, 689]. Nevertheless, currently, surgical management of stress incontinence (SUI) in elderly women is the same as in younger stress-incontinent patients [690, 691][567, 568] and also in men choice of surgical intervention, mostly due to urinary incontinence after radical prostatectomy is rather dependent on incontinence severity than on age or comorbidity. However, the outcomes of anti-incontinence surgery in frail elderly patients may be very well affected by inherent co-morbidities, as well as impaired bladder and pelvic floor function. Frailty is a biological syndrome of decreased reserve and resistance to stressors that increases with age. Especially age greater than 80 years, is associated with increased complications.

12.2. Incontinence surgery in frail older women

Surgical intervention is the most effective and durable approach for the treatment of SUI. Especially the minimally invasive nature of the midurethral sling procedures has increased the number of older women, who are considered as surgical candidates for anti-incontinence procedures. Multiple retrospective and prospective cohorts have reported on favourable outcomes of older women undergoing these procedures In a large secondary analysis of the National Health and Nutrition Examination study Ellington et al. state that risk of perioperative complications are noted to be higher in women aged 80 years or older compared with the younger woman (odds ratio [OR], 1.4; 95% CI, 1.3–1.5) [692].

Many single institution cases series have reported excellent surgical results with well-selected octogenarians and nonagenarians undergoing surgeries for incontinence and other pelvic floor disorders [693]. These patients have been demonstrated to do well with antiincontinence surgery and have significant gains in QOL. However, major gaps in our knowledge exist about which surgical treatments will benefit individual women who may not have been represented in clinical trials because of age, multiple comorbidities, functional disability, or cognitive impairment [692]. It also should be kept in mind that older women are more likely to undergo surgical retreatment for SUI compared to younger women. Research to identify which treatments for UI are most appropriate in real-world settings for different older women is needed.

We identified nine studies dealing with colposuspension and 83 studies investigating different techniques of sling surgeries or other types of surgical procedures using vaginal tapes published after 2012. All studies were targeted at middle aged women and although some studies included older women, results were not stratified by age. Long term outcome evaluation of a subgroup of patients enrolled in the SISTEr study (Design of the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr) only confirmed that age was one of the preoperative baseline factors which were individually associated with recurrent incontinence in a follow-up of up to seven years following incontinence surgery [694].

A wide variety of surgical techniques have been described, among which the mid-urethral sling procedures have gained worldwide popularity. In a large survey with 15,009 patients from the National Health Insurance (NHI) claims dataset in Taiwan the authors compared the surgical trends for female stress urinary incontinence (SUI) during the time frame of 2006–2010 with the timeframe of 1997–2005. Midurethral sling (MUS) application increased significantly from 53.09 % in 2006 to 78.74 % in 2010. This study further confirmed that patients' age is one of the factors that the appropriate surgical type selection should take into account. They also noted that during the course of time more primary SUI surgeries were carried out in patients aged ≥60. The authors suggest that higher incidence of mixed urinary incontinence and pure urgency urinary incontinence in older age groups could be a factor in the decision on the choices of surgical type – but more research is needed to clarify if and with which procedure especially frail elderly benefit and which surgical options to choose for this age group especially in those with mixed urinary incontinence [695].

Several studies have used U.S. national hospital discharge databases to examine surgical rates, but unfortunately they either age-adjusted results [696] or used relatively young cut-off points (e.g., </> 50 years) [697]. Even in series that do specifically look at elderly women (mean age 78, range 68-90), most patients are cognitively intact (95%) [698]. Cognitive impairment appears to bias against having surgery: in one study, only 0.11% of operations for UI were done in women with dementia, cerebrovascular disease, or hemiplegia combined. Despite the fact that absolute numbers of ambulatory UI surgery cases in women increased from 1994-1996, the percent done in those aged > 80 years remained the same (4-5%) [699], with the same proportions for pelvic organ prolapse surgery (5%) [700]. In the US, surgery rates in elderly women vary by region and race [701].

One single-centre, community-based series of 54 patients aged 70 years and above provides a picture of this surgical population. Twenty-eight per- cent of patients were aged > 80, four resided in a nursing home or assisted living facility, 82% had significant comorbidities, and 32% were classified as American Society of Anaesthesiology class III risk. Intra-operative complications occurred in 11% of patients; postoperatively, 11% required intensive care monitoring, 6% had serious complications, 7% became delirious, and 9% experienced a slow return of bowel function. The authors concluded that discharge planning was especially important for these patients, and recommended pre-surgical planning with regard to discharge destination and likely need for assistance [702].

Although higher complication rates generally reflect the comorbidity common in frail elders (10.4% complication rate with comorbidity vs. 5.8% without it, p<.001) [699], some studies have found age protective (in one, age >73 years is associated with lower risk of vaginal cuff infection and recurrent prolapse following vaginal sacrospinous fixation [703]. The morbidity and mortality for geriatric patients undergoing anti-UI procedures appear to be similar to those of other major non-cardiac surgical procedures [704]. Mortality is inconsistently associated with increased age, and most strongly related to cardiac or cancer complications [705]. Many studies do not uniformly control for the impact of comorbidity on mortality [705]. Pre-operative administration of oestrogen appears ineffective in promoting wound healing [706]. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard administration of medications in cognitively intact geriatric patients [706]. Choice of anaesthetic agent may affect postoperative cognition and urinary retention. The use of methyl naltrexone to treat opioid-related urinary retention or constipation may become an important adjunct to surgical care in frailer patients [707]. There are few age specific data on outcomes available, and no studies systematically examine quality of life, functional outcome, or discharge destination.

With the advent of newer "minimally invasive" procedures, there has come some modicum of use in older, albeit, not frail patients. Injection of bulking agents in women appears to be as little effective in younger women as in elderly patients and age does not appear to relate to outcomes [704]. There are several published reports examining outcomes of tension-free vaginal tape (TVT) in the elderly population. However, most of these studies are limited by short term follow-up, small patient groups and confounding variables [708-710]. Hellberg et al. showed that at three months, women ≥ 75 years old had a cure rate of 81.6% compared with a rate of 92.8% in women <75 years old. At later follow-up, regardless of duration since the TVT procedure, the proportion of women with cure for 'any' incontinence decreased with increasing age. Very obese women ≥ 75 years old had a cure rate of 55.7%, compared with 79.9% in women < 60 years old (p= 0.0001) [711]. In one single institutional study, authors showed no significant difference in cure rate (85% vs. 91.3%, respectively). However, follow-up was only 10.4 months [712]. In a randomised controlled trial of tension-free vaginal tape (TVT) versus 6-month wait-list control, the intervention group at 6 months had a statistically significantly greater improvement in mean I-QOL score, patient satisfaction score, and urinary problem score [713]. There was no objective measure of cure. Perioperative complications were common, with bladder perforation by needle in one-in-five women (22.6%) which required 24 hours of in- dwelling catheterisation; urinary retention (12.9%), and less than 5% with either a urinary tract infection or new urinary urgency (3.2%). In an uncontrolled case series examining the use of the suprapubic arch (SPARC) sling procedure, the outcomes in 43 older women (ages 65-91) were separately examined. Objective cure rate was evaluated by clinical and urodynamic examination and subjective cure rate by using a visual analogue score. At a mean follow-up of 36 months (range, 12 - 54 months), objective and subjective cure rates in 997 women were 91% and 95%, respectively [714]. There was statistically significantly improvement in pad weight, pad use and on the visual analogue score. No severe intra- or postoperative complications were observed, and no patient developed *de novo* urgency UI. In a case series, long-term clinical outcomes following placement of a retropubic mid-urethral sling (SPARC) in patients aged 70 and over were compared with outcomes of a younger cohort. Overall success rate after a follow-up of 4 years was 83.2% in the younger group and 53.1% in the group of older patients (p= 0.0003) [715]. In a comparative prospective single-centre study examining safety and efficacy of TVT-O in elderly versus younger stress-incontinent women, after mean follow-up of 30±17 months, early and late postoperative morbidity was similar in both groups, except for significantly more cases of postoperative recurrent UTI's among the elderly women (13.7% vs. 6.2%). The incidence of persistent urodynamically confirmed overt SUI was similar in both age groups (5%). However, asymptomatic urodynamic SUI was significantly more common among elderly patients (19% vs. 3.7%, P<0.05). The incidence of persistent OAB was similar in both groups (68% and 62%, respectively), while de novo OAB was significantly more common in elderly patients (11.9% vs. 4.7%, P<0.05) [716].

12.3. Incontinence surgery in frail older men

Since 2012, three studies have examined the effect of sling surgery in men [717-719] and one at the outcome following implantation of an artificial sphincter [720]. Bates et al. [721] conducted a systematic review and meta-analysis of artificial urinary sphincter (AUS) placement after radical prostatectomy (RP) and external beam radiotherapy (EBRT) including 1886 men with mean (SD) age of 66.9 (1.4). They concluded that additional external beam radiation created a risk of infection, erosion and urethral atrophy, resulting in a greater risk of surgical revision and also a higher risk of persistent urinary incontinence compared with RP alone.

But as noted in the 5th ICI, no specific conclusions can be drawn regarding surgical treatment of UI in frail men. Typical studies of anti-UI surgery in elderly men are very small or fail to stratify results by age and/or comorbidity [722, 723]. One small study (n=46) found that advanced age was not a risk factor for poor outcome after collagen injection for post-prostatectomy UI [724], while another (n=12, mean age 80 years) of trans-urethral resection prostatectomy (TURP) for obstruction-associated urgency UI concluded that cognitively impaired men demonstrated the greatest UI improvement [725]. In a single-institution case series

of men aged > 80 years old undergoing TURP (68% of whom had urinary retention), 80% were satisfied with their outcome. Of the men with retention, 80% were able to void with a small PVR by six weeks. Complication rates were 41% (early) and 22% (late) [726]. Urodynamic evaluation of post-prostatectomy UI was recommended prior to surgical treatment, such as implantation of an artificial sphincter [723].

12.4. Surgery for idiopathic or neurogenic detrusor overactivity

Since the 5th ICI, we located 9 new studies about dose finding, treatment of idiopathic and neurogenic DO evaluating safety, efficacy and improvement of quality of live using intradetrusor injection of onabotulinumtoxinA second line therapy. However, although some larger studies included elderly patients only one paper looked specifically at the frail elderly [727]. The authors concluded that safety and efficacy were similar between elderly patients without frailty and younger patients. However, an increased risk of finding a large post-void residual urine volume and a lower long-term success rate in frail elderly patients were noted.

12.5. General issues in the surgical care of frail older persons.

Frailty is becoming increasingly recognised as an important prognostic factor in surgical outcomes. However measured, the presence of frailty is associated with an increased likelihood of surgical complications, increased lengths of hospital stay and a greater probability of requiring an increased level of care following hospital discharge [728-730]. Important factors in the surgical care of frail patients include: preoperative risk stratification (e.g., American Society of Anaesthesiology class, Charlson index, Modified Cardiac Risk Index, Burden of Illness Score [731]; ensuring adequate nutrition, especially when patients cannot take oral feeding or become delirious; proactive management of comorbid heart disease, diabetes, and pulmonary disease; prevention [732, 733], recognition [734], and treatment of postoperative delirium [735]; adequate pain assessment and treatment, especially in cognitively impaired persons [736]; recognition of the hazards of prolonged bed rest [737] and the prevention [738] and treatment of functional impairment; use of specialised care units for the elderly [739]; and discharge planning regarding rehabilitation, need for assistance, and site of discharge. All need to be actively considered and dealt with in any plan of surgical care of frail elderly patients. Although some single institution case series have reported excellent surgical results with well-selected octogenarians and nonagenarians undergoing surgery for incontinence and other pelvic floor disorders these findings should be treated with caution because they tend to describe the results from surgery in robust, carefully selected patients undergoing procedures at specialised centres. To what extent these results are generalisable is unclear; the true risk of surgery in frail older patients is likely higher than in these reports.

Attention to cognitive and functional outcomes as well as quality of life are also important to consider in this population.

Summary of the evidence

1. No studies were identified regarding gynaecological surgery in institutionalised elderly women. (**Level 4**)
2. Exogenous administration of oestrogen is ineffective in promoting wound healing after gynaecological surgery in older women. (**Level 3**)
3. Injection of bulking agents for SUI appears to give minor benefit in women, however the technique is minimally invasive and age does not appear to correlate with outcomes. (**Level 3**)
4. Injection of onabotulinumtoxinA might be an option als in patients with idiopathic or neurogenic overactive bladder although risk of residual urine and a lower long-term success rate have been described. (**Level 3**)
5. No studies were identified that evaluate functional or quality of life outcomes after UI surgery in frail older persons (**Level 4**)
6. Risks of morbidity and mortality for frail patients undergoing anti-UI procedures are similar to those of other major non-cardiac surgical procedures. (**Level 2**)
7. Surgical mortality risks are still low in elderly persons, and when deaths do occur, they are often due to cardiac or cancer complications. (**Level 2-3**)
8. Operative mortality is inconsistently associated with increased age, and most studies do not uniformly control for comorbid conditions (**Level 2-3**)
9. Patient-controlled analgesia provides adequate pain control and sedation and increased patient satisfaction compared with standard fixed and time-administered medications in cognitively intact geriatric patients. (**Level 2**)
10. Choice of agent for patient-controlled analgesia may affect postoperative cognition. (**Level 3**)
11. Some case series and waitlist-controlled trials suggest that minimally invasive surgical approaches may be useful in older adults, yet these trials may have little to do with whether surgical treatments are appropriate in the frail elderly (**Level 3**)

Recommendations for management

1. Age alone is not a contraindication to surgical treatment of UI (**Grade C**).
2. Urodynamic evaluation should be done before considering surgical treatment of UI in frail older persons (**Grade B**).

3. Preoperative risk should be stratified using established indices (**Grade A**).
4. Validated frailty scales may aid prognostication and planning from post surgical care in frail older adults (**Grade C**)
5. Ensure adequate post-operative nutrition, especially in patients who cannot take oral feeding or who become delirious (**Grade C**).
6. Programmes to prevent post-operative delirium should be utilised (**Grade A**) along with proactive use of established measures to diagnose delirium (**Grade A**).
7. Pain assessment in cognitively impaired persons should use measures specially-designed for this population (**Grade B**).
8. Proactive preventative approaches to hospitalisation-related functional impairment should be used (**Grade A**).
9. Specialised care units may improve selective outcomes for frail older patients (**Grade A**).
10. Discharge planning should begin before surgery takes place (**Grade C**).
11. Patient controlled analgesia can be used in cognitively-intact frail older persons (**Grade B**).
12. Analgesic agents associated with delirium (e.g., meperidine) should be avoided (**Grade B**).
13. Long-term outcomes before the operation should be discussed with the patient (**Grade C**).

Recommendations for research

Further research is required to:

1. identify risk factors for surgical outcome in frail elderly.
2. identify which treatments for UI are most appropriate in real-world settings for different older men and women.
3. define pre- and postsurgical care to improve surgical outcome in frail elderly.

III.NOCTURIA

1.1. Background

Nocturia is defined as waking at night from sleep one or more times to void, with each void being preceded and followed by sleep [740]. Overall, nocturia is a highly prevalent and bothersome symptom [741]. While a single episode of awakening to urinate would be considered nocturia, patients are more likely to be experience significant bother and have decreased quality of life [742], or consult a provider about nocturia if they have three or more episodes [743]. Many clinical trials include only participants with two or more episodes [744]. Additionally, if only a void interrupting sleep and preceding sleep counts, the annoying situation of waking to void and not being able to return to sleep again would not be nocturia, but would still be disruptive [745]. This definition does not take into account the wide range of sleep patterns of older adults. Since some older adults will spend six hours sleeping while others might spend twelve hours in bed, having three episodes of nocturia would be very different for these individuals [746].

Several detailed reviews on nocturia [747, 748] and two convened consensus conferences reports [744, 749] have helped summarise and update the current knowledge regarding nocturia. Even with these sources, the prevalence, impact, pathophysiology, diagnostic assessment, and treatment of nocturia differ meaningfully with respect to the older adult and the frail elderly [746] and merit a targeted discussion. As is the case with urinary incontinence, nocturia often results from the reduced physiological reserve of multiple systems. Nocturia is associated with increased all-cause mortality and mortality in those falling if they had nocturia (While nocturia has been associated with increased mortality (15-year survival rates of 76.5 and 84.8 percent for individuals with and without nocturia, respectively), this association may be attenuated when adjusting via multivariate analysis (for factors such as hypertension, diabetes, chronic pulmonary disease, cardiac symptoms, smoking, and age) (but perhaps not when adjusted for sleep dysfunction)[750-753]. Older men with nocturia and low body mass may be at increased risk of death [754]. Because of this fact, diagnostic assessment must be detailed and comprehensive, and multi-component interventions may be necessary for successful treatment.

1.2. Quality of the data

There are multiple, quality sources of epidemiological data across a broad range of countries and cultures regarding the prevalence of nocturia and associated risk factors. There is a smaller, but growing, body of evidence regarding the incidence and impact of nocturia. In particular, studies of the pathophysiology of nocturia in the elderly have generally been small and disease-focused, examining a single, potential underlying cause of nocturia. As with UI, there are limited data on optimal diagnostic assessment, and therefore recommendations are generally based on expert opinion [755, 756]. The evidence base regarding treatment, particularly with respect to the frail older person, is somewhat thin. While there are some treatment RCTs, they are small, include few very elderly subjects. The treatment literature regarding vasopressin and its analogues is robust, yet use of the therapy in the older patient continues to be limited because of the side effect of hyponatraemia. We located only limited randomised controlled trial pilot data on the effectiveness of multi-component interventions for nocturia in the elderly [757].

1.3. Prevalence, incidence and impact

The prevalence of nocturia increases with age, and has been reported to be as high as 90% for one episode per night in persons over age 80 [758-763]. The prevalence of two or more episodes among men between 70 and 79 is nearly 50 percent [763, 764]. This increasing prevalence is largely due to age-related conditions that underlie the pathophysiology of nocturia, such as smaller maximum voided volume and increased nocturnal polyuria [765]. (see below). With respect to sex, nocturia in young adults is more common for women than men, but this sex ratio reverses after age 60 when more men have nocturia [764]. For those over 75 years of age, the prevalence of nocturia of at least two or more times is much more common in men (70%) than in women (50%) [766]. It is still a burdensome condition for both sexes in women as well as men, and in a cross-sectional study of over 2000 women aged 40 or older, 40 percent of women who had nocturia had no other urinary tract symptoms [763, 767].

Whilst increased age is associated with more nocturia, what happens to nocturia as an individual ages, is a slightly different question. Nocturia is more prevalent in older populations, yet the concept of incidence of nocturia is difficult as the condition both "begins" and "resolves" over time and varies due to imprecision of self-reporting and estimates as to the frequency over a past period. In one recent study, participants recorded their urination frequency and voided volumes. Over a 2-year period, the incidence rate of nocturia of an average of two or more times per night was 23.9% and the resolution rate was 36.7%. For the oldest adults participating (70-78 years), they had the highest nocturia incidence (47.1%) and the lowest resolution rate (26.2%) compared to their younger counterparts [768]. In an additional study, men receiving placebo as part of a randomized trial for treatment of BPH, nocturia regression varied between 2 and 33 percent, while nocturia progression varied between 8 and 54 percent [769].

Recent data have also highlighted that the prevalence of nocturia in older adults differs by racial group. Multiple population-based epidemiological studies have shown a higher prevalence of nocturia in older men and women who are African-American when compared to whites [763, 770, 771]. While controlling for socioeconomic factors eliminated the differences in prevalence between non-Hispanic whites and Hispanics, differences persisted, although somewhat attenuated, between blacks and whites [772, 773].

Nocturia is also associated with chronic medical conditions such as hypertension [774, 775] (including night time hypertension and absence of night time blood pressure dipping) advancing renal insufficiency [776-778] and cardiovascular disease [779, 780]. Nocturia has been shown to be associated with diabetes mellitus, [774, 775] but nocturia and the metabolic syndrome are associated in younger, but not older, men [781]. Clinically, nocturia may be the herald symptom of significant underlying medical conditions and problems, which, if overlooked, might result in significant morbidity and even mortality [744]. Therefore, an older patient presenting with bothersome nocturia should be evaluated not only for the causes of nocturia, but also for unrecognised comorbidity, including cardiovascular disease, sleep apnoea, restless leg syndrome, moderate alcohol usage, poor nocturnal glycaemic control, and conditions causing night time pain [744].

Nocturia is associated with other important conditions. Nocturia has been shown to be associated with accidental falls [257, 265]. Frail elderly persons with nocturia, who also have gait and balance disorders and other risk factors for falls, are clearly at increased risk for falls [256, 782], injury and hip fracture [783], and consequent morbidity [254, 753]. Despite these facts, no nocturia treatment trials to date have evaluated any impact on fall reduction. Nocturia also has adverse effects on quality of life [784], including an increased risk of depression and poor self-rated health, probably as the result of the impact on sleep. [785]. Adults with nocturia also complain that nocturia "makes them feel old" and they worry about falling at night [786]. Older individuals described nocturia as simultaneously debilitating, frustrating, distressing and puzzling [787].

To better appreciate the deleterious effects of nocturia, it is important to understand the important associations between nocturia and disrupted sleep [744, 788-790]. When a group of 1,424 elderly individuals, ages 55–84 were presented with a checklist of symptoms that potentially disrupt sleep, nocturia was chosen by 53% of the sample as a self-perceived cause of "every night or almost every night". Nocturia was cited four times as frequently as pain, which was the next most identified cause of sleep disruption [791], and cited as a frequent reason for insomnia in patients with congestive heart failure [745, 792]. There is growing evidence to suggest that bother from nocturia is related to the number of trips to the bathroom, but also with the difficulty experienced in trying to return to sleep [745, 788, 793, 794]. In particular, those with nocturia who report difficulty in going back to sleep, the prevalence of falls is higher [793]. Nocturia has been shown to be significantly associated with worse scores on sleep questionnaires, and a shorter time to first nocturia void is also associated with worse whole-night sleep [789, 795]. While the relationship between nocturia and sleep disruption might appear to be self-evident, other lower urinary tract symptoms are also highly correlated with sleep disturbances [796].

There has been recent and meaningful development in understanding the impact of nocturia on quality of life, particularly showing that nocturia is related to depression and anxiety [797]. A condition-specific instrument commonly used for assessing the impact of nocturia is the ICIQ-NQOL [798], which was developed using a pool of only men (average age 68.2, age

range 32-88) recruited from urology practices. Given the absence of women and the likely predominance of men with benign prostatic enlargement as informants, there remains a chance that the instrument does not broadly represent the experiences of all individuals who have nocturia. Other focus groups and one-on-one interviews performed independently with a broader representation of both men and women did demonstrate similar themes, suggesting content validity [786]. Two missing themes, however, were that nocturia was an "indication of getting older" and made them fearful of falling. Use of the Nocturia Nocturnal Enuresis and Sleep-interruption Questionnaire, which was specifically developed in older men and older women (60-80), showed a greater impact of nocturia in the younger elderly and a greater bother among women compared to men.[663] Use of the generic quality of life instrument, the 15-D, demonstrated statistically significant and clinically meaningful decreases in 15D score and in all 15D dimensions except eating with increasing nocturia [742]. In this study, older women were less bothered by nocturia than were younger women; older and younger men were equally bothered [742]. In several case series, nocturia was most often identified as the chief complaint related to the lower urinary tract [799] and the least responsive to treatment, particularly in the older patients [799, 800].

Several recent studies have shown strong associations between nocturia and Parkinsonss disease (PD), including a negative impact on quality of life, depression, anxiety and severity of disease [801-804]. Nocturia is a frequent, early non-motor symptom in PD that is bothersome, and a common cause of sleep disruption [805, 806]. Nocturia in PD is associated with increasing age of the patient, but also with the increasing severity of PD [807]. Age of onset of PD, in addition to age, may be associated with worse nocturia [808]. Patients with PD have more nocturia episodes than their spouses, and number of nocturia episodes may be related to nighttime and total levodopa dosages [809]. While it might be difficulty to clinically separate idiopathic PD from drug-induced parkinsonism, urinary symptoms including nocturia are much more common in PD even after controlling for age and sex [810]. Additionally, nocturia and other non-motor symptoms often began prior to being diagnosed with PD, and may be a biomarker for the condition [810].

Notable recent work has shown nocturia to be associated with poorly controlled diabetes mellitus, congestive heart failure, worsening renal insufficiency is associated with bad outcomes. Whether, or not, these associated conditions should be statistically controlled for is not clear, as they might represent a part of the causal pathway. The association with mortality when examined across the age spectrum shows a stronger relationship with younger individuals than with older [751]. With careful controlling for comorbidities, this association between mortality and nocturia sometimes remains independently significant [811] and other times does not [752]. Though much of the impact of nocturia is believed to result from its impact on sleep, nocturia remains independently associated with mortality even with controlling for sleep disordered breathing [812].

1.4. Pathophysiology

The pathophysiology of nocturia is multifactorial; this is particularly true for nocturia in frail elderly persons. In age-adjusted analyses from a large survey in Finland, no single factor related to nocturia was present in greater than 50% of those with nocturia [813]. The factors with the greatest impact at the population level were (urinary) urgency, "benign prostatic hyperplasia", and snoring for men, and overweight and obesity, urgency, and snoring for women [765, 813]. Colder ambient weather or internal temperatures may be associated with greater nocturia [814, 815].

A commonly used framework for clinical diagnosis and treatment is that nocturia can be related to one or a combination of three primary underlying causes, all of which increase with age: low bladder capacity usually as a component of OAB, DO, urgency UI, or BOO in men; nocturnal polyuria; and primary sleep disorders [747, 748, 816]. Nocturia was shown in retrospective analysis of 213 cases (mean age 72) who had detrusor overactivity, out of a total of 777 men studied using pre-operative urodynamics to be highly associated with volume at which the first detrusor contraction occurred [817]. Somewhat in contrast, in one prospective case series of 987 ambulatory women aged 55-75 years, a higher post void residual (>200 mL, 100-199 mL, 50-99 mL versus <50 mL) was not associated with reporting more nocturia [818]. While nocturia may be said to result from sleep dysfunction, this relationship is likely bi-directional (with sleep dysfunction also likely resulting from nocturia) [819].

The proportion of 24-hour urine volume produced at night increases with age, even among healthy older adults free of overt comorbid conditions [820, 821]. Studies of frail elderly have shown that the proportion of urine produced at night is close to 50%, rather than less than 30% as in young healthy adults [822-824]. Nocturia is a common symptom in nursing home residents with Parkinson's disease and contributes to worse sleep and worse quality of life [825]. Nocturnal polyuria (NP) is more common in older compared to younger nocturics [683-685], yet the proportion of individuals who have NP is highly sensitive to the definition used [826]. In some elderly persons, this is due to mobilisation of excess volume caused by peripheral oedema, which may be due to venous insufficiency, medications, and/or heart failure. In the case of calcium channel blockers, women younger than 55 years of age, but not older women or men, were shown to have higher rates of nocturia in cross-sectional analyses [827]. In that same study, both hydrocholorothiazide and loop-diuretic usage in men were associated with higher rates of nocturia.

Some studies have suggested that there is an abnormality in the secretion and/or action of arginine vasopressin (AVP) or a loss of the normal diurnal rhythm (with inappropriately low values at night) in many elderly patients with nocturia. [828, 829], which may approach as many as 4% [828]. Another, however, failed to find an association between AVP deficiency (detected by water deprivation testing) and nocturnal polyuria in a series of elderly persons with nocturia [830]. Other research suggests that some frail elderly persons with nocturia have high atrial natriuretic peptide (ANP) levels at night; [831, 832] however, these investigators did not use echocardiography or brain natriuretic peptide levels to detect occult heart failure.

Sleep disordered breathing and sleep apnoea, also have been associated with nocturia and nocturnal UI in the elderly [831, 833-835]. Community-based elderly populations who have higher levels of sleep disordered breathing (>25 breathing events per hour), have nearly double the number of nocturia episodes compared with those with low rates of sleep apnoea [695]. Nocturia is so tightly associated with sleep apnoea that in a population of adult patients presenting to a sleep clinic, it performed similarly as a screening question for OSA when compared to asking about "snoring' [836]; whether this held true for the subset of older patients was not reported. Whether this relates to increased ANP production, [831] mechanical forces on the bladder generated during apnoea events, [834] or other mechanism(s) is unknown.

Nocturia may be a marker or a result of endothelial dysfunction [837], vascular flow disruption, white matter hyper-intensities [838], or inflammation [839].

1.5. Diagnostic assessment

The approach to the assessment of nocturia should be similar to that for UI described above. Special considerations include:

- A frequency-volume chart of at least 24 hours duration that includes timing and volume of each void at night as well as during the day, as well as a specific indication of when the individual went to bed with the intention of going to sleep at night and awoke in the morning. Some patients may find this difficult to perform, [840] but face-to-face explanation of the procedure, a hand-held urinal or a receptacle to place in the toilet to measure volumes, and involvement of caregivers may improve compliance and accuracy.
- Additional questions in the history that focus on the possibility of a primary sleep disorder, such as asking about sleep quality, daytime sleepiness, snoring, and leg movements at night (this history is enhanced by questioning the bed partner).
- Additional history and focused physical examination related to volume overload (e.g.,lower extremity venous insufficiency, congestive heart failure); in some cases, additional testing such as an echocardiogram or a brain natriuretic peptide level may be helpful in ruling out the latter diagnosis.

1.6. Treatment

While many clinical investigations are trials of single agents, experts [746] would argue that treatment of nocturia in elderly patients should be based on a holistic approach informed by identification of multiple potential underlying causes. There is, unfortunately, little high quality evidence for most treatments, and certainly with respect to combined treatments, for nocturia in this age group. As well, cure, or the complete resolution of nocturia, is infrequently achieved in either clinical practice or research.

The most common primary outcome in clinical trials is reduction in nocturia episodes, as measured by voiding diary or self-reported, average nocturia over a given period of time. Some trials have reported the percent of participants who achieving a 33% [698] or 50% [830, 841-845] reduction in nocturia from the baseline level or the percent of individuals having a reduction equal to 1.0 fewer mean nightly episodes of nocturia [841, 843, 844]. There are few treatments that offer robust reductions of nocturia, with most ranging from 0 to 0.8 fewer episodes of nocturia. The net reduction of an intervention, subtracting the benefit seen in the control or placebo arm is often even smaller. Whether this is due to regression to the mean due to random variation in the symptom of nocturia or a result of monitoring and recording night-time voids is unclear. Patient-level outcomes related to general satisfaction questions, nocturia- related bother, and nocturia-specific quality of life are therefore even more meaningful. Most trials examining nocturia as an outcome were performed prior to the validation testing of the ICIQ-NQOL instrument [798]. An additional important target for therapy is reduction in bother due to nocturia. Unfortunately, there have been few meaningful successes in relating the number of nocturia episodes to the hours spent in bed, which may vary considerably in older persons [787].

There are several approaches to drug therapy for elderly patients with nocturia; most of the published guidelines suggest targeting "primary" or "principal" causes of nocturia (e.g., nocturnal polyuria). Because older adults with nocturia have multiple potential causes, treatment often will require combination treatment. While some trials may report statistical significance for reduction in nocturia, the clinical meaningfulness of these changes is suspect [845]. Although no specific data are available on RCTs of multi-component interventions, elderly patients with nocturia may benefit from an approach to treatment [846] that combines behavioural strategies, therapy for medical and sleep disorders, and nocturia-specific drug therapy. In another uncontrolled study, lifestyle modification of 1) restriction of fluid intake, 2) refraining from excess hours in bed, 3) moderate daily exercise and 4) keeping warm in bed resulted in a positive reduction of nocturia from 3.6 episodes per night to

2.7 for 56 participants aged 59-85 (mean age 74.5, 84% male) [847].

1.7. Behavioural approaches and treatment of comorbidity

The use of specific behavioural strategies (e.g. altering fluid intake, reducing sodium intake, leg elevation for oedema) on nocturia in older patients have largely been made based on consensus. Using bedside commodes or urinals, and minimising the distance necessary to reach a toilet and providing a safe, adequately lit path may be helpful in reducing the risk of night-time falls related to nocturia, especially in those with underlying gait instability and other risk factors for falls.

The first secondary data analysis of a RCT which demonstrated that behavioural therapy, with an emphasis on pelvic floor muscle exercises and urgency suppression strategies, showed that nocturia was reduced in women (mean age 68) with urgency- predominant UI [841]. The median reduction of 0.5 episodes per night was significantly more effective than drug treatment with oxybutynin IR titrated from 2.5mg per day to 5.0 mg three times a day, (0.3 episodes) or placebo (no reduction). A second secondary data analysis of an RCT, that did not show benefit with respect to the primary endpoint of urgency incontinence in women (mean age 55), did not show benefit of behavioural therapy when added to tolterodine 4 mg LA for nocturia [848]. An additional RCT in men (mean age 64) examined the impact of the addition of either titrated bladder relaxant therapy (oxybutynin XL 5-30mg) versus behavioural therapy for pelvic floor muscle exercise in whose 24-hour urinary frequency was not resolved with alpha-blocker therapy. In this trial, nocturia was a secondary outcome. In this study, the behavioral group showed greater reductions in nocturia (mean= -0.70 vs. -0.32 episodes/night; P = .05) [849]. There are currently no trials of pelvic floor muscle exercises or urgency suppression strategies where individuals were enrolled on the basis of having nocturia with reduction in nocturia as the primary outcome.

Individuals with refractory nocturia may have undiagnosed symptoms of sleep disorders, and many men [850]and women [851] with nocturia have a positive screening test for sleep dysfunction. Those shown to have nocturia and obstructive sleep apnoea (OSA) should be treated for OSA., which can effectively reduce nocturia in many, and may also reduce hypertension associated with OSA [852].

1.8. Pharmacotherapy

1. Antimuscarinic therapy

Members of a recent nocturia consensus conference agreed on the following statements with regards to overactive bladder and antimuscarinics:

1) most patients with nocturia do not have overactive bladder; 2) most patients with OAB do have nocturia; 3) antimuscarinics are not usually efficacious for nocturia; and 4) antimuscarinics may be effective for nocturnal voids due to urgency [749, 853]. In general, if the history, bladder diary, and physical examination suggest that nocturia is related primarily or in part to OAB/DO/urgency UI, then treatment with an antimuscarinic agent should be considered (see Pharmacological Treatment above). There are several trials examining the effect of antimuscarinics for nocturia reduction, including trials of oxybutynin-IR, [841] solifenacin, [634] and tolterodine [854, 855]. Four recent trials have compared placebo to active drug for nocturia without statistical improvement [856-859]. There is evidence to suggest that these agents may be best used in combination with other therapies [860] rather than as single modality therapy. Even when agents from this category have shown statistically significant reductions in nocturia, the net benefit of reduction in nocturia (above that effect shown with placebo) is only by 0.0 to 0.3 episodes. A recent “positive” trial showed a statistical advantage of solifenacin 10 mg over placebo of a net difference of -0.12 episodes per night [861]. Tolterodine demonstrated statistical reduction in nocturia accompanied by urinary urgency (but not overall nocturia) [855]. The clinical importance of nocturnal urgency is evident to the patient with the symptom (“I would like to not wake up and have to rush to the bathroom”), but this outcome is not fully nor well established within the literature. Use of anticholinergic medications should be used with caution in at-risk individuals as they may cause worsening of confusion or delirium.

2. Agents directed towards benign prostatic obstruction

Alpha-adrenergic agents used in patients with symptoms suggestive of BPO have a modest impact on nocturia, with a mean reduction of slightly less than one episode per night [830, 862]. 5-alpha reductase inhibitors [830] and saw palmetto (*Serenoa repens*, saw palmetto berry extract) [863] have not shown statistical benefit for nocturia except in one study within one subset of participants age >70 [842]. This statistical advantage did not persist beyond one year, and the net benefit compared to placebo was a difference of < 0.2 fewer nocturia episodes.

3. Other medication approaches

Among postmenopausal women, one uncontrolled trial of oestradiol in combination with a progestogen showed a dramatic reduction in nocturia over 6 months [864]. There are few studies that have focused on treatment of nocturia with the use of medications for sleep. One RCT evaluated melatonin for treatment of nocturia associated with BOO in older men [865]. Melatonin showed only a trend towards reduction in nocturia compared to placebo (-.03 and -0.05 episodes from baseline 3.1 episodes, respectively) but did significantly reduce reported bother from nocturia. A second study compared the addition of either melatonin or a sedative hypnotic (rilmazafone) to older men and women (mean age 72)

who were already taking a medication for nocturia, and found the addition of either treatment further reduced nocturia one episode (from 3.5 to 2.5 in both groups) [866]. Reducing volume overload associated with lower extremity venous insufficiency or congestive heart failure with a late afternoon dose of a rapid acting diuretic may be helpful in reducing nocturnal polyuria and nocturia in selected patients [867, 868]. Diuretics (specifically bumetanide and furosemide) have been conferred Level 2 evidence, Grade C recommendation by the Committee for Establishment of the Clinical Guidelines for Nocturia of the Neurogenic Bladder Society [869]. Treating sleep apnoea with continuous positive airway pressure can reduce nocturia severity, but these trials have not usually included the frail elderly [774]. Treatment with very short-acting benzodiazepines for patients with primary insomnia, and with dopaminergic agonists for patients with restless leg syndrome, may improve sleep quality, but there are no data to support these approaches.

4. Antidiuretic treatment: desmopressin

Most older patients with nocturia have increased nocturnal urine output, which is less common in younger patients [870]. Nocturnal urine volume is strongly associated with the number of episodes of nocturia [871]. A large number of studies over the last 20 years have examined the potential role of exogenous AVP (desmopressin or DDAVP) for the treatment of nocturia in older patients [823, 843, 844, 872-886] (Table 10). While many have been uncontrolled case series involving relatively small numbers of subjects, more are robust RCTs. In some cases, however, the inclusion criteria, outcome measures, and route, dosing, and duration of DDAVP treatment have varied considerably. The first two, large RCTS using oral DDAVP employed essentially identical designs, with one conducted in men [844] and the other in women [843]. While these trials included men over age 75, the mean age of the participants was closer to "middle" rather than "old" age (65 and 57, respectively). Both found significant reductions in nocturia and nocturnal urine volume, and increases in mean duration of self-reported first time to night-time awakening from sleep. However, there were some unusual elements of the trial design. The randomised controlled portion was preceded by an open-label dose-titration run-in, with the subsequent exclusion of subjects who did not experience >20% reduction in nocturnal urine volume or who were intolerant to the medication. Although this approach may be useful for targeting therapy in clinical practice, it raises questions about selection bias and the generalisability of the results. Most individuals in DDAVP oral tablet trials were titrated up to an oral dosage of 0.4 mg, [843, 844] yet older patients can have a significant reduction in night-time urine with much lower doses of 0.1 or 0.2 mg orally[882, 887, 888]. A major concern related to DDAVP treatment in elderly patients is fluid retention (which can exacerbate underlying cardiovascular disease) and hyponatraemia. In one study, one of the 57 individuals randomised to 0.1 mg DDAVP for year was described as having a "consciousness disturbance due to hyponatraemia (116 mmol/l)" which left him unable to "complete the protocol" [887]. Many older persons may have pre-existent hyponatraemia due to a variety of medical conditions and drugs and will develop renal insufficiency or congestive heart failure. One review [889] found the incidence of hyponatraemia with DDAVP in older persons to be 0-9% (depending on definition with the exception of the RCT in men discussed above, in which the incidence of any hyponatraemia was 22% (4% with sodium < 130 mmol/L). Because so few frail elderly were included in these trials, the actual incidence of clinically significant hyponatraemia from DDAVP that might occur with monitoring outside of a clinical trial is unknown. A further review of pooled trial results found that the incidence of hyponatraemia in subjects with normal baseline sodium was <1% (3/336 subjects) in per- sons < 65 and 8% (22/260) in those >65, and 75% (6/8) in older patients with a low baseline serum sodium [890]. Pharmacodynamic studies in younger older men (aged 55-70) found that DDAVP had a prolonged half-life which was in part responsible for hyponatraemia [891]. DDAVP is not useful in frail older persons in nursing homes with nocturia and/ or nighttime UI because of the lack of efficacy for reducing night-time voids and the very high rate of hyponatraemia [888]. The overall safety has been recently reviewed [892] and ddAVP was an addition to the most recent revision of the Beers review for potentially inappropriate medications in the elderly [893].

Several attempts at delivering the efficacy of antidiuretic therapy without the side effects have focused on the dosing, mechanism of achieving anti-diuresis, half-life of the agent, and delivery system. Since the last ICI review, data about the efficacy and safety of an orally-disintegrating tablet formulation of DDAVP have been published [872]. The theoretical advantages of such a formulation would be the ability to deliver smaller and consistent level of the drug. The study design evaluated co-primary outcomes of decrease in night-time voids from baseline versus placebo and the ability to achieve a 33% decline in baseline nocturia. Participants were stratified by age <65 and ≥ 65, with 500 individuals over 65 in the study having safety endpoints. At enrolment, all participants needed to have a serum sodium of >135 mmol/L, an estimated creatinine clearance of greater than 60 ml/min (the largest single reason for exclusion during screening, 15%), and a post void residual of less than 150 mL, and, for men only, a peak uroflow of >5 mL/second. The results showed that for men, the minimal effective dosage was 50 micrograms (-1.38 versus -0.84 for placebo) and for women it was 25 micrograms (-1.22 versus -0.88 for placebo). Side effects appeared in a dose-dependent fashion, that depended upon both age (older had higher side effects) and gender (women had higher side effects). For those participants over 65 years of age, the following percentages of participants had a reduction of sodium of either 125-130 or <125: on 100 micrograms, 14.1% and 4.7%; on 50 micrograms, 6.6% and 2.6%; for 25

micrograms, 2.6% and 0%. While the 2011 nocturia treatment consensus guidelines [744] stated that ”the mechanisms behind desmopressin-induced hyponatraemia are well understood”, newer information suggests that the hyponatraemia in women is not fully explained by pharmacokinetic profile [894]. For elderly individuals, antidiuretic therapy via DDAVP orally absorbable tablets still has a narrow therapeutic window where the dosage that allows for efficacy in the absence of meaningful and potentially serious side effects may be difficult to find. Severe hyponatremia has occurred even within the context of a clinical trial with enhanced, structured monitoring and use of a lower-dose desmopressin as an adjunct to BPH therapy [881] There have also been trials with staggered DDAVP and diuretics, which have greatly reduced nocturia [883]. Of the participants who completed the trial, 5% had hyponatraemia, not counting individuals who had hyponatraemia during run in.

1380

Table 10. Selected studies of desmopressin (DDAVP) for older patients

Reference No. (Yr.)	Study Design	N	Sex	Age Mean, (SD)	Nocturia Definition	DDAVP Dose[1]	Outcomes	Level of Evidence
van Kerrebroeck 2007[885]	RCT, placebo controlled Dose titration	127	70%M	63.4 (12.8)	> or =2 voids/night	0.1, 0.2, 0.4 mg	39% reduction in the mean number of nocturnal voids with desmopressin vs. 15% with placebo, p<0.0001 duration of the first sleep period prolonged by 108 min with desmopressin vs. 41 min with placebo; p<0.0001)	2
Johnson 2007[886]	double-blinded, placebo-controlled, crossover trial of individually titrated oral ddAVP.	14	NS	74 (5)	any nighttime void between going to bed and morning awakening	0.1, 0.2, 0.4 mg	NUV in subjects receiving ddAVP treatment was significantly lower than at baseline (197mL reduction,) and than in subjects taking placebo (126mL less,). NUVof subjects at baseline and of those taking placebo were not significantly different	3
Wang 2011 [888]	long-term efficacy and safety of low dose oral desmopressin in elderly patients with benign prostatic hyperplasia	126	M	74.5 (5.99)	2 or more voids nightly nocturnal polyuria =nocturnal uri ne volume greater than 30% of total daily urine volume	0.1	decrease of 2 or more voids per night) achieved by 35 (61.40%) patients receiving desmopressin and by 8 (13.80%) on placebo (p _0.001).	2
Fu 2011[884]	randomized double-blind treatment period. with DDAVP and staggered furosemide	80	58 men and 22 women,	67 (8)	at least two voids per night	0.1, 0.2, 0.4mg	46% patients in the study group compared with 4 (10%) patients in the control group reported that the treatment had a 50% or greater reduction in the number of nocturnal voids	2

5. Surgical and procedural treatments

Posterior tibial nerve stimulation has been used in OAB trials. A recent trial [895] demonstrated in 214 individuals a favourable outcome for nocturia reduction in the active treatment group (2.9 at baseline to 2.1 with treatment) that was statistically superior to the effect of sham (2.9 to 2.6, net benefit of active over placebo -0.4 reduction). Of note, there were more individuals over 65 years of age (50%) compared to the sham group (41%) biasing against demonstrating benefit if it were true that older adults responded less well; whether or not these gains are maintained without on going treatment is not known [896].

Surgical approaches to treatment of nocturia have long been recognised to be effective, yet overall symptoms improve more than does nocturia specifically. The evidence from trials shows that older patients with the highest symptom scores prior to surgery benefit the most from transurethral resection of the prostate [897], yet nocturia often persists and may be the least responsive symptom for improvement following the procedure [897-899]. Yet, surgery does reduce lower urinary tract symptoms and may result in reductions in nocturia and improvement in many symptom specific QOL areas [900], but not all [901]. In one consecutive group of 56 patients treated with either TURP or radical prostatectomy (mean age 69) for persistent symptoms despite six months of medical therapy. The group monitored postoperative nocturia counts, hours of undisturbed sleep, and the ICIQ-NQOL which were compared to baseline. In this uncontrolled series, patients had significant improvements in all measured domains, including a 0.8 episode reduction per night [902]. The NQOL outcome measure was most favourable in individuals with the greatest reductions in nocturia or the most uninterrupted sleep. One study used a retrospective evaluation of 298 patients (mean age 70) over a 10-year period, and found that younger men with lower preoperative urinary maximum flow rates had the best postoperative results [899]. Not surprisingly, symptoms post-operatively were not strongly correlated with objective urodynamic findings [903]. On average, less than half of the men operated on had a reduction of nocturia by 50% or more [899]. In a rare RCT where 66 men, aged 52–81 years (mean 68.6), who were believed to have nocturia solely due to “benign prostatic hyperplasia” and who had received no previous treatments of any type, were randomized in a 1:1 fashion to either alpha-blocker therapy (tamsulosin 0.4 mg) or TURP. The prostate volumes and baseline nocturia nearly differed in a statistically significant manner at baseline (51 cm3 and 2.0 mean nocturia episodes versus 59 cm3 and 2.4 for those allocated to surgery). Both groups had a reduction of nocturia to 1.5 (3 months) and 1.4 (6 months), as well as statistical improvements in the ICIQ-NQOL. No treatment was superior to the other and both were statistically significantly improved from baseline [900].

Summary of the evidence

Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions. **(Level 2)**

If OAB, DO, and/or urgency UI is felt to be a major contributor to nocturia, antimuscarinic agents should be considered. **(Level 3)**

If nocturia is due to insomnia alone, then a very-short acting sedative hypnotic may be considered. **(Level 3)**

DDAVP should not be used in frail elderly because of the risk of hyponatraemia. **(Level 1)**

Recommendations for management

Nocturia investigations should be carried out utilising both frequency-volume charts and validated questionnaires capturing QoL and bother related specific to nocturia (e.g. NQoL). **(GoR C)**

Recommendations for research

- Validation and clarification of the definition of both nocturia (in regards to any night awakening owing to the
- desire to pass urine, the ICS definition vs. the more clinically bothersome nocturia, of 2 or more episodes)
- Studies to elucidate the reason for awakening
- Ways in which to understand, and potentially diminish, the robust effect of placebo/control arms
- Epidemiological research regarding studies of nocturia involving the following aspects: incidence/ natural history, bother, effect on quality of life
- Research regarding what would be a clinically significant improvement
- Further clinical trials examining the impact of sleep focused treatments
- Trials examining the effects of multiple incremental and multicomponent therapies for nocturia
- Algorithms for both initial and subsequent (e.g., cause-specific management of frail elderly, and men versus women would seem to be desirable.

IV. FAECAL INCONTINENCE IN FRAIL OLDER PERSONS

1.1. Background

Faecal Incontinence (FI) in older people is a distressing and social isolating symptom and is associated with a possible increased risk of morbidity [904, 905] and dependency [905-908]. Frailty, defined by having weight loss, and/or limitations to physical activity, along with multi-morbidity may be independent risk

factors for FI in community-based and institutionalised populations of older adults [909-913] Many older individuals with FI will not volunteer the problem to their general practitioner or nurse, and, health care providers do not routinely enquire about the symptom or follow guidelines regarding evaluation and treatment [361, 914, 915]. This 'hidden problem' can therefore lead to a downward spiral of psychological distress, dependency, and poor health. The condition can especially take its toll on informal care providers of home-dwelling patients, [916] with FI being a reason for requesting nursing home placement and even mortality [905, 906, 917, 918].

Even when older people are noted by health care professionals to have FI, the condition is often managed with the use of absorptive or containment products, especially in the long-term care setting where it is most prevalent. Current surveys show that the level of awareness regarding appropriate assessment and treatment options is limited among primary care physicians [919]. The importance of identifying treatable causes of FI in frail older people rather than just managing passively (e.g. pads provision without assessment) is strongly emphasized in national and international guidance, [904, 920] but audits show that adherence to such guidance is generally poor, with non-integrated services, and sub-optimal delivery by professionals of even basic assessment and care [361, 921].

This section covers specific issues for frail older people with FI. Evaluation and management of urinary incontinence and FI should be considered simultaneously given that 40-60% of older adults with and without frailty with urinary incontinence also have fecal incontinence [912, 922-926]. Healthy older people should be managed using the interventions covered in the Chapter 16 "Assessment and Conservative Management of Faecal Incontinence and Quality of Life in Adults."

For the 5th ICI, the literature review covered the period 2008 to 2011. We identified new population-based studies on the prevalence and incidence rates of FI specifically including frail, older adults (see Table 11). Table 11 includes all studies published through from December 2008 through August 2016 which met the following criteria: (1) sample representative of the general population (not a convenience sample or sample recruited from a specialty/primary care medical clinic or other setting in which there is a probable selection bias), (2) sample involving specific models of care for the older adult (i.e., hospital care, home care, long term care), and (3) sample of specific disease or co-morbid condition.

The PUBMED.gov database was searched from December 2011 to August 2016 using the following keywords:

(i) 'anal, bowel, faecal, fecal' and 'incontinence'

(ii) constipation

(iii) 'urinary' and 'incontinence'

(iv) laxatives, enemas, suppositories

(iv) other relevant phrases such as 'comprehensive geriatric assessment' ' stroke'

(v) level of care, 'nursing home,' institutionalisation', long-term care,' 'acute care,' 'hospitalisation'

Additional articles were identified by examining reference lists, and other recent systematic reviews.

1.2. Prevalence and risk factors for FI

Prevalence estimates for FI vary widely: 2.2% to 25% in the general community-dwelling population, 9-30% in older community-dwelling adults, 18% to 33% in acute care settings, and may approach up to 50% in long term care and institutionalised settings [927, 928]. A 2015 systematic review only identified 38 studies with 6 high-quality studies and only 3 studies performed in a representative sample [927]. Incident FI varies from 6% to 17% in community dwelling populations, with less information known about incident rates in specific care settings [929-931]. The variability in the prevalence rates may be related to the case definition and the frequency of FI reported. Case definition may involve frequency of loss and the type of stool consistency or gas, including loss of flatal incontinence, as well as solid and liquid stool. Often, passive FI, or seepage, is not differentiated from solid or liquid stool FI in population-based studies. A few studies have also defined a category of soiling of underwear only. In this review, FI refers to the loss of solid or liquid stool or mucus. Studies are specified that use other definitions, such as flatal incontinence (anal incontinence) or soiling.

Prevalence and incidence estimates of FI in community-dwelling older adults. FI is strongly associated with aging in many studies and studies only involving older adults have higher prevalence estimates. The National Health and Nutrition Examination Survey (NHANES) in the United States (US) provides one of the best estimates of FI prevalence to date because it surveyed both sexes, all major races represented in the US, and a range of older adults by age decade (55-69 and 70 years of age and older) [932, 933]. NHANES also provided separate estimates for different types of FI (e.g., solid, liquid, mucus, and flatus) and frequencies of stool loss. The age-adjusted prevalence of FI (defined as accidental loss of solid, liquid, or mucus incontinence in the month preceding the interview) in the non-institutionalised population of the United States is 8.9% of women and 7.7% of men, with higher rates in older adults (16.6% in adults aged 70 years of age and older, equally prevalent in older men and women) [932, 933]. Liquid stool incontinence was the most common type of FI reported in the NHANES data. Rates of FI in older, frail adults are not sex-specific, with recent studies suggesting equal rates of FI among older men and women [908, 909, 934-938]. Table 11 gives prevalence estimates for FI in older adults where this data is available, but differences in survey methodology make it difficult to interpret or

pool prevalence rates [905, 911, 930, 931, 934, 935, 939-942].

1384

Table 11. Population based surveys of FI prevalence in older adults

Source	Design	Prevalence/Incidence	Risk Factors	Notes
Whitehead et al (2008)[944]	US representative sample of 2229 women and 2079 men, aged 20+ years. FI assessed with the FISI. FI defined as any involuntary loss of mucus, liquid, or solids in the last month.	Prevalence among older adults aged 70+: 15.3% overall No gender differences	Age Loose stool consistency >21 bowel movements/week – women Inability to do activity – women Chronic illnesses – women Poor self-rated health – men Urinary incontinence - men	Cross-sectional, population-based national survey. No subgroup analysis for risk factors in older adults.
Rey et al (2010)[945]	Random sample of 5,400 adults aged 50 yrs and older from Olmstead Co, MN. Respondents (n=1540, 64%) answered questions on FI at baseline in 1993 and 674 responded a mean of 9 years later.	10-year incidence rate was 7% for any FI	Urgency with bowel movements Self-reported diarrhoea Incomplete evacuation Pelvic radiation	Community sample, not population- based No separate analyses by sex Mean age of sample at follow up was 67±9 years
Markland et al (2010)[946]	1000 Medicare beneficiaries age 65+ in 3 counties of Alabama. In-person interviews at baseline and 4- years. Sex/race stratified. FI excluded flatus.	4-year Incidence rates reported. 17% overall for any FI 6% for monthly FI No gender differences	White race/ethnicity - women Chronic diarrhoea – women Urinary incontinence – men and women Depression – women	Population-based longitudinal study with in-person interviews Mean age of 78 ± 5 years
Joh et al (2010)[947]	Convenience-based survey in adult senior centres and health centres in Korea, n=981, mean age 73.6±6.8 years	Prevalence of FI in the previous 3 months, 15.5%. No differences in men and women, p=0.08	Urinary incontinence – men and women Hemorrhoids – men and women Poor self-rated health – men Diabetes – women Infrequent dietary fiber - women	Community sample, not population- based
Sharma et al (2011)[948]	Postal survey of 2000 adults, 18 years and older in New Zealand, mean age 51.6 years	Prevalence of monthly liquid or solid stool was 12.6%	Study did not assess risk factors, only variations in prevalence by 3 scales	No Sex or age group sub-analyses

Source	Design	Prevalence/Incidence	Risk Factors	Notes
AlAmeel (2010)[42]	Population-based Canadian Health and Aging Study, n=8917, among adults 65 years of age and older	4% overall prevalence rate for any FI in the past year	Older age More common among women Poorer self-rated health More dependency in ADLs Cognitive impairment	Population-based study No increased mortality or institutionalization after 10 years when adjusting for all significant confounding factors No separate analyses by sex

New additions to the literature include prevalence estimates of urinary incontinence and FI in populations receiving specialty services in the home, such as home health care/home visits by physicians and other care providers, and in populations receiving hospice care.

Rates of incident (i.e., rate of new onset) FI in non-institutionalised populations have been reported in a few studies [929-931]. These studies surveyed older adults in the community and reported FI incidence rates after 4 years, 6 years, and 9 years, from the initial survey period [929-931]. Incident rates for FI were 17% (95% confidence interval 13.7% to 20.1%) after 4-years in one study (n=557),[930] 9% after 6-years (n=34/252),[929] and 6.3% (95% confidence interval 4.5% to 8.6%) after 9-years in the other (n=683) [931]. For FI occurring at least monthly, the incidence rate was 6% (95% confidence interval 4.0% to 8.3%) after 4-years [930]. Differing FI incidence rates may be due to the age range of those surveyed at baseline. In the Markland et al and Nuotio et al studies, the average age of those surveyed was greater than 70 years of age at 4-years and 6 years, whereas the Rey et al study surveyed adults 50 years and older at baseline.

Prevalence estimates of FI in hospitalised older adults. Like the variability of prevalence rates of FI in community-dwelling population, hospitalised older adult populations also vary depending on the type of acute care setting or hospital setting, type of populations being studied (i.e. those under surveillance for certain types of infections), and duration of the hospital stay. Rates of FI in hospital or acute care settings range from 6-33%. In one study, the rates of FI in the acute care setting for adults (mean age of 67 years) was 33% (50/152 with diarrhoea under surveillance for infections) [943]. In another study, FI (17.6%) was almost as common as urinary incontinence (19.7%) in 608 hospitalised adults (age range 4 years to over 80 years).[944] Another study reported FI occurring in 20% (n=221/1083) hospitalised adults and an increased rate in the intensive care unit setting [945]. Loose stool or watery stool, along with medications, were associated with FI [945]. Older age was associated with increased rates of FI in hospitalised adults [944-946].

Prevalence estimates among older adults receiving home health care. Many older adults receive health care services in the home setting or in a residential setting due to acute or chronic illnesses that are associated with being home bound or needing supportive care. These older adults are considered more independent with supportive care rather than those in long-term care or nursing home settings who require skilled care. Less is known about FI these frail older adults [928]. Using the Outcome and Assessment Information Set (OASIS), a standardised and administrative assessment tool used to document patient needs in home care settings in the United States, urinary incontinence was identified in 27%-33% of home health care patients and 7%-9% had FI on admission to the home health agency/provider [947]. The Centers for Disease Control (CDC) and the National Center for Health Statistics published a report in 2014 that compares prevalence rates of urinary incontinence, FI, and having both urinary and fecal incontinence across 4 different US representative surveys: NHANES (reported above), the National Home Health and Hospice Care Survey (NHHCS), the National Survey of Residential Care Facilities (NSCRF), and from Long-term Care Data using the Resident Assessment Instrument - Minimum Data Set (MDS) [928]. Rates of any FI reported by home health agency providers was 49% from the NHHCS. FI rates were higher among older adults receiving home health care who resided in residential facilities and long term care (33%) than those residing in a private home or apartment (13%). Similar patterns for FI were seen in older adults receiving hospice care. FI rates were higher among older adults receiving hospice care who resided in residential facilities and long term care (66%) and those in a hospital hospice setting (70%), than those residing in a private home or apartment (41%).

Prevalence and incidence estimates of FI in long-term care residents. Additional studies were identified that reported prevalence rates of FI in nursing home or long-term care resident facilities [913, 928, 948, 949]. Data are limited by the type of facility or type of data used to report FI rates [922, 950-954]. Recent FI prevalence studies confirm high prevalence ranges of FI occurring at least weekly or more often, which varies from 40-57% of long-term care residents [913, 928, 948-951, 955]. However, one recent study using MDS data reported differences in FI prevalence rates from nursing home residents with short-term stays (33%) compared to long-term care (60%) [928]. Little is known about the FI incidence rate in this specific population of frail adults, with rates reported as 20% during a 10-month period after admission for long-term care [918].

Faecal incontinence in older adults – the "hidden" problem. Recent evidence re-affirms that about 30% of adults with FI seek care and that health care practitioners are not likely to inquire or document discussions regarding FI [361, 915, 917, 919, 956, 957]. Increasing awareness is important aspect of the identification, prevention, and treatment of FI in older adults [904]. Using appropriate terminology for FI for individuals that is consistent with health literacy levels may be an important factor. Terminology such as "bowel" or "accidental bowel leakage" may be more appropriate than the term "faecal" or "faecal incontinence" [958]. Barriers that prevent adequate identification and treatment include: social and cultural issues about discussing symptoms, duration of symptoms, perception that treatments may not exist, access to trained health care providers in the community, access to providers in long-term care settings, and access to training and treatment protocols. Given the high prevalence rates of FI in the hospital, home

care, and long term care settings, health care practitioners should directly inquire or directly observe bowel control issues and document any findings. Other high risk groups of older adults that should be questioned about bowel control include older adults that have: mobility problems, cognitive impairment/dementia, frailty syndrome, prior pelvic/lower abdominal radiation exposure, prior anal or rectal surgery, urinary incontinence, chronic constipation, chronic diarrhoea, and older adults with multi-morbidity.

Risk factors associated with FI in older adults. Age has been established as a risk factor for FI in many population-based studies [908, 925, 934, 959]. Other factors that have been associated with increased rates of FI include: female gender, co-existence of UI, poor general health, physical limitations, cognitive impairment, stool consistency, prior colorectal surgery, and high body mass index [960-964]. However, among population-based studies among older adults, risk factors specific to women (e.g. vaginal deliveries, parturition characteristics) are no longer significantly associated with FI when controlling for all other factor [934, 965]. Many diseases and co-morbid disorders are associated with FI and include: diabetes, dementia-related incontinence, irritable bowel syndrome, inflammatory bowel disease, systemic sclerosis, and neurological diseases, such as cerebrovascular disease [908, 931, 960, 966-970]. The association between faecal incontinence and loose stool consistency (diarrhoea) is robust in community-dwelling populations and nursing home studies [930, 931, 934, 952, 964, 965]. As supported by the epidemiological data, the etiology of faecal incontinence remains multifactorial and treatment depends on the underlying mechanisms or specific co-morbid disorders, as well as the overall burden of multimorbidity including medications used to manage multiple chronic disorders..

Frailty and Multi-morbidity as Risk Factors for FI in older adults. Frailty and multi-morbidity are not often studied as associated factors for FI in representative samples. However, some representative studies have included an evaluation of functional dependency, mobility, multi-morbidity, and other markers of frailty among older women [911, 912, 942].

1.3. Anorectal function in older adults

The pathophysiology of FI is covered elsewhere, this section considers factors physiological factors specific to frail older people.

Quality of the data

Physiological studies of the lower bowel in older adults tend to be variable due to a) a variety of different techniques used in measuring anorectal function, b) unclear definition of the normative range of manometric measures for older people, c) poor matching between cases and controls of clinical factors which may affect gut function (e.g. level of mobility or functional status), or inadequate clinical information, d) usually small subject numbers, e) few studies deal with subjects over 80 years, and f) improvements in imaging quality with anorectal manometry with new 3-diminisional equipment, endoanal ultrasound, and MRI with and without defecography [971-974]. Studies reviewed are cohort case-control to evaluate age-effect,[975-982] young-old healthy subject comparisons,[983-986] and age- and sex-matched case-control studies of continent versus incontinent patients [987, 988] .

Anorectal Function in Healthy Older Adults

Studies of age effect in healthy volunteers have shown a linear reduction with ageing in squeeze pressures (external anal sphincter tone) in women after the age of 70, and in men from the 9th decade onwards [982]. Studies of normal men and women demonstrated a significant but similar linear decrease in anal resting pressure and maximum squeeze pressures in both men and women with increasing age [986, 989]. Studies of asymptomatic females showed a significant decrease in both anal resting and squeeze pressures with age [989, 990]. Two studies comparing young and old continent women found a decrease in anal resting pressure but no decrease in squeeze pressures between the two groups [977, 984]. Age beyond 70 years was associated with reduction in anal resting pressures (internal anal sphincter tone) in both sexes, but to a greater degree in women than men,[980, 982] but not reaching statistical significance [991].

Rectal sensory thresholds may also decrease with aging in healthy older adults despite normal compliance and tone [985]. There was a significant increase in pudendal nerve latencies with age in women; [981] however, clinical practice guidelines do not recommend testing pudendal nerve latencies [992]. In patients older than 65 years there is >30% loss of enteric neurones when compared to people aged 20 to 35 years. This loss is associated with an increase in fatty tissue deposition [866][993]. Increase in thickness of internal sphincter may be related to an increase in collagen deposition, with increased thickness seen in older versus younger women and in older nulliparous women [979, 984]. In addition, the increase in internal sphincter thickness was associated with a significant decrease in the external anal sphincter thickness in women [863] [864][994, 995]. A study of men and women using endoanal MR imaging showed a significant decrease in the external anal sphincter thickness in men but not women with age [996].

Other studies in humans have found increases in elastin and collagen deposition in the myenteric plexus in the colon. It is unclear if rectal motility is affected by healthy aging, [997] but there is an age-related increase in anorectal sensitivity thresholds [981, 985, 986]. Rectal compliance was not affected in one study but reduced rectal sensation was associated with reduced rectal compliance in another [985] [989]. Other studies have evaluated the impact

of the relationship of glycaemic control on gastric emptying and found that fasting blood glucose levels were associated with faster gastric emptying [998].

Gut microbiome and metabolome studies in older adults show that diet and antibiotic usage have an impact on gut microbiome and metabolome findings [999, 1000]. Older adults residing in long-term care have less variation in the gut microbiome compared to older adults in the community [1001]. These changes in the gut microbiome from older adults in long-term care settings may also be influenced by diet and inflammatory biomarkers [1001].

Anorectal function in older adults with faecal incontinence. Studies have reported an age-related increase in pudendal neuropathy in incontinent women, that may be unrelated to squeeze pressures [872][1002, 1003]. A study comparing anorectal function in young (mean age 42) and old (mean age 72) women with FI (patients with constipation and/or pelvic floor dysfunction excluded) showed that older women were more likely to have bilateral pudendal neuropathy, but less likely to have a sphincter deficiency of >90 degree and less likely to have had a previous sphincteroplasty [983]. Anorectal function in older incontinent patients and continent age- and sex-matched controls showed that individuals with FI had reduced anal resting pressures [984, 1004]. In one study comparing 8 older incontinent women (mean age 71.6 SD 7.5) with 9 older continent women (mean age 71.6 SD 7.5) and 9 younger continent women (mean age 28.7 SD (7.3) found women with FI were more likely to have decreased maximum squeeze pressures and levator ani (LA) defects [1005]. Older FI females tolerated lower balloon anorectal manometry volumes before urge to defaecate indicative of rectal hypersensitivity [984].

1.4. Causes of faecal incontinence in older adults

Stool consistency is important aspect of determining the cause and the associated factors for the evaluation of FI in an older adult [930, 931, 965]. Loose, as well as hard, stool can be related to FI in frail, older adults [918, 951, 1006]. Evidence shows that loose stool consistency and chronic diarrhoea are important contributing factors for FI [930, 931, 934, 952, 965]. Loose stool and chronic diarrhoea can result from multiple causes, such as malabsorption syndromes (e.g., lactose intolerance, gluten sensitivity, and fat-malabsorption), acute diarrhoeal illnesses, microcytic colitis, irritable bowel syndrome – with diarrhoea predominant symptoms, and other causes of chronic diarrhoea. Any change in stool consistency along with other warning symptoms (weight loss, bloody stools, change in stool calibre, and painful defaecation) should prompt further evaluation for colorectal cancer. Potential reversible causes of loose stools may include: excessive laxative use, lactose intolerance, drug-related side-effects, bacterial overgrowth, and possible bowel obstruction with “overflow” FI. “Overflow” FI secondary to constipation and stool impaction is also important to consider in older adults, potentially more common in men than women, [1007, 1008] those with mobility problems, [951, 1006, 1009] and those that reside in nursing home settings [951, 1009].

Overflow incontinence or FI that results from stool impaction can be difficult to diagnose, may be more common in certain frail, older populations, and should be evaluated and treated when suspected. Evidence suggests that constipation and symptoms of constipation are common among nursing home residents with FI [951, 1009, 1010]. However, the true prevalence of impaction and FI in nursing home residents is not clearly identified. Constipation (according to bowel movement frequency) and associated symptoms (straining and incomplete evacuation) were common among nursing home residents in a 4-site randomised controlled trial to improve FI and urinary incontinence among nursing home resident by giving a multi-component intervention involving toileting assistance, exercise, and dietary snacks [951]. At baseline, 81% of the 111 nursing home study participants had less than 3 bowel movements in 5 days. Another study that identified factors associated with FI in different health care settings found that 70% of nursing home residents experienced “fecal loading” compared to 63% in rehabilitation wards, 57% in acute care wards, and 20% in the home care setting [1009].

Urgency associated with bowel movements is also an important bowel-related factor that should be assessed in older adults. Many studies do not evaluate urgency as an independent risk factor. However, among the studies that evaluated a sense of urgency associated with bowel movements, urgency consistently is strongly related to FI and having a negative impact on quality of life even after controlling for other known confounding factors [931, 1011, 1012].

Other **bowel-related disorders or complications of prior anorectal surgery and radiation** can contribute to FI in older adults who otherwise would be continent, especially when functional status, mobility and cognition become impaired. Other bowel related disorders that have been associated with FI in adults (but not limited to frail older adults) include: haemorrhoids, [983, 1007] posterior compartment prolapse (rectocele), [965] inflammatory bowel disease, [1013] and irritable bowel disease [965, 1014].Types of prior anorectal surgery that contribute to FI include: haemorrhoid surgery, [1007] prior fistula repair, [1015, 1016] sphincterotomy for anal fissures, [1017] partial or total colectomy, [1018] low anorectal resection and re-anastomosis for colorectal cancer, [1019, 1020] prostatectomy, [937] and prior pelvic/perineal radiation [937, 1021]. All of these bowel-related disorders, surgeries, and radiation should be part of the focused history in older adults with FI. More studies are needed to identify causal pathways for FI in the older adult.

Functional FI, as defined by mobility problems or restraints that restrict accessibility to the toilet despite

normal bowel sensation and capacity, is also cited as a common reason for FI in epidemiological studies among community-dwelling older adults and those in residing in nursing homes [909-911, 918, 924, 942, 952-954, 1022-1024].

Other causes of FI in older adults can be related to **co-morbid chronic disorders, increased body mass index, and multimorbidity**, especially diabetes and neurological disease, which increases the risk having FI. Even after adjusting for age and sex, **diabetes mellitus** is associated with gastrointestinal symptoms including FI in population-based studies, [936, 968, 1025] nursing home residents, [1024] and has been associated with impaired rectal sensitivity and sphincter weakness [966]. **Neurological diseases** that contribute to FI in older adults include cognitive impairment, stroke, traumatic brain injury, and sacral cord dysfunction. Older adults are living longer with significant neurological conditions. Cognitive impairment and dementia have been found to be independent risk factors with FI in older adult populations from epidemiological studies and among those in nursing homes [918, 924, 937, 952]. Having a stroke is an important risk factor for FI with three and half times the rate of FI compared to adults who did not have a stroke in one population-based study [1026]. FI affects 30-56% of stroke survivors in acute period after having a stroke (1-30 days), with a lower prevalence (11%) of FI after 3-months, and 11-22% at 12-months following the initial stroke event [967, 1027]. It is unclear whether the functional disability from having a stroke or that the disruption in neurological pathways (sensory mechanisms) that promote continence contributes more to FI among stroke survivors. Traumatic brain injury has also been linked with urinary incontinence and FI, but limited data exist on older adults from registry studies and single site studies [1028, 1029]. Spinal cord injury (depending on the level of injury) may result in impaired muscular strength of the external anal sphincter, delayed transit time, abnormal defaecation reflexes, and impaired sensation [1030].

Summary of evidence for prevalence and risk factors for FI in frail older people

Summarised below are key points that are specific to the frail elderly population. The level of evidence is given in brackets.

- FI affects 1 in 5 older people (aged 65+) living in the community and in residential care facilities, and half of those residing in long-term care homes [**LoE1**]
- The prevalence of FI increases with age alone, particularly in the 8th decade and beyond **[LoE1]**
- The prevalence of FI is higher in the acute hospital, and nursing home setting than in the community **[LoE 1]**, thus the group most affected is frail older people.
- The prevalence of FI in frail older men is equal to or greater than in women in the community and in long-term care residents **[LoE 2].**
- The prevalence of FI varies dramatically between institutions in nursing home studies due to measurement differences **[LoE 2].**
- FI usually coexists with urinary incontinence in frail older people **[LoE 1]**
- Aside from age, the following are primary risk factors for FI in older people **[LoE 2]:**
  - Stool consistency -- Loose stool
  - Bowel-related disorders, such as prior rectal surgery
  - Impaired mobility
  - Functional impairment
  - Dementia
  - Neurological disease
  - Diabetes mellitus
  - Chronic medical conditions
  - Depression
- Loose stool or diarrhoea may be a cause of transient FI in older people, if the diarrhoea is evaluated and treated **[LoE 2]**
- Faecal loading and constipation are clinically linked to FI, but there is little epidemiological work assessing this association **[LoE 3]**
- Physicians and nurses in primary care, acute hospital, and long-term health care settings do not have a high awareness of FI in older people **[LoE 2]**
- Within nursing homes, there is a low rate of referral by nursing staff of residents to primary care physicians or continence nurse specialists for further assessment of FI **[LoE 2**], and there is a tendency toward passive management (e.g. use of pads only without further evaluation) [**LoE 2].** Faecal loading is often present in older care home residents with FI **[LoE 2]**
- Older people may be reluctant to volunteer the symptoms of FI to their health care provider for social or cultural reasons, or due to a popular misperception that the condition is part of the aging process and therefore 'nothing can be done about it' **[LoE 2]**
- FI is associated with reduced quality of life, and poor health perception **[LoE 2]**

Recommendations – identifying faecal incontinence in frail older people

Bowel continence status should be established by *direct questioning and/or direct observation* in:

- all nursing/long-term care and residential home residents
- hospital inpatients aged 65 and over
- people aged 80 and beyond living at home

- older adults with impaired mobility
- older adults with impaired cognition
- older adults with neurological disease
- older adults with chronic disease, especially diabetes
- older adults with constipation
- Primary care staff, hospital ward staff, home health staff, and long-term care staff should routinely enquire about FI in frail older patients
- Enquiry about FI should be systematic and include stool consistency, severity of FI and impact on activities of daily living and quality of life
- Health care providers should be sensitive to cultural and social barriers discouraging patients from talking about the condition
- Frail older patients with restricted ability to access primary care such as nursing home residents, and those with mobility, chronic illness, or cognitive impairment, should be screened for FI through systematic case-finding methods
- Systematic outreach programmes which make it easier for frail older people and those who care for them to volunteer the problem to their primary care provider should be implemented
- There are significant geographic variations in provision of specialist expertise in bowel care (both medical and nursing) nationally and globally, which may affect case-finding in older people
- Further examination of underlying reasons for the variations in prevalence of FI between nursing homes (standards of care, patient case-mix, reporting) is needed
- Urinary and FI often coexist; continence care workers (e.g. nurse specialists) should be trained in identification and management of fecal as well as urinary incontinence in older people
- Key requirements to improving detection in the practice setting should be implemented:
  - education of health care workers to embed both a sense of value in identifying FI, plus confidence that the condition can be treated
  - protocols should be in place clarifying all details of screening enquiry (who will ask, how to ask, when to ask, and who to ask)
  - patients and caregivers should have access to educational materials at the point of enquiry

1.5. Evaluation of FI in frail older adults

The algorithm contained in this chapter delineates a systematic approach to the clinical evaluation of frail older people with FI.

An initial assessment can be undertaken by any suitably trained health care practitioner, often this will be by either a physician or clinical nurse specialist. In the majority of cases, a clinical history of bowel symptoms, dietary assessment, [1031] and symptom evaluation will provide sufficient diagnostic information upon which to base further management. There are available questionnaires which can assist in this process, although psychometric validation of specific instruments to asses FI severity and impact on quality of life in frail older adults compared to healthy adults are not available. Bowel diaries, including assessments of stool consistency, may also be useful to diagnose the type and frequency of FI [1032]. Self reports of bowel symptoms are reliable and reproducible in older people, including those in long term care [1033].

The use of formal testing is hampered by both lack of relevant data from frail older people and the poor correlation between symptoms and abnormalities [971, 972, 977, 1034-1036]. Evidence that the assessment of faecal incontinence in older people is poorly done despite the existence of guidelines has been a persistent finding throughout the history of this chapter [361, 1037]. What actions need to be taken to ensure that older people receive assessments which are consistent with current guidelines remain to be defined.

Digital rectal examination can assess resting anal sphincter tone, muscle isolation, and squeeze pressure and appears to be as good as sphincter manometry in discriminating continent from incontinent people, although not the frail elderly [1038]. Constipated patients with an empty rectum on digital examination may have high impaction and need further radiological evaluation. Abdominal radiographs to assess the extent of faecal loading and to rule out an obstruction or sigmoid volvulus could be considered. For adults with FI, it is important that current guidelines for colon cancer screening be followed, along with careful consideration of screening in older adults with limited life expectancy [1039, 1040]. While a change in bowel habits with weight loss, anaemia, rectal pain and rectal bleeding should raise the suspicion of an underlying malignancy, prior review of colonscopy findings and discussion with gastroenterologists for further testing may be warranted. The symptom of FI and chronic constipation does not usually warrant colonoscopic investigation, however, little data exist to guide evaluation in frail older adults. Given the increased difficulty of adequately preparing frail older people for either endoscopy or barium studies and potential increased risks of hyponatraemia with hospitalisation [1041, 1042]; CT colonography may be considered as an alternative investigation where available [1040].

Evaluation of the capacity to successfully toilet should include an assessment of mobility, visual acuity, manual dexterity and cognition. If acceptable to the older person, observing the process of transferring to the toilet, manage their clothing, redress and leave the lavatory is a good measure of ability. Caregivers

should additionally be aware of the surroundings in which the frail older person lives in terms of access, lighting, distance and clutter. The design of commodes should also be considered in the light of the individual's capabilities.

Faecal incontinence is also associated incontinence-associated dermatitis and with the development of pressure ulcers in older people with impaired mobility although whether this is a causal association is debatable, [1043, 1044] however, an assessment of skin integrity and provision of appropriate pressure relief is important. A pelvic examination to rule out rectal prolapse and posterior compartment vaginal prolapse is also important given the association between FI and prolapse in women [1045-1047].

1.6. Treatment of FI in frail older adults

Quality of data

Trials discussed are based prior chapter findings, Cochrane reviews for nonsurgical and surgical treatments for FI, [1048-1052] clinical practice guidelines, [920, 992] expert consensus statements, [1053] meta-analysis, [1054] and systematic reviews, including a recent Agency for Healthcare Research and Quality Systematic Review that included studies and case series published from 1980 to June 2015 [1055-1057]. No trials were identified on the prevention of FI in high risk, older adults. Many FI intervention studies have small sample sizes, inadequate power to detect clinically meaningful difference in outcomes, and biased methodology along with low strength of evidence ratings. Given these limitations, FI treatments applicable to older adults were considered and include: multi-component behavioural treatments for FI, pharmacological treatments for FI, treatments aimed at specific populations of older adults (e.g. nursing home populations and neurological conditions), anal bulking injections, transcutaneous and percutaneous tibial nerve stimulation, bowel-control devices, and less-invasive surgical options. Issues related to more invasive surgery, containment with absorptive products, and skin care are discussed in other chapters.

Multi-component biofeedback and behavioural treatments for FI. Given the multifactorial causes for FI in older adults, few studies exist in the literature involving multi-component interventions. In 2012 and 2013 the Cochrane group updated three reports showing a limited number of trials for FI with methodological weaknesses do not allow for a definitive assessment of the role of pelvic floor muscle training and/or biofeedback, pharmacological therapy in the treatment of FI, or the treatment of FI and constipation in adults with central neurological diseases [1048, 1050, 1051].

The Cochrane report on biofeedback and sphincter exercises also noted that some evidence does exist that biofeedback and electric stimulation may enhance the outcome to treatment with pelvic floor muscle exercises compared to exercises alone or sham treatment [1050]. In a 2016 AHRQ systematic review report, 63 nonsurgical studies were identified with 38 being randomised controlled trails (RCTs). Of the 38 RCTs, 13 evaluated biofeedback and pelvic floor muscle therapy (PFMT) [1055]. The AHRQ report concluded that PFMT and biofeedback with electrostimulation was no more effective than PFMT with biofeedback alone. The report also concluded that more research is needed to establish whether PFMT and biofeedback works for FI. Outcome measures varied considerably in the RCTs and did not allow further evaluation with meta-analysis. Few RCTs exist that treat frail, older adults with PFMT-BF.

Pharmacological treatments for FI. New low-strength evidence exists that psyllium may be beneficial compared to placebo for improving FI episodes (n=206, mean age 55-60 years per randomisation group) [1058] and psyllium was better tolerated while having no differences in efficacy compared to loperamide for improving FI episodes (n=80, mean age 61 ±10 years) [1059]. Overall, the AHRQ report identified few trials with outcomes past 3- or 6-months. Most RCTs evaluated symptoms in middle-aged women. According to the AHRQ review evidence was treatment benefit was insufficient for loperamide, topical phenylephrine, zinc-aluminum ointment, oestrogen cream, and valproate sodium. Clonidine given orally was not effective for improving FI severity compared to placebo (n=44). One small RCT (n=64 women, median age 58, range 27-78 years) evaluated biofeedback compared to loperamide then both groups had combined treatment [1060]. The authors concluded that combined treatment was superior to either treatment alone, but variable times for the interventions and sample size limit these conclusions [1060].

Small studies have also evaluated the safety of a new adrenergic alpha-1 receptor agonist suppository, NRL001, for FI treatment in adults, with safety data in older participants [1061, 1062]. Results from a 4 group parallel designed placebo-controlled RCT (n=446, mean age 62.1 years) did show difference in FI severity scores after 8 weeks of treatment with 3 different dosages of the alpha-1 receptor agonist suppository compared to placebo [1063]. Evidence for pharmacological treatments for improving FI in community-dwelling frail older adults with cognitive or functional impairment was not found.

Treatment of FI in long-term care/nursing home settings. Treatments for FI in long-term care settings also involved the treatment of constipation and faecal loading or faecal impaction. In a French study among 206 nursing home residents in 4 different homes, lactulose alone was compared to lactulose plus daily suppositories along with weekly tap-water enemas for reducing FI episodes. Although there were no differences between the two groups, residents that achieved complete rectal emptying also reduced the number of FI episodes by 35% while also reducing staff workload by 42% (soiled laundry counts) [1010]. Schnelle et al (2010) completed a multi-centre, multi-

component intervention for improving FI and constipation in cognitively impaired nursing home residents (n=112, mean age 86 ± 10 years) [955]. In this controlled trial in 6 United States nursing homes (n=112), the intervention was compared to a usual care control group. The intervention group received toileting assistance, exercise, and choice of food/fluid snacks every 2 hours for 8 hours/day for 3 months. Participants in the intervention group compared to the usual care control group had improvements in bowel movement frequency and the percentage of bowel movements in the toilet ($p<0.01$), but not the frequency of FI episodes determined by direct checks from research staff. Urinary incontinence episodes also improved with this intervention ($p<0.05$). Among the 29 nursing home residents who had anorectal manometry, a dyssynergic defaecation pattern was identified in 89%. The authors concluded that this multi-component intervention improved some factors associated with FI in nursing home residents, but further work to improve stool consistency and treatments for dyssynergia may be warranted.

Additional work is ongoing to improve nursing education, evaluation, and treatment of FI in long-term care settings [1064, 1065]. By improving knowledge of nursing staff, outcomes related to FI management and treatment may also improve [1064].

Treatment of FI in Adults with Neurological Conditions The 2013 Cochrane report on the treatment of FI and constipation in adults reviewed evidence from 20 clinical trials involving 902 adults [1048]. From this review, the conclusion was "remarkably little research" and "low methodological quality" evidence exists on bowel management in specific neurologic conditions. Most of trials are single-site, measuring outcomes against control and without comparative effectiveness data. Individuals trials did report symptom improvement using bulk-forming laxative (psyllium) in Parkinson's disease, an isosmotic macrogol laxative to manage bowel symptoms, abdominal massage, electrical stimulation and an anticholinesterase-anticholinergic drug combination (neostigmine-glycopyrrolate) in spinal cord injury compared to no treatment or controls. There was also evidence in favour of transanal irrigation (compared to conservative management) in spinal cord injury, oral carbonated (rather than tap) water, and abdominal massage with lifestyle advice (compared to lifestyle advice alone) in stroke survivors [1048]. In a 2015 RCT among 200 bedridden acute care patients with neurological impairments such as cerebral infarction, traumatic or spontaneous cerebral haemorrhage, intracranial infection, myelitis, and brain tumour, a suspension positioning system similar to that used for immobilised patients with pelvic fractures was evaluated for improvements in FI compared to usual care. Usual care consisted of nursing care for dietary modifications, health education, and social support for caregivers and family treating FI. Rates of perianal faecal contamination, skin breakdown, incontinence associated dermatitis, pressure ulcer development, and urinary tract infection (UTI) were significantly lower in the suspension positioning system than in the usual care group ($p<0.05$) at 6-months after treatment [1066].

Perianal injectable bulking agents for the treatment of FI have data limited to healthy adult populations with limited data related to older, frail adults [1052, 1055]. Use of dextranomer tissue-bulking injections were more effective than sham injections for improving FI-free days, 50% reductions in FI episodes and quality of life (n=206, mean age 61 years, age range for recruitment 18-75 years), but not more effective than pelvic floor muscle exercises and biofeedback (n=126) [1055, 1067, 1068].

Percutaneous tibial nerve stimulation (PTNS) for FI compared to sham stimulation has RCT evidence (n=227) [1069]. After 12-weeks of treatment, PTNS (n=115) and sham (n=112) groups had improvements in participants (mean age 58 years) who had at least a 50% reduction in FI episodes without any difference between the groups (38% vs 31%, respectively, $p=0.4$). However, participants in the PTNS did have some improvements in the total number of FI episodes ($p=0.02$) and the urge FI episodes ($p=0.02$) compared to those in the sham stimulation group. In one other pilot study in older adults (mean age 84.2 ± 10 years), transcutaneous posterior tibial nerve stimulation (TPTNS) or sham stimulation was given weekly for 12-weeks to older adults (n=30) in residential care homes. Lower urinary tract symptoms improved during the pilot study, but the rates of improvement in bowel leakage did not meet thresholds for statistical improvement (47% in the TPTNS group, 27% in the sham group, $p=0.11$) [1070].

Other Nonsurgical Management Options include use of anal plugs and a vaginal bowel control device. Anal plugs (n=76) [1071] and a new vaginal bowel control device (n=110) [1072] have prospective trial data showing improvements in 50% reduction of FI episodes, overall FI episodes, and quality of life. But, sub-group analyses of older adults in either study were not described.

Less invasive surgical management for FI includes sacral nerve modulation and antegrade continence enemas. Sacral Nerve Stimulation has prospective multi-centre trial data showing significant improvements in FI episodes, symptoms, and quality of life compared to baseline measurements [1073]. In the larger studies with data at 2- and 3-years, the mean ages were 54.3 ± 11.3 and 60.5 years (range 30-88 years) without subgroup data from older age participants [1074-1076]. Evaluating and selecting older adults and adults with specific neurological conditions who may benefit from permanent implantation is an important consideration [1077, 1078]. Data on sacral neuromodulation for FI and surgical outcomes including adverse events for frail, older adults are limited [1079]. Other less invasive surgical options include the antegrade continence enemata involving the creation of a proximal colonic stoma to use for the

enema to promote lower bowel evacuation [1057]. There are no data on older adults.

Summary of evidence treatment of FI in frail older people

- Current evidence shows that stimulant laxatives, osmolar laxatives (PEG and lactulose), suppositories and enemas can be effective in treating faecal impaction in older people at risk of overflow **[LoE2]** . ***Included in 5th ICI chapter***
- Complete rectal clearance is required to reduce overflow FI **[LoE2]** but may be hard to achieve in frail older patients **[LoE 2]**.
- Structured multi-component approaches to bowel care did not reduce the frequency of FI in the nursing home setting, but did improve bowel frequency and number of bowel movements in the toilet **[LoE 2]**
- Older people with FI may benefit from biofeedback and sphincter strengthening exercises if they are able to comply **[LoE 3]**
- Loperamide can reduce frequency of FI, particularly when associated with loose stool (once infection and other causes have been excluded) but should be used with caution **[LoE 2]**
- Additional fibre supplementation to loperamide may not improve FI outcomes **[LoE 2]**
- Multi-component structured nurse-led assessment and intervention can improve bowel symptoms and alter bowel-related habits in older stroke patients **[LoE 2].**
- More data are needed on the use of sacral neuromodulation in specific higher risk older age populations.

Recommendations: treatment of FI in frail older people

All following recommendations are Grade C

- Patients identified as having constipation with overflow should have effective bowel clearance (using a combination of laxatives and enemas), and then maintenance therapy with stimulant or osmotic laxatives ***Included from 5th ICI chapter***
- Suppositories are useful in treating rectal outlet delay and preventing recurrent rectal impaction with regular use
- Loperamide is a useful treatment in FI, in the absence of constipation, but should be used with caution in older adults
- Causes of loose stool must be identified and treated.
- All frail older people with FI should have structured multidisciplinary assessment and treatment of their bowel problem.
- Patient and caregiver education (using verbal and written materials) should be undertaken to promote self-efficacy and other coping mechanisms, and where appropriate self-management (e.g. reducing risk of constipation and impaction through dietary and lifestyle measures, advice on how to take loperamide). Advice on skin care, odour control, and continence aids is also important.
- Privacy and dignity of care during defecation should be afforded to all older people in insitutionalised settings. Particular attention should be paid to this in patients with FI, as privacy may be relatively overlooked in their care.
- Greater emphasis needs to be placed on systematic and effective management of FI in older people backed up by sound communications between all health care providers, especially in the nursing home and acute hospital setting.
- Education of health care providers with regards to heightening awareness of the problem plus methods of identification, assessment and management of FI in older people should be broad-ranging and include geriatricians, general practitioners, hospital physicians, hospital, community, general practice and long-term care nurses, and related disciplines (physiotherapists, occupational therapists, dieticians, pharmacists).
- Cyclical national audit with provider accountability, of current practice in managing FI in older people is needed to lay the ground-work for standardised care, and provide a culture of continuous quality improvement. Such audit tools should be developed using standardised consensus methods. Incentives to providers could be benchmarking their practice against national averages, opportunities to share successful practice change strategies, and professional validation linked to good practice.

Recommendations for research

- Trials of laxative and nonpharmacological treatment and prevention of faecal impaction and overflow are needed to optimise standards of prescribing and care.
- Multicomponent interventions to treat FI in frail older people should be evaluated to assess effective ways of FI management in acute care settings
- Multidisciplinary study assessing the feasibility and efficacy of a step-wise approach to the management of dementia-related FI in nursing home residents (prompted toileting in those with mild to moderate dementia, scheduled toileting plus

suppositories next step, and a bowel programme of controlled evacuation in those with persistent incontinence) would provide useful evidence

- it is important to balance feasibility and practicality in clinical trials versus high strength intervention, i.e. a team of specialist continence nurses in nursing homes are likely to have an impact, but at what cost, and what carry-over will there be when they are gone? Other methods (e.g. pre-post with multivariate case-mix adjustment) should also be considered.
- Evaluation of case-finding methods for FI in different settings including the fundamentals of staff education, screening protocols, patient's educational information would be very informative.
- Testing the feasibility of providing an integrative approach to assessment of FI in the frail older person, including a range of health and social care providers and different health care settings (acute, intermediate or sub-acute, long-term care and community) would be relevant to national implementation of bowel care improvement programmes.
- Examination of the variability of FI rates between nursing homes within single nation states, (taking into consideration case-mix) will highlight problems areas both organisationally and clinically. Nursing home administrative factors such as resident:nurse staff ratios should be evaluated as a contributing factor to FI.
- Further epidemiological studies are required to document causes of FI in frail older people in different health care settings. Such studies should include evaluation of unmet need for patients and caregivers.
- Evaluation of aetiologies, and in particular the pathophysiological basis for high prevalence of FI in older men. Evaluation of potentially preventable causes of loose stools in institutionalised older people, and impact of their treatment on FI.
- Nurse-led initiatives are needed to develop care pathways for assessing of bowel problems in frail older people with a view to establishing integrated service delivery.
- Examine the research question, 'Do educational interventions by health care providers to informal caregivers of home-dwelling older people with FI reduce caregiver burden and improve quality of life for patient and caregiver?'

V. CONTINENCE AT THE END OF LIFE

1.1. Background

Excluding those who die suddenly, most people will experience UI at the end of life [1080-1082] and many will experience FI [1083-1085]. In this section, we consider the specific incontinence issues faced by these patients and their caregivers, focusing on the last weeks and days of life.

Although incontinence is experienced by most people at the end of life, very little is known about the impact that it has or about preferences for care. We found no evidence to support any particular approach to assessment or any management or care interventions. Care at the end of life has much in common with care of the frail elderly, including a focus on maintaining quality of life, and much of this chapter is relevant to end of life care. However, end of life care is characterised by an increasing prevalence of incontinence or toileting difficulties [1084, 1085] and is likely to progressively focus on symptom management and comfort, rather than actively treating underlying causes.

1.2. Quality of data

Given the overall low level of research in end of life care and the methodological difficulties faced by researchers are well acknowledged [1086-1088], the lack of studies on incontinence at this life stage should not be surprising. The only area where relevant large scale studies were found was in the assessment of prevalence of incontinence at the end of life. The only literature found to focus on the assessment or management of incontinence at the end life were local audits, expert opinions and literature reviews.

1.3. Prevalence and impact

High rates of incontinence at the end of life are associated with functional and cognitive decline, with additional impact from curative and palliative treatment [1089-1091]. Prevalence of UI and FI in the last weeks and months of life varies by diagnosis and proximity to death, with significant correlation with both physical and cognitive functional decline [1080].

In a study of over 7000 community dwelling adults in the last year of life from 1998 to 2010, Singer and colleagues (2015) [1082] found that in the last year of life patients experiencing a period of at least one month with UI or FI ranged from 43.9 to 47.6. Prevalence varied by decedent, with sudden death associated with lowest rate (range 28.6-37.0%) and frailty the highest (65.3 – 67.2%). For patients with dementia, McCarthy et al (1997)[1092] reported a rate of 72% of a sample of 170 patients experienced UI in the final year of life.

Closer to the point of death, rates of incontinence rise. In a retrospective review of medical notes for the last

3 months of life for 229 patients, Jakobsson and colleagues (2008) [1080] found 56.8% experienced urinary incontinence, rising to 72.5 for those who were ADL dependent and 71.4 for those with cognitive impairment for the three month period. A study of 198 nursing home residents with dementia in the Netherlands found 89% were incontinent of urine in the last month of life [1081]. Another study focusing on the impact of caring for the terminally ill (n=151) found the number of patients who required assistance with toileting rose from 37% at 1-3 months before death to 67% in the month before death [6]. In an acute palliative care unit for people with advanced cancer (n=203), Hui et al [1084] reported urinary incontinence increased in last 7 days of life from 30 to 65%, with faecal incontinence rising from 10 to 30%.

Fewer studies report on the impact of incontinence. Hoben and colleagues [1083] reported on the prevalence and burden of symptoms in the last quarter before death for over 6000 nursing home residents. The two most prevalent symptoms were urinary incontinence (at least twice per week) (79.7%) and faecal incontinence (at least once per week) (66.7%). The burden (as rated by care providers) of both urinary and faecal incontinence was found to be medium, with the cost of urinary incontinence rated as high and faecal incontinence rated medium. Veerbeek and colleagues [1093] reported on the patient symptom burden (rated post-death by a nurse closely involved in care) for the last three days of life in different care settings. The burden was found to be higher for non-cancer patients and for patients dying in their own home or a nursing home (compared to an acute setting). For patients dying in their own home or a nursing home, the burden of incontinence was rated higher than that of pain [1093].

It should be noted that, although the prevalence of UI increases in the final few days of life, urine output often decreases. Indeed, decreased urine output is associated with high likelihood of death within three days (Likelihood Ratio 15.2 95% CI: 13.4–17.1) [1094].

1.4. Assessment and management options for urinary or faecal incontinence at the end of life

Assessment

Assessment at the end of life should be focused on thorough investigation of the patient's experience of their symptoms, changing needs and preferences and planning ahead, including a holistic assessment of the impact of symptoms [1095, 1096]. No validated assessment or outcome measurement tools focusing on end of life incontinence were found. Despite the high prevalence of incontinence at the end of life, generic assessment tools assessing a broad range of symptoms at the end of life often exclude reference to incontinence (for example Edmonton Symptom Assessment Scale or Memorial Symptom Assessment Scale). Although many elements of generic incontinence questionnaires discussed in Chapter 6 such as the Kings Health Questionnaire are unlikely to be relevant at the end of life, they may offer prompts for assessing the impact of incontinence on patients' quality of life.

As patients' ability to communicate deteriorates in the last days and hours of life and many care settings implement a 'dying phase' care pathway to manage symptoms [1097]. A recent Cochrane review of these pathways concluded that there is currently limited evidence to support their use [1098]. In the UK, there has been considerable activity to replace the now withdrawn Liverpool Care Pathway with more individualised care, including the Royal College of Physicians "End-of-Life Care in the Acute Care Setting [1099] and NICE Guideline "Care of dying adults in the last days of life" [1096]. Neither of these resources refer to incontinence.

Management Options

No studies or guidelines that report on management options at the end of life were found. Generic end of life guidance states that symptom management should focus on minimising the impact of symptoms to maintain quality of life in accordance with the patient's values and preferences [1095, 1096, 1100]. Suitability of active treatment (rather than containment) should be judged on remaining life expectancy, patient preferences and care goals as described earlier in this chapter.

There is no evidence to support any of the pharmacological, lifestyle or behavioural interventions described earlier in this chapter for people in the last days and weeks of life. It is unlikely that most will be apposite, although behavioural interventions such as prompted voiding could have benefits with some patients for a limited time before mobility deteriorates.

Although no studies were found to support interventions with long-term staff and care givers and the end of life population, some of the principles described earlier in this chapter might be relevant. In particular, recommendations for educational support for care givers, adaption of interventions to the local context and individual patients and the use of a multi-component, interdisciplinary and person-cantered approach are likely to be valid.

It is likely that management in the last days and weeks will include the use of appropriate absorbent products or containment devices (Chapter 20). IDCs are commonly used, but there is uncertainty about what constitutes best practice at the end of life regarding IDC insertion [1101]. Guidelines widely accept comfort at the end of life as a valid reason for placing a catheter [1102]. An audit of patients who died on two oncology wards in the UK showed that 63% of patients had an IDC during their admission [1103]. According to the findings of another study, involving 61 patients with terminal illness due to cancer admitted to a palliative care unit (PCU), IDCs may be used in up to 75% of such patients [1104]. In this study, 38% (n=23) admitted to the PCU had an IDC

in situ prior to their admission and another 36% (n=22) were catheterised during their admission. Complications associated with the use of IDCs in this cohort included: bacteriuria (n=28), encrustation (n=8), bladder spasms (n=4), fever (n=2), and urethritis (n=2). Despite these complications, staff cited 'patient comfort' as the main rationale for the use of an IDC. Clearly, further research is warranted to guide clinical care in this area.

1.5. Special considerations: Care preferences, place of dying and informal caregivers.

Very little is known about patients' preferences for incontinence care at the end of life, however, more widely, we do know that place of death and maintenance of dignity are viewed as important to patients and their informal caregivers [1095].

The majority of people wish to die at home [1105, 1106], but most do not achieve this wish [1107]. This can be due to the lack of support available in community settings and even in countries where palliative care provision is advanced, the lack of "dying out of hours" services leads to the burden of care falling to informal caregivers [1095, 1100]. As the population ages, healthcare policy makers are increasingly supporting caring for terminally ill patients at home, with the potential for substantial impact on informal caregivers [1085].

The provision of continence care by informal caregivers at the end of life has been found to be potentially problematic for both the patient and the caregiver. Patients often worry about becoming a burden and might not want intimate care provided by family members [1108] and coping with incontinence problems has been demonstrated to greatly add to distress and workload for carers [1109, 1110]. Caregivers have requested more practically focused information to help avoid crises [1111] and report feeling unprepared and unsupported in their role [1112]. To achieve the goal of allowing people to die at home, information, support and guidance for both patient and caregivers needs to be improved [1113]. This should include continence care.

Recommendations for practice

1. Physical and cognitive function will often vary from day-to-day. Regular assessment and individual management plans are required, taking in to account patient preferences and the context of care.
2. Timely environmental or behavioural interventions might be of benefit for individual patients for a limited period dependent on the illness trajectory.
3. Caregivers (professional and informal) should be educated in supporting the changing incontinence needs of dying patients.

Recommendations for research

Further research is required to:

1. Explore the patients' preferences for the management of UI and FI at the end of life.
2. Explore how carers (professional and informal) can be supported to care for the incontinence needs of people dying in different settings.
3. Identify the risks and benefits of using IDCs to provide comfort at the end of life.

Evaluate the impact of environmental and behavioural interventions to improve comfort and quality of life.

The present chapter would not have been possible without the work of the previous editors, Katherine Moore [2013], Jean hay Smith [2008] and don Wilson [2000, 2004]. They produced the remarkable framework for the present review. In addition, we would like to acknowledge the indispensable contribution of Pauline Campbell to the reviewing, analysis and reporting of POP section. Finally, this chapter would not have been possible without the untiring dedication of Yvonne Ruella.

I. INTRODUCTION

Conservative management of urinary incontinence (UI) or pelvic organ prolapse (POP) is defined as any intervention not involving surgical or pharmacological approaches (1). These comprise lifestyle modification, pelvic floor muscle training (PFMT) (either alone or with the addition of biofeedback), vaginal cones, electrical stimulation, magnetic stimulation, posterior tibial nerve stimulation, scheduled voiding regimens, complementary/alternative medicines and supportive rings/pessaries. In this chapter, we cover studies that provide comparative data between a conservative management approach and the absence of treatment or placebo, between two conservative management approaches or between a conservative management approach and medications or surgery.

Conservative management approaches are considered relatively low cost and non-invasive, with minimal adverse effects that are typically guided by a healthcare professional and depend on user participation. It is generally accepted that conservative interventions are part of initial management at the primary care level for individuals suffering from either UI or POP. Conservative intervention is also indicated for those for whom other treatments are inappropriate, for example, those unwilling to undergo or unfit for surgery and women who plan future pregnancies. Other indications include individuals awaiting surgery or who wish to delay surgery and those whose symptoms are not severe enough for surgical intervention.

The research base on which to judge the effectiveness of conservative interventions is growing although some aspects, such as lifestyle modification interventions and alternative and complementary medicines in particular, require considerably more well-designed trials. In this chapter we add to the 2013 5th Edition ICI chapter on conservative management (2), integrate the evidence and upgrade the recommendations from the 5th ICI. We also add a new section on posterior tibial nerve stimulation with its levels of evidence and recommendation.

The updated literature search covered publications from July 1st, 2011 to September 9th, 2015 according to the following search strategy:

- Cochrane Incontinence systematic reviews

Relevant Cochrane systematic reviews were identified, for each section of this Chapter, by two of the authors (CD, SW) assessing the full list of reviews (Cochrane Incontinence (3) or on request). The leads for each section were given lists of these relevant reviews. Additional searches of the Cochrane Incontinence Specialised Register were provided to each section author to bring the searches up to date or, if there was a gap in review coverage, a full search of the Register was conducted (search date: September 9th, 2015).

- Additional searches for this ICI Chapter

Electronic searches

We identified relevant trials from the Cochrane Incontinence Specialised Register. For more details of the search methods used to build the Register please see the Group's module in the Cochrane Library (4). The Register contains trials identified from the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, MEDLINE In-Process, ClinicalTrials.gov, WHO ICTRP, UK Clinical Research Network Portfolio and hand searching of journals and conference proceedings. The search covered:

- For sections covered by existing Cochrane reviews – from the date of last search for the published version of the review to September 9th, 2015.
- For sections not covered by existing Cochrane reviews – complete search of all contents of the Register on September 9th, 2015.
- Searching other sources

We searched the reference lists of relevant articles for other relevant trials.

We did not impose any language or other limitations on any of the searches described above.

In continuity with the last edition of the ICI chapter on conservative management and to ensure consistency throughout the chapter, the primary outcomes to be reported were *patient-reported outcomes*: cure and cure and improvement, UI-specific or POP-specific quality of life or symptoms-validated questionnaire and/or number of leakages (as per the diary). Cure and improvement were based on patients' self-report when available; if not, cure and improvement based on quantifiable measures such as a diary and pad tests were reported.

Secondary outcomes were *clinician-reported outcomes* (pad test, POPQ score, etc.). These were chosen in relation to each subsection's specificity and in continuity with our previous chapter.

Each subsection concludes with the level of evidence, grade of recommendations and factors affecting outcome. Separate chapters in this 6th Edition address incontinence in the frail older person, children, pessaries and products for continence, those with neurological conditions and those suffering from faecal incontinence.

Where summary statistics are presented, the raw data from which these are derived can be found in the tables within each subsection, in trial reports and systematic reviews cited in the chapter. The Chapter is intended as a stand-alone document and adds to the comprehensive reports from previous ICI editions.

II. URINARY INCONTINENCE IN WOMEN

1. LIFESTYLE MODIFICATION INTERVENTIONS

Lifestyle modification Interventions for women

A number of lifestyle factors may play a role in either the development or resolution of UI. Lifestyle modification interventions are defined as application of interventions in management of lifestyle-related health problems (1). They are low cost, non-invasive alterations in lifestyle such as weight loss; dietary changes; fluid intake modification; reduction in caffeinated, carbonated and alcoholic drinks; avoidance of constipation; stopping smoking; and physical activity.

As reported in the 5th ICI (2013) evidence for the efficacy of lifestyle modification interventions for urinary incontinence is lacking, there are few lifestyle modification interventions that have received scrutiny in randomised controlled trials, although weight loss and dietary factors have been examined and prospective studies and observational studies have been undertaken for diet, smoking and constipation. For more details, refer to ICI 5th Edition (2).

This review section updates the evidence on the use of lifestyle modification interventions to improve incontinence and related symptoms in females. It revealed 10 potentially eligible new trials. Table 1 illustrates the number of studies included in the 5th ICI edition as well as the new studies identified in the current update. Characteristics of each new trial are presented in subsequent tables for each lifestyle modification intervention for which there is new data.

Table 1 Studies included in the updated review 2016

Lifestyle modification Interventions	ICI 2013	ICI 2016	Total
Weight loss	3 RCT 4 prospective cohort 7 cross sectional cohort 1 retrospective cohort 1 case control study	2 RCT 1 cohort study 1 meta-analysis 1 prospective longitudinal study	5 RCT 13 cohort studies 1 case control study 1 meta- analysis 1 prospective longitudinal study
Physical activity	2 prospective cohort 2 observational cohort	1 prospective cohort study 1 case control study	3 prospective cohort studies 2 observational cohort study 1 case control study
Smoking	2 case control studies	1 RCT (pilot, secondary analysis)	1 RCT pilot 2 case control studies
Dietary factors	3 observational studies	1 case control study 1 prospective cohort study 1 cross sectional cohort study	3 observational studies 1 case control study 1 prospective cohort study 1 cross sectional cohort study

Questions addressed are:

- Are lifestyle modification interventions (e.g. weight loss, increased/decreased physical activity/ smoking cessation/ dietary or fluid change) effective in the prevention of UI?
- Are lifestyle modification interventions (e.g. weight loss, increased/decreased physical activity/ smoking cessation/ dietary or fluid change) better than no treatment, placebo or control in the treatment of UI?
- Is one lifestyle modification intervention (e.g. weight loss, increased/decreased physical activity/ smoking cessation/ dietary or fluid change) better than another?

In 2015 a Cochrane review was published (5) which included all available trials of lifestyle modification interventions for urinary incontinence. These trials are included in this review, along with new trial data since the Cochrane search was undertaken (October 27th, 2014) as well as other cohort evidence where no trial data are available.

1.1. Prevention

Are lifestyle modification interventions (e.g. weight loss, increased/decreased physical activity/ smoking cessation/ dietary or fluid change) effective in the prevention of UI?

In the last ICI chapter (5th ICI, 2013), there were no trials on prevention of UI. No new trials have been published.

Based on the clear lack of evidence in the literature of RCTs or observational studies of lifestyle modification interventions to prevent UI, no evidence based recommendations can be made.

Prevention should be an area for future research investment and comprise robust economic evaluation to determine the benefits of prevention strategies in specific age groups.

1.2. Treatment

1.2.1 Weight Loss by Obese or Overweight Women

Urinary incontinence and obesity are both common problems for women. It is recognised that obese women have higher intra-abdominal pressures than non-obese women, and it has been suggested that this chronically elevated pressure may predispose to incontinence by weakening pelvic floor support structures (6).

One new trial was identified which examined weight loss in overweight/obese women (7) (Table 2). The study was conducted to determine the effect of an intensive weight loss programme over 4 years on a subset of female participants (n=2739), previously outlined in the Look AHEAD trial(7). All participants were randomised to an intensive weight loss programme or a diabetes support and education group. Self-report of incontinence, nocturia and daytime voiding frequency were recorded at baseline and 1 year. Each kilogramme of weight loss reduced the odds of developing UI at one year by 3% (OR 0.97, 95% CI (0.95-0.99); p=0.1). There was uncertainty over the risk of selection bias for several key parameters, including: random sequence generation and allocation concealment. Performance bias was unclear as the blinding of participants and staff was not undertaken. The study ensured the blinding of outcome assessment but did not provide complete outcome data and provided only selective reporting indicating possible reporting bias.

A single study not identified in our previous searches from 2008 was discovered (8). This prospective longitudinal study examined the effect of weight loss offered as part of a weight reduction programme which included low calorie diet and exercise, 64 obese incontinent women were included. Weight loss of ≥5% of baseline weight was associated with significant reduction in pad test loss (median difference, 19 g; 95% confidence interval, 13-28 g; $p < 0.001$). They also report a statistically significant improvement in quality of life measures. They suggest that weight reduction of 5% of initial body weight can improve UI severity and its effects on quality of life in obese women. There was uncertainty over the risk of bias in all parameters for this study due to the poor reporting style.

Further analysis on the effect of weight loss on changes in health-related quality of life are reported by Pinto *et al.* 2012 (9). In a study conducted for the Programme to Reduce Incontinence by Diet and Exercise (PRIDE), a longitudinal cohort analysis was undertaken of 338 obese and overweight women with UI and health related quality of life assessed at baseline, 6 and 18 months. They concluded that weight loss and increased physical activity but not reduction in frequency of UI were strongly associated with improvements in QoL.

More recently in 2014 a systematic review and meta-analysis of non-surgical weight loss interventions in overweight women was published by Vissers *et al.* (10) drawing on the studies from the ICI 2013 chapter and the more recent Cochrane review (2015); this concluded that whilst few (n=6) studies were available, non-surgical weight loss should be considered standard practice for overweight women with UI. This review did not identify any additional studies for inclusion here. It is important to note that this review sought to determine the effect of non-surgical weight loss interventions on urinary incontinence in overweight women, but, in fact, included studies of both obese and overweight women.

Table 2 Summary of data on weight loss

Author, year	Comparator	N	Study population	Age	Outcomes/results	Follow up	Notes (side effects, loss of follow up, risk of bias)
Phelan 2012(1)	Intensive weight-loss vs a structured education programme on weight loss	2994	Women in a diabetes trial	Group 1 57.8 Group 2 58.1	Decrease of at least 2 incontinence episodes a week assessed by a validated self report questionnaire. Mean weight loss at 1 year Group 1 : 7.7 group 2 0.7; p value<0.0001	12 months	Random sequence generation: unclear Allocation concealment – unclear Blinding of participants – high risk Blinding of outcome assessment – low risk Incomplete outcome data – unclear risk Selective reporting – unclear risk
Breyer 2014(2)	Intensive weight loss versus a structured education programme on weight loss	1910	Men in a diabetes trial	59.9	Decrease in incontinence episodes or cure assessed by a validated self-report questionnaire	12 months	Random sequence generation : unclear Allocation concealment – unclear Blinding of participants – high risk Blinding of outcome assessment – low risk Incomplete outcome data – unclear risk Selective reporting – unclear risk
Auwad 2008(3)	Commercial programme of diet and exercise versus no control group	64	Obese women with urodynamically proved urinary incontinence	52.2	Decrease in pad test loss	18 months	Blinding of outcome assessment – unclear risk Incomplete outcome data – unclear risk Selective reporting – unclear risk
Pinto 2012(4)	Behavioural weight loss intervention versus a structured education programme on weight loss	338	Overweight and obese women with UI	53 +- 11 years (SD)	Health related QoL	18 months	Secondary analysis of data: Random sequence generation : low risk Allocation concealment – low risk Blinding of participants – high risk Blinding of outcome assessment – low risk Incomplete outcome data – low risk Selective reporting – unclear risk

4. Pinto AM, Subak LL, Nakagawa S, Vittinghoff E, Wing RR, Kusek JW, *et al*. The effect of weight loss on changes in health-related quality of life among overweight and obese women with urinary incontinence. Quality of Life Research. 2012;21(10):1685-94.

Summary

Evidence from 1 RCT, 2 cohort studies and one meta-analysis support lifestyle modification interventions promoting weight loss as a tool to reduce urinary incontinence in women who are overweight or obese. Weight loss of 5% of initial body weight has an impact on the reduction of urinary incontinence symptoms and the odds of developing UI at one year can be reduced by 3% for every kilogram lost by overweight and obese women. **(Level of Evidence: 1**)

Recommendations

Weight loss as a non-surgical intervention, should be recommended to obese and overweight women with UI. **(Grade of Recommendation: A)**

1.2.2 Physical Activity

No new RCT data have been published on either the benefits of moderate physical activity or the adverse effect of strenuous activity on UI in women. One relevant prospective cohort study (11) and one case control study have been reported since the last review Table 3.

The prospective cohort study (11) determined that low physical activity may be a causal factor in the development of overactive bladder. This study developed a hypothetical causative model for OAB involving secondary analysis from the Leicestershire UK MRC Incontinence study and included 3411 women free from OAB and 277 incident cases aged 40+. The study used graphical chain modelling to EStimate the associations between variables and identify the likely causal pathways. Low physical activity was a direct risk factor linked to the development of over active bladder (OAB) with incontinence (RR 2.47;95% CI 1.82, 3.36). They identified the need for further research to demonstrate a causal link between lifestyle and OAB. This study was difficult to combine as it used sophisticated statistical modelling to determine a causative model for use in future research. This research indicated that poor lifestyle factors causally linked to diabetes and obesity and suggest that this may contribute to the onset of OAB. The authors identify that low physical activity could be an important modifiable causal factor for OAB operating via pathways involving obesity or diabetes.

Summary

Non RCT evidence is building which suggests that moderate exercise decreases the incidence of UI although the level of evidence remains low **(Level of Evidence: 3)**.

Recommendations:

In the absence of robust randomised controlled trials **(Grade of Recommendation: C)**

1.2.3 Strenuous Physical Activity

The previous ICI identified no research evidence which suggested that strenuous exercise causes UI. Minimal uncontrolled data did suggest that women engaged in occupations which involved heavy lifting may be predisposed to genital prolapse or UI (12). A case control study conducted by Nygaard *et al.* (13) to determine lifetime physical activity and stress incontinence enrolled 1528 women between the ages of 39-65. Each participant underwent a Pelvic Organ Prolapse Quantification examination, 213 cases were identified and matched 1:1 to controls. Physical activity was measured using the Lifetime Physical Activity Questionnaire in which women recall their past physical activity. Lifetime strenuous activity was not associated with SUI (OR, 1.11; 95% CI, 0.99-1.25) and increased lifetime activity did not affect the odds of developing SUI (OR, 1.11; 0.99-1.25; p=0.06) (Table 3).

Summary

Evidence for the association between strenuous physical activity and incontinence need to be replicated using larger populations and more robust design before recommendations can be made. No further data was identified. **(Level of Evidence: 3)**

Recommendations:

In the absence of robust randomised controlled trials **(Grade of Recommendation: C)**

1.2.4 Smoking

In 2014, a pilot study investigated the effect of smoking cessation on overactive bladder symptoms (14). The authors explored the hypothesis that smoking abstinence would be associated with improvements in OAB symptoms. The sample was randomised to one of three arms: 1) very low nicotine cigarettes; 2) very low nicotine cigarettes and a 21g nicotine patch; 3) patch alone. All participants had at least one OAB symptom including urinary frequency, urgency, nocturia or urgency urinary incontinence, smoked 10-40 cigarettes a day for a year and were in good physical and mental health. The ICIQ-OAB was used at baseline and 12 weeks, 6 weeks after completion of the trial intervention. Outcomes included self-report of smoking cessation and OAB symptoms and score. 96 (47%) of the 202 participants met the inclusion criteria for this secondary analysis and 57 (59%) (37 women and 20 men) completed the study and were included in the analysis. Data was not presented separately for women and men. Those who were abstinent from smoking at 12 weeks were more likely to have a reduction in urinary frequency (p=0.042) and the ICIQ-OAB score showed no change for those who were abstinent or those who resumed smoking (4.6$\pm$0.5 vs 4.3$\pm$0.3, respectively, p=ns). The authors conclude that smoking cessation and its effect on OAB would need to undergo more rigorous evaluation in further trials with larger sample size to determine the effect of smoking abstinence on OAB symptoms (Table 4).

Summary

Data suggest that smoking increases the risk of more severe UI. This small new study indicates that urinary frequency may be improved by smoking abstinence. **(Level of Evidence**: **3)**

Recommendations

There remains a need for further prospective studies of smoking cessation for urinary symptoms **(Grade of Recommendation: C)**

1.2.5 Dietary Modification (Elimination Diet)

Dietary factors can be divided into three groups: Diet; Fluid Intake and Caffeine. There have been no new published RCTs evaluating the effect of diet or fluid intake on urinary incontinence, but one small new RCT (15), three new observational studies (1 case control study, 1 prospective cohort study, 1 cross sectional cohort study) examining the effect of caffeine on urinary incontinence, one in men presented in section IV (16), one in women (17) and one in both men and women (18) (Table 5).

A small double blind randomised crossover study by Wells *et al.* of 14 patients with OAB was conducted in which women were allocated to one of two groups. Group A were allocated to a 14 day caffeinated drink period followed by a 14 day de-caffeinated period. Groups B were allocated to a 14 day de-caffeinated period followed by a 14 day caffeinated period. Both were preceded by a 14 day run-in period. The primary outcome was reported episodes of urgency, frequency and volume per void recorded in a 3 day diary. Secondary outcomes included OAB symptom severity and health related quality of life (QOL). Of the eleven women who completed the study, a significant reduction of urgency ($p<0.1$) and frequency ($p<0.5$) were reported. Risk of bias was minimised using a double blind design, but conclusions must be cautious due to the very small sample size (15).

Three studies examined the association between caffeine and UI, Gleason *et al.* (2013) (17) examined the association in women in the US and Hyrayama *et al.* (2012)(18) in men and women in Japan and Davis *et al.* (2012)(16) in a male sample in the US.

In the cross sectional female US survey study, UI status was collected using the Incontinence Severity Index and food diaries were used to collect data on caffeine intake in 4309 women aged 20 or over. This study found an association between caffeine consumption in the highest quartile (>204mg day) was associated with any UI (prevalence odds ratio 1.47, 95% CI 1.07, 2.01), but not moderate or severe. Caffeine consumption at the very highest level was found to be associated with UI in a very large sample of US women. All parameters in terms of risk of bias reporting were unclear or high risk. The blinding of participants and personnel and blinding of outcome assessment were at high risk of bias and the likelihood of incomplete outcome data and selective reporting was also high.

Hirayama and Lees study comprised a sample of 683 men and 298 women (results for men are reported separately) aged 40-75 who completed a food frequency questionnaire and the Consultation on Incontinence short Form (ICI-SF). The data showed a slight increase in the risk of UI at the highest level of caffeine consumption (similar to the US data), but this was not significant after adjusting for confounding factors with OR: 95% CI, 1.12 (0.57-2.22) for women. The risk of bias reporting was largely unclear in this study with blinding of participants and personnel and blinding of outcome assessment, incomplete outcome data and selective reporting all of high risk. The sample of women did not show an association between caffeine and UI, they suggest the need for further larger samples to explore any association further.

Summary

There have been no new data on dietary content modification and UI since 2013, the existing evidence suggests that dietary content may play a role in urinary incontinence **(Level of Evidence: 3).**

Minimal evidence exists on the role of macronutrient intake and reduction of UI. Fluid intake may play a minor role in the pathogenesis of UI **(Level of Evidence: 2).**

Caffeine consumption is likely to play a role in exacerbating UI and related symptoms such as urgency and frequency. Small clinical trials suggest that decreasing caffeine intake improves continence**. (Level of Evidence: 2)**, new epidemiological evidence from a large cross sectional study supports this conclusion however it does not change the **Level of Evidence: Level 2.**

Recommendations

Recommendations for fluid intake and dietary intake have not changed **(Grade of Recommendation: B).** Further RCTs to assess the role of diet in UI are warranted.

A reduction in caffeine intake is recommended for those with incontinence and related symptoms **(Grade of Recommendation: B)** Larger RCTs to assess the effect of caffeine and other dietary factors are feasible and important.

Table 3 Summary of data on physical activity

Author, year	Comparator groups	N	Study population	Age	Assessment	Follow up	Outcomes
McGrother 2012(1)	Development of a Causative model for OAB	3411	Women in a UK epidemiological study of UI free from OAB at baseline	40+	Food frequency questionnaire and OAB recorded in a postal questionaire	no	Low physical activity linked to the onset of OAB. Older women reporting less activity than their peers had more than double the risk of developing OAB.
Nygaard 2015 (2)	Case control study	1538	Women seeking gynaecological primary care	39-65	POP assessment, severity index score (indicating SUI), Lifetime physical activity questionnaire	no	SUI odds increased with overall lifetime activity (OR 1.20 per 70 additional metabolic equivalent of task-h/wk; 95% CI, 1.02-1.41.

1.2.6 Constipation

No new trials on constipation were found. Therefore, the evidence remains the same (small observational studies) suggesting that chronic straining may be a risk factor for the development of UI **(Level of Evidence: 3).**

Recommendation

Further research is needed to define the role of straining in the pathogenesis of UI.

1.3. Other LUTS

No data were found.

1.4. Factors Affecting Outcome

No data were found.

2. PELVIC FLOOR MUSCLE TRAINING (PFMT)

Pelvic floor muscle training (PFMT) is defined as exercise to improve PFM strength, endurance, power, relaxation or a combination of these parameters (1). PFMT remains a key factor in the treatment of UI. Because pelvic floor muscle (PFM) integrity appears to play an important role in the continence mechanism (see report from Chapter 4: Pathophysiology), there is a biological rationale to support the use of PFMT in preventing and treating SUI in women (19-21). The role of PFMT in the treatment of UUI came later, when it was recognized that PFM contraction can also be used to occlude the urethra to prevent leakage during detrusor contraction, as well as inhibit and suppress detrusor contraction (22, 23). More details about the biological rationale regarding PFMT for SUI and UUI can be found in the last edition of this chapter (2).

PFMT is an intervention that involves the understanding of PFM activation and the pursuit of a repeated PFM exercise programme over time. Because effectiveness depends on the participant's adherence during the intervention and afterwards (in the maintenance phase), a better understanding of adherence mechanisms and how they can be promoted is of major importance. The 2011 International Continence Society State of the Science Seminar on Adherence produced 4 papers and a Consensus Statement reviewing present literature and making recommendations to increase PFMT adherence that could be useful, both in the clinical and research settings UI (24-28)

This section presents evidence for the use of PFMT in the prevention and treatment of UI in women. Questions addressed are:

- Is PFMT effective in the prevention of UI?
- Is PFMT better than no treatment, placebo or control treatments in the treatment of UI?
- Is one type of PFMT programme better than another in the treatment of UI?
- Is PFMT better than other treatments in the treatment of UI?
- Does the addition of PFMT to other treatments add any benefit in the treatment of UI?
- What factors might affect the outcome of PFMT in the treatment of UI?
- What is the effect of PFMT on other lower urinary tract symptoms (LUTS)?

2.1. Prevention and Treatment (Pregnant and Postnatal Women Only)

This subsection specifically considers PFMT for the prevention and treatment of UI in pregnant and postnatal women (called childbearing women). As the physiological changes of childbearing can affect PFM function, it is possible that the effect of PFMT might differ in this group compared to non-childbearing women; therefore, this group is treated separately.

Since the last ICI (2013), 11 randomised controlled trials aiming at prevention and/or treatment of UI were identified and reviewed for this subsection (29) (30) (31) (32) (33) (34) (35) (36) (37) (38) (39) (Table 6). An updated Cochrane review was published in 2012, analysing data from 22 trials involving 8485 women (40). Trials in this section have been grouped in 3 areas: 1) trials of PFMT for prevention of UI (performed in women without UI symptoms when randomised); 2) trials of PFMT for treatment of UI; and 3) trials of PFMT for the prevention and treatment of UI (participants with and without UI symptoms enrolled). Trials were further separated into those beginning during pregnancy (antenatal) or postnatal.

The primary outcome of interest was self-reported UI (cure, improvement, number of leakage episodes). Other outcomes of interest included adherence measures.

2.1.1 Is PFMT Effective in the Prevention of UI in Childbearing Women?

This section addresses the question of PFMT effectiveness for primary and secondary prevention of UI in childbearing women. Clinically it can be difficult to effectively screen trial participants to ensure that a disease process is altogether absent (for primary prevention studies) or present, although asymptomatic (for secondary prevention). Trials investigating prevention of UI usually enrol people purely on the basis of the absence of symptoms. Thus, the trials in this section likely represent a combination of primary and secondary prevention effects.

Since last chapter edition three new prevention trials were found (30, 36, 38) (Table 6) adding to the six previously existing trials.

Two studies (30) (38) recruited nulliparous or primiparous women during pregnancy, and one recruited

"pregnant women" (36). Primigravidae were recruited at weeks 6-9 (30), 10-14 (38) and 14-20 (36). In all trials, PFMT began during pregnancy while controls received usual antenatal care, which may have included advice on PFMT, from their maternity caregivers (30) (36) (38) There were some variations in the PFMT parameters (intensity and supervision) (Table 6).

Quality of data

Two were RCTs (30, 38), while one was a quasi-randomized trial (36). Allocation concealment appeared adequate only in the trial by Pelaez (2014) (38). The outcome assessors were not blinded in the trials by Kocaoz (2013) (36) and Pelaez (2014)(38), while Barakat (2011)(30) gives no information about blinding of evaluators. Dropout rates were 16% (30), 10-14% (38) and 22% (36), and quite similar in both study groups. Outcomes were measured at various times: outcome in late pregnancy was measured only after delivery (30), 36 weeks of pregnancy (38); 28 and 32 weeks of pregnancy then at three months postpartum (36). None of the trials applied intention-to treat analysis.

Results

- Late pregnancy (34 weeks or later): Pelaez (38) found a statistically significantly lower frequency of UI ($p<0.001$) in the intervention group compared to the control group between 36 and 40 weeks of pregnancy, and concluded that PFMT was effective in primary prevention of UI in primiparous pregnant women, while Barakat (30) reported no difference in frequency of urine loss between the exercise (supervised moderate physical exercise including PFMT) and control groups in late pregnancy.
- Mid postpartum (three to six month postpartum): Kocaoz (36) reported a statistically significant difference between the intervention and control groups in terms of development of stress urinary incontinence at the 28th and 32nd weeks of pregnancy and the 12th postpartum week ($p<0.05$).

Summary

Two studies documented the effectiveness of PFMT on primary prevention of UI during pregnancy (36, 38). One study included only nulliparous women and reported UI in late pregnancy (38). The other study also included multiparous women and reported UI in late pregnancy and 12 weeks postpartum (36). (**Level of Evidence: 1)**

Recommendations

Offer continent, pregnant women a supervised (including regular health professional contact) and intensive strengthening PFMT programme to prevent antepartum and postpartum UI **(Grade of Recommendation: A)**

Research recommendation

Additional trials with long-term follow-up (more than 12 months postnatal) are needed to determine long-term benefits of antenatal PFMT.

The only study including multiparous women is a quasi-randomized trial. Thus, large and good-quality RCTs are needed to investigate the effect of antepartum PFMT on preventing postpartum UI in multiparous women.

2.1.2 Is PFMT Effective in the Treatment of UI in Childbearing Women?

Since last chapter edition two trials assessing the treatment effect of postnatal PFMT were found (29) (34) (Table 6) adding to the four previously existing trials.

Kim (2012) recruited a mix of primiparous and multiparous incontinent women less than six weeks (34) after delivery, while Åhlund (2013) recruited only primiparous women 10-16 weeks after delivery (29). The control group in the trial by Åhlund received standard care, which included ante and postpartum advice on PFMT (1), whereas the control group/unsupervised training group in Kim's study were instructed in PFMT and followed the same PFMT programme as the supervised training group (34). The PFMT interventions varied (Table 6).

Quality of data

Both studies were RCTs, but random allocation concealment was inadequate. In one trial (34) evaluators were blinded to group allocation. Åhlund (2013) and Kim (2012) reported an 8% and 1% loss to follow up, respectively. Similar dropout rates were found in both study groups in both trials. Outcomes were measured, before, 3 months after delivery (34) and 6 months after delivery (29). Kim did not report analysis by intention-to-treat, while information is lacking in the trial by Åhlund.

Results

In the trial by Åhlund the results showed significantly improved continence in both groups, however there was no between group comparison. Kim reported significant difference in UI symptoms in favour of the supervised PFMT group.

Summary

Data from one trial showed significantly better treatment effect of supervised PFMT compared to unsupervised PFMT. The other trial did not compare difference in treatment effect between groups. The addition of the new trials does not change the level of evidence. **(Level of Evidence: 1)**

Recommendations

PFMT should be offered as first line conservative therapy to women with persistent UI symptoms three

months after delivery. **(Grade of Recommendation: A)**

An 'intensive' PFMT programme (in terms of supervision and exercise content) is likely to increase the treatment effect. **(Grade of Recommendation: B)**

Research recommendation

There is a need for at least one large, pragmatic, well-conducted and explicitly reported trial with long term follow-up (five plus years) of postpartum PFMT that investigates the long term effect of 'intensive' PFMT.

2.1.3 Is PFMT Effective in the Mixed Prevention and Treatment of UI in Childbearing Women?

Since last chapter edition six mixed prevention and treatment trials were found adding to the ten previously existing trials. Five trials assessed the effect of antenatal PFMT (31) (35) (37) (39) (32), and one the effect of postnatal PFMT (33) (Table 6).

In five trials, nulliparous, primiparous or multiparous women were randomised to either supervised antepartum PFMT or usual antepartum care (31) (32) (35) (37) (39). One study randomised nulliparous women to supervised postpartum PFMT or usual postpartum care (33). Ko (2011) and Miguelutti (2013) recruited nulliparous women and Stafne (2012) multiparous women between 16-24 weeks' gestation. Bø's study (2011) differed in that the primary aim was to assess the effect of regular exercise on weight gain in pregnancy. Primiparous, sedentary women within the first 24 weeks of pregnancy were recruited. Fritel (2015) included nulliparous women between 20-28 weeks of gestation.

i) Antepartum PFMT versus usual care

The PFMT interventions varied (Table 6).

Quality of data

- Antepartum PFMT versus usual care: The four RCTs had adequate random allocation generation and concealment and thus had a low risk of bias (31) (32) (37) (39). In two of the trials a blinded method of collecting patient-reported incontinence symptom data was used (32) (39). Sample sizes varied between 105 and 855 women (31) (39), and the proportions of lost to follow up were 20%, 2%, 33% and 11% respectively (31) (37) (32) (39). Losses to follow up in intervention and control groups were quite similar in all trials. Intention-to-treat analysis was performed by all, except for Bø (2011).
- Postpartum PFMT versus usual care or no PFMT: Random allocation generation and concealment was adequate and a blinded method of collecting patient-reported incontinence symptom was used in the trial by Hilde (2013) (33). Lost to follow up was 9%, in the control 14% and in the exercise group 3%. Analysis was by intention-to-treat.

Results

i) Antepartum PFMT versus usual care

Ko (2011), Miquelutti (2013) and Stafne (2012) showed that women who were randomised to antepartum PFMT had significantly less risk of UI in late pregnancy compared to a group receiving usual care in late pregnancy.

Three of the new five new mixed prevention and treatment trials assessing the effect of antenatal PFMT (35) (37) (39), reported a significant effect of PFMT during pregnancy, and 3 months after delivery (35). Bø (2011) found no difference in late pregnancy and 3 months postpartum, between a group following an aerobic fitness class including PFMT and a control group. While Fritel (2015) showed no difference in prevalence or severity of UI between a group receiving written instructions and a group receiving an additional eight PFMT sessions with a midwife or physiotherapist in late pregnancy, 2 and 12 months postpartum.

Some adherence outcomes were included for four antepartum (31) (35) (32) (39) trials; >80% of the PFMT women attended every group session, and at 36 gestational weeks, 87% reported PFMT practice at least 75% of the time (35); 40% of the exercise group attended >80% of the weekly exercise classes (31); 67% of the women in the intervention group and 40% in the control group performed PFMT three times per week or more (39); 54% in the intervention and 63% in the control group performed postpartum PFMT (32).

ii) Postpartum PFMT versus usual care or no PFMT

The only new mixed prevention and treatment trial assessing the effect of postnatal PFMT (33), found no differences in the prevalence of UI between a supervised PFMT group and a control group receiving instructions in correct PFM contractions and written information. Adherence was 96% in the intervention group (33).

Summary

The effect of antepartum PFMT or postpartum PFMT, in groups of women where some did and some did not have prior UI symptoms, varied by study with some showing a benefit on UI prevalence whereas others did not. The characteristics of the new trials, all methodologically robust, that demonstrated reduced UI prevalence in late pregnancy (35) (37) (39) and six months postpartum (35), were high adherence to a supervised PFM strength training program and home exercises. **(Level of Evidence: 2)**

However, a similar training protocol in postpartum women by Hilde (2013) did not show any difference between groups. Even if the combined results from the published trials still are not conclusive, the benefit of PFMT in the majority of the studies and the lack of adverse effects of PFMT should be taken into account.

Recommendations

Health providers should carefully consider the cost/benefit of population-based approaches to health professional taught antepartum or postpartum PFMT, that is, health professional instruction to all pregnant or postpartum women regardless of their current or prior continence status

(Grade of Recommendation antepartum PFMT: A)

(Grade of Recommendation postpartum PFMT: B)

Where a population approach is used, the 'best' evidence to date suggests the following: (a) an intervention comprising of a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting at 16-24 weeks' gestation for pregnant women, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more). **(Grade of Recommendation: C)**

2.2. Prevention (Other Women)

Although there are multiple trials of PFMT for prevention of UI in peri-partum women (see section II.2.1) and in men undergoing prostatectomy (see section IV.2), there is little research on prevention of UI in non-childbearing women. A single randomised trial (41) was found that investigated the preventive effects of a multi-component behavioural modification program, including PFMT, Bladder Training (BT), and other behavioural skills, compared to no intervention in 359 older women who were essentially continent (0-5 days of incontinent episodes in previous year). The intervention was a 2-hour class followed 2-4 weeks later with an individualized session to test PFMT technique and reinforce adherence. After 12 months, continence status was the same or better in 56% of the prevention group compared to 41% of the control (p=0.01).

In this trial, randomisation was conducted prior to eligibility assessment, leading to a relatively high rate of non-completion (97/238 in the treatment group and 65/242 in the control group; 162/480 overall). Analysis was not ITT. The method of randomisation was not described but the randomization block size was set at 16 to minimize the chance of prior recruiter knowledge of subject assignment. The assessors were not blinded.

Summary

There is preliminary evidence that PFMT may help prevent UI in older women. **(Level of Evidence: 2)**

However, more definitive trials are needed to clarify the effects of this multi-component program or other approaches to using PFMT as a prevention strategy in older women.

Recommendations

Without robust randomised controlled trials on the preventive effect of PFMT on UI the **Grade of Recommendation** is **Grade C (New).**

With limited new data on the effects of preventive PFMT on UI in older women, this association should be investigated further.

2.3. Treatment (Other Women)

2.3.1 Is PFMT Better than No Treatment, a Placebo, or a Control Group Treatment?

This updated literature review identified 19 new trials that compared PFMT to no treatment, sham treatment, or control treatment. Six trials were excluded from this summary because they selected women with "OAB," "lower urinary tract symptoms," or "pelvic floor dysfunction," thereby including women without urinary incontinence (42-47). Some included continent women, while others did not provide sufficient information to determine the continence status of participants. One additional trial was excluded due to insufficient detail about the intervention needed to discern whether PFMT was part of the treatment (48), and one was not considered because the sample consisted of residents in long-term care facilities (49). The 11 additional trials included in the analysis were diverse and included studies from 10 countries (See Table 7). Samples included young, nulliparous volleyball athletes, older women, peri-and post-menopausal women, obese women, and gynaecological cancer survivors. Most samples were drawn from community-dwelling populations.

PFMT Details

Most trials involved 12 weeks (3 months) of intervention, but some were of 6 weeks (50) or 8 weeks duration (51). Most involved supervised PFMT accompanied by a regimen of home-based exercises by a physiotherapist or nurse. One study tested a new smart phone application (52) with no face-to-face

contact. In several trials, PFMT was delivered on an individual basis (50, 53-57), while others were conducted in a group class (51, 58). Some trials were restricted to PFMT with or without functional PFM contraction to prevent SUI episodes (stress strategies, the Knack) (50, 57), while in others, PFMT was embedded in a multi-component programme with other behavioural or exercise components (Table 7). One trial included PFMT in a broader programme of general physical exercise (58).

Risk of Bias

Some of these 11 trials may have been limited by small sample size. Only 3 included more than 100 women, 3 included 50-100 women, and 5 had fewer than 50 participants. Two trials reported intent-to-treat analysis (52, 55). Three reported the method of randomisation (54, 55, 58); five reported concealment (52, 55, 58-60); and two reported using blinded outcome assessors (55, 58). Two studies were reported as abstracts making it difficult to assess some aspects of the methods and data quality (52, 55).

Results

A variety of outcome measures were used, including bladder diaries, validated questionnaires, global patient ratings, and pad test. Most trials used multiple measurements to evaluate outcomes.

Bladder diaries were used in 7 studies to assess change in incontinent episode frequency (52, 54-59). In all studies, reductions in incontinence episode frequency were significantly greater in the treatment group.

The UDI or UDI-6 was used in 4 trials to report change in urinary symptoms (54, 55, 57, 60). Significant differences were found in the two larger trials (54, 55). The ICIQ-UI was used as an outcome measure in two trials (51, 52), both demonstrating greater benefit for PFMT compared to control.

In 4 trials, the IIQ-7 was used to assess change in impact of UI. Two found significant between group differences (54, 59); one found significant change in the treatment group, but not in the control group; and the third did not observe improvement on this condition-specific quality of life measure (60).

The PGI-I was the primary outcome in one study that found 80% of women in the treatment group and 40% in the control group were “much better” or “very much better” (60). Similarly, in another trial, 55.7% of women in the treatment group were “better” compared to 5% in the control group (52).

Urine loss, assessed by 1-hour pad test (with provocation), was the primary outcome for one trial (50). Reductions in urine loss were greater in both treatment groups (individualized PFMT and group administered PFMT) compared to the control group. In four other studies that used a pad test as a secondary outcome, significant reduction and group differences were reported in two (54, 56), no differences in a third (55), the within and between group differences did not reach statistical significance (57).

Summary

PFMT is effective as a stand-alone therapy, as part of multi-component therapies embedding PFMT with concomitant behavioural strategies, lifestyle changes, and as part of more general physical exercise programmes to improve physical function in older women.

Results expand the evidence base to include PFMT implemented by mobile technology, with a potentially broader reach, cost savings, and impact on rural health.

Benefits are shown across age cohorts and UI type, in various cultural contexts, using several different training regimens, and assessed by multiple outcome measures. **(Level of Evidence: 1)**

Recommendations

Supervised PFMT should be offered as a first-line conservative therapy for women of all ages with urinary incontinence **(Grade of Recommendation: A).**

2.3.2 Is One Type of PFMT Programme Better than Another?

A number of factors can influence the outcome of a PFMT programme such as the way it is taught and/or supervised, the parameters of the actual exercises, and adherence to the training regimen. What, therefore, is the most effective PFMT programme?

This updated search revealed 24 new potentially eligible RCTs to address this question. Of them, one was excluded due to insufficient information on the incontinence outcome and inter-group comparison (61) and three because they did not report any incontinence outcomes but focused on PFM outcomes (62-64). Table 8 shows the studies included in the previous edition as well as those identified in this update. Characteristics of each new RCT are presented in Table 9.

Table 7 Summary of data on PFMT vs no treatment, a placebo or a control group treatment

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Abdulaziz 2012 (1)	No therapy	N=56 Tx: 29 CG: 27	Obese, older, peri-menopausal Saudi women with SUI (40-50 years)	3 months of supervised PFMT taught at physio clinic; 10 repetitions of 8 maximal contractions each, progressed to 12; 36 sessions	Fewer UI episodes on self-report (not BD) and better score on VAS (but p>0.05 for group diff) Tx group: significant change and 90% cured CG: no change and 19% cured	Small N may have affected results
Asklund 2015 Abstract (2)	Delayed treatment	N=123 Tx: 62 CG: 61	Women with weekly SUI (≥18 years; mean 45 years)	3 months of Smart phone app; PFMT exercises at different levels (6 basic and 6 advanced); graphic support and functions for statistics and reminders. No face-to-face contact	Web-based questionnaires and 2-day leakage diary; ICIQ-UI-SF, PGII, IEF, ICIQ-LUTSqol, use of incontinence aids, patient satisfaction (Tx group only). Tx group showed greater improvements on all outcomes (p<0.001).	ITT analysis Allocation concealment with sequentially numbered envelopes
Celiker 2015 (3)	Wait-list	N=130 Tx: 65 CG: 65	Women with SUI/MUI Excluded weak muscles	12-weeks of PFMT, 30 min sessions, supervised by physiotherapist, X3 per week initially, taught by perineal palpation, individually prescribed, home-based exercise. Included advice on bladder hygiene	UDI-6, IIQ-7, 3-day bladder diary, stop test, pad test. Tx group showed significant improvement on all outcomes and greater improvements than CG (p<0.0001).	Not ITT; randomization computer generated; allocation concealment Tx included behavioral/lifestyle advice.
Dumoulin 2011 (4) Abstract	Education program on osteoporosis (3 hours) and follow-up phone calls	N=48 Tx: 24 CG: 24	Postmenopausal women with osteoporosis and SUI, UUI, or MUI (55+ years)	12 weeks of Individualized PFMT, weekly 30-min PT sessions; daily home exercise; BF, urge control, BT, dietary advice and constipation advice.	7-day BD, 24-hour pad test, UDI. Post-treatment, Tx group had greater improvements on IEF (p=0.04) and UDI (p=0.04), but not pad test. At 1-year follow up, there were significant differences on IEF (p=0.04), UDI (p=0.03) and pad test (p=0.01).	Randomization computer generated Allocation concealment ITT analysis Blinded assessors No adverse events Tx included behavioral/lifestyle advice.
Ferreira 2014 (5)	Summary of PFMR education program via pamphlet	N=32 Tx: 16 CG: 16	Nulliparous, female volleyball athletes with SUI (13-30 years)	3 months of PFMR; “educational action,” awareness of PFM, and informational pamphlet; weekly visits; home exercise - 30 sustained contractions and 4 quick contractions daily; daily bladder diary for awareness	7-day BD and pad test (15 min during practice). Tx group showed greater reductions on IEF (p<0.001) and pad test (P<0.001).	Randomization by lottery (participant drawing paper from a box) Small N

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Karger 2015 (6)	No Tx	N=50 Tx: 25 CG: 25	Elderly women with SUI (60-74 years)	Two months; eight 45-min group training classes taught by a nurse; 8-12 contractions in each of 3 positions, 6-8 second contractions with 3-4 fast contractions added; home exercise: 8-12 high intensity contractions, X3 daily. Strength, awareness, and relaxation training for other muscle groups.	ICIQ-UI and self-esteem. Group differences observed on ICIQ-UI (p=0.001), and on individual items of frequency, amount of leakage, and QoL.	Tx included other types of exercise.
Kim 2011 (7)	General health class monthly for 3 months	N=127 Tx: 63 CG :64	Elderly Japanese women with SUI, UUI, or MUI (70+ years)	3 months, multi-dimensional exercise Tx; twice weekly group classes, PFM and general strength exercise. PFMT: 10 fast contractions (3 sec), 10 sustained contractions (8-10 sec); lying, sitting, and standing positions. One-hour class X1/month during 7-month follow-up. Home exercise: 2-3 sets as learned in class, at least X3/week for 30 min/day	Primary outcome was cure based on 7-day BD and ratings on 5-point scale (in BD); ICIQ Tx group showed greater change in urine leak score (p=0.007) and cure. Tx group 44.1% cure rate post-Tx and 39.3% at 7-month follow up vs 1.6% and 1.6% in CG (p<0.001).	Not ITT Computer generated randomization Randomization procedure blinded Blinded assessors
Leong 2015 (8)	Advice and pamphlet on management of UI	N=56 Tx: 27 CG: 28	Older Chinese women with SUI, UUI, or MUI (55+ years)	12-week PT program, 30-min individual training sessions, 8 sessions taught with manual palpation and verbal feedback; progressive exercise program starting with 10 slow submaximal contractions (5 sec) increasing to 25 per session; urge suppression + bladder training (BT).	7-day BD, IIQ-SF-7, 11-point VAS for perception of improvement and satisfaction. Tx group showed greater improvement in IEF (p<0.001) and IIQ-7 (p=0.001) and greater perception of improvement (p=0.004) and satisfaction (p=0.001). Reductions significant in Tx group only.	Computer generated randomization and allocation concealment Tx accompanied by urge suppression and bladder training
McLean 2013 (9)	No treatment	N=40 Tx: 20 CG: 20	Women with predominant SUI (18+ years)	12-week individualized PFMT program with weekly 30-min sessions; PFMT taught by manual palpation; home exercise: 3 sets of 12 PFM contractions daily	3-day BD, pad test, IIQ-7, UDI-6. Tx group showed greater changes on IEF (intragroup p=0.007) and IIQ-7 (intragroup p=0.0003); Neither group had significant change on pad test or UDI-6	Randomization by automated computer algorithm. Primary purpose of the study was to examine urethral morphology and mobility. Measures of UI were secondary outcomes.

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Pereira 2011 (10)	No treatment	N=49 Group: 17 Individ: 17 CG:15	Women with SUI only (18+ years)	6 weeks PFMT in group or individual sessions; two 1-hour sessions weekly (12 sessions); taught by vaginal palpation in both Tx groups; 3 s and 5-10 s contractions; repetitions and duration progressed; average of 100 contractions per session.	Primary outcome: pad test; secondary King's questionnaire and satisfaction. Both Tx groups showed greater improvement on pad test than CG ($p<0.0001$). Improvements shown in both Tx groups but not CG.	Randomization was by participants drawing envelope from a box; assessments not blinded; not ITT Purpose of the study was to examine group vs individual. No adverse events. Small N
Rutledge 2014 (11)	Usual care (no handout)	N=40 Tx: 20 CG: 20	Gyn cancer survivors with UI (37-79 years)	12 weeks; single 15-min training session; taught using levator ani palpation; 10 contractions 5 s duration; handout on behavioral management tips: fluid intake, reduction of caffeine and bladder irritants; constipation management; Home exercise: 3 sets of exercises daily for 12 weeks.	PGI-I and UDI-6 PGII: 80% in Tx group vs 40% in CG were "much better" or "very much better" ($p=0.02$). UDI-6: Groups not significantly different: Tx 70% vs CG 50% reported lack of bother ($p=0.62$).	Randomization generated by random number table. Allocation concealment Not ITT analysis Treatment included behavioral/lifestyle advice.

Quality of data

Of the 20 RCTs, 12 provided sufficient detail supporting adequate randomisation and allocation concealment methods (34, 50, 65-74). Of these, seven RCTs stated that the outcome assessors were blinded (34, 65-70). Pereira *et al*. (50) reported adequate randomisation and concealment but the evaluators were not blinded. Of the remaining eight RCTs, seven did not report sufficient information on allocation concealment methods and had unblinded assessors (75-81).

None of the included trials was large and half (10/20) included only 20 to 51 participants per group (65, 68, 69, 72, 74, 75, 77, 79-81). Eight had fewer than 20 participants per comparison group (34, 50, 70, 71, 73, 76, 78, 82). Six of the eight were reported as a pilot study (70-73, 76, 78). Only two RCTs had a larger sample size involving a total of 174 (66) and 245 women (67).

In four RCTs, a dropout rate of more than 46% in one study arm was reported. For instance, Dohanhoe *et al*. (78) reported 60% dropout in the PFMT combined with hip training and 20% in the PFMT group. Delgado *et al*. (72) had 37% and 57% in the PFMT group and PFMT combined with resistance, respectively. Liebergall-Wischnitzer *et al*. (67) reported a 46% and 37% dropout rate in the paula and PFMT group, respectively while Cruz *et al*. (65) had 42-53% dropout in the supervised and unsupervised PFMT group. The results of these RCTs should therefore be interpreted with extreme caution (65, 67, 72, 78).

Ongoing RCTs

Based on a research on protocol registry database, there is currently one ongoing large non-inferiority RCT comparing group versus individual supervised PFMT (83) (comparison 2). Involving 364 elderly women with SUI or MUI, this study is expected to be completed by March 2017. Moreover, the study of Buen *et al*. (84) is also ongoing and will compare the efficacy of PFMT and Pilates in preventing and treating UI (N=80) (comparison 3). The study of Navarro *et al*. (85) will evaluate the efficacy of hypopressive exercises in 78 women with various pelvic floor disorders including UI (comparison 3). Expected in July 2017, the study of Radlinger *et al*. (51) will assess the benefit of adding motor learning to PFMT in 96 women suffering from SUI or MUI (Comparison 8). Rao *et al*. (86) undertook a study comparing the addition of abdominal muscle training to PFMT in 300 women (Comparison 9). Three upcoming RCTs will assess the benefit of adding clinic-based BF to PFMT (87-89).

Results

- Comparison 1. Supervision of training: amount of contact with health professionals?

Subgroup 1.1: additional group supervision

No further studies investigated the effect of adding an additional supervised group exercise session.

Subgroup 1.2: additional phone calls

No new studies investigated the effect of adding supervisory phone calls to PFMT programmes.

Subgroup 1.3: individual supervision versus no supervision

Four new RCTs were included in this comparison (34, 65, 71, 75). The PFMT programmes evaluated differed with regard to the amount of health-professional contact but were similar in type and quantity of PFM exercises.

Self-reported cure: Women in the supervised group were more likely to report cure in comparison with women following unsupervised PFMT (71). Although non-statistically significant, Cruz *et al*. (65) also reported a higher cure rate in the supervised group.

Improvement: Two RCTs reported improvement in UI symptoms as assessed with validated questionnaires (34, 65). Both showed that women receiving supervised treatment reduced their UI symptoms significantly more than women in the unsupervised arm (34, 65).

Leakage episodes: There was no statistically significant difference in the number of leakage episodes when comparing supervised and unsupervised PFMT in women (71, 75).

Pad tests: Two of the four RCTs measured UI severity with pad testing (71, 75). Fitz *et al*. (13) showed that supervised treatment resulted in a more significant reduction of leakage than unsupervised PFMT while Ferreira *et al*. (71) reported a non-significant difference.

- Comparison 2. Supervision of training: individual versus group

Two new RCTs were included in this comparison; both studies used the same PFMT program and differed only according to the type of supervision (group vs individual). It should also be underlined that Pereira *et al*. (50) conducted an individual assessment of the PFM to teach active PFM contraction to all women prior to class training while Lamb al. (66) included this assessment only when required.

Self-reported cure: No data were reported.

Improvement: Non-significant differences in the symptom severity index were found between group and individual PFMT in the study of Lamb *et al*. (66) However, both Lamb *et al*. (66) and Pereira *et al*. (50) favoured individual treatment with regard to self-rated treatment benefits and the impact of UI (personal relationships and emotion domains), respectively. The study of Pereira *et al*. (50) involving 17 women per group, may be insufficiently powered to detect significant difference between groups. In the study of Lamb *et al*. (66), a large sample was included (n=174).

However, the information was limited in regard to whether this sample was sufficient to conclude treatment equivalence (as per sample size calculation in non-inferiority design).

Leakage episodes: No data were reported.

Pad test: Only the study of Pereira *et al*. (50) used the pad test and reported a non-significant difference between the two groups.

- Comparison 3. Exercise programme: direct versus indirect exercises

This comparison encompassed six subgroups evaluating direct versus indirect training. In "direct" PFMT, women specifically performed voluntary contractions of the pelvic floor muscles while in the "indirect" PFMT, women focused on other muscle groups in order to facilitate or stimulate pelvic floor muscle contractions.

Subgroup 3.1: PFMT versus sham/imitation

No new studies were found comparing PFMT to sham or imitation PFMT treatments (e.g. crossing the ankles and pulling the legs apart).

Subgroup 3.2: PFMT versus the 'Paula method'

The previous ICI chapter on conservative management included the study of Liebergall-Wischnitzer *et al*. (90) comparing PFMT to the Paula method. The 6-month follow-up of this study was included in the current review (67). It should be emphasized that the two groups did not receive the same amount of supervision by a health professional because the Paula group was individually supervised and the PFMT group had group teaching.

Subgroup 3.3: PFMT versus the 'Sapsford' approach

Our search revealed no new RCTs evaluating incontinence outcomes for this subgroup.

Subgroup 3.4: PFMT versus Pilates

No new RCT were found evaluating Pilates treatment in comparison to PFMT.

Subgroup 3.5: PFMT versus hip rotator training

One RCT was included in this subgroup evaluating the effectiveness of hip external and internal rotator training compared to PFMT (76).

Subgroup 3.6: PFMT versus hypopressive training

Our search revealed no RCT including hypopressive training conducted in women with UI.

Self-reported cure: No data were reported in the different sub-groups.

Improvement: Liebergall-Wischnitzer *et al*. (67) in subgroup 3.2 showed that UI results were maintained at the 6-month follow-up in both the Paula method and the PFMT groups. Women who received the Paula method intervention were more likely to report a lower rate of UI than women after PFMT. In subgroup 3.5, non-significant differences were found between hip rotator training and PFMT with regard to subjective UI improvement and UI symptoms and related impact (76).

Leakage episodes: Jordre *et al*. (76), subgroup 3.5, reported that women who received hip training had significantly fewer UI episodes than women in the PFMT group.

Pad test: Neither of the two new RCTs used pad-testing measurements.

- Comparison 4. Exercise programme: generic versus individualized exercises

No further evidence was available.

- Comparison 5. Exercise programme: submaximal versus near maximal contractions

No further evidence was available.

- Comparison 6. Exercise programme: daily versus three times per week.

No further evidence was available.

- Comparison 7. Exercise programme: addition of upright exercise position.

No further evidence was available.

- Comparison 8. Exercise programme: addition of strength training to motor learning.

Junginger *et al*. (68) evaluated PFMT and motor relearning taught with ultrasound imaging in comparison to regular PFMT using EMG biofeedback in women with SUI or MUI. Both groups had the same amount of contact with health professionals.

Self-reported cure: No data were reported.

Improvement: There was no difference between the two groups in the number who reported 'some' or 'great' improvement. However, women in the PFMT group were more likely to switch to the motor relearning group at RCT completion.

Leakage episodes: No data reported.

Pad tests: The pad-testing measure was not included (68).

- Comparison 9. Exercise programme: addition of abdominal or hip muscle exercises.

This comparison encompassed two subgroups evaluating the addition of either abdominal muscle (subgroup 9.1) or hip muscle (subgroup 9.2) training to PFMT.

Subgroup 9.1: PFMT vs PFMT+ abdominal muscle exercises

One new RCT evaluates the effectiveness of adding transverse abdominis exercises to PFMT (77). Limited information was available about the training protocol in this abstract report.

Subgroup 9.2: PFMT vs PFMT+ hip muscle exercises

Two RCTs investigated the addition of hip muscle exercises to PFMT in women with SUI (78, 82). The same amount of health-professional supervision was given to each group (78, 82).

Self-reported cure: No trial reported this outcome.

Improvement: There was no significant benefit of adding abdominal muscle exercises to PFMT in the study of Konstantinidou *et al*. (77) (subgroup 9.1). Likewise, Donahoe-Fillmore *et al*. (78) showed a non-significant difference between adding hip muscle exercises to PFMT training as assessed with the King's health question and the Incontinence Severity Index (sub-group 9.2). Results from the UDI-6 questionnaire, favoured the combined treatment (78). These findings should be interpreted with caution given the small sample size of Donahoe-Fillmore *et al*.'s study (78) (n=11).

Leakage episodes: Non-significant differences in leakage episodes were found when adding abdominal muscle (77) or hip muscle exercises (82).

Pad and paper towel tests: No data were reported.

- Comparison 10. Exercise programme: addition of intravaginal resistance device

The study of Delgado *et al*. (2009) (91), presented as an abstract, was included in the previous ICI edition. The complete published manuscript has now been included in the current review (72) along with a new study evaluating the addition of an intravaginal resistance device to PFMT in women with SUI or MUI (69). Both RCTs were the same in all aspects except that one group used an intravaginal device designed to increase resistance to the PFM contraction. In both RCTs, the resistance device was composed of a spring-loaded device with two limbs (69, 72).

Self-reported cure: There was no statistically significant difference between the groups in terms of the number of women who indicated they were 'cured' (72).

Improvement: There was no statistically significant difference between the groups in terms of self-reported improvement and reduction of symptoms as assessed with standardised questionnaires (69, 72).

Leakage episodes: No data were reported for this outcome.

Pad and paper towel tests: No data reported.

- Comparison 11. Exercise programme: addition of adherence strategy

No new RCTs investigated the efficacy of adding adherence strategies to PFMT.

- Comparison 12 Teaching programme: Addition of biofeedback (BF)

Six new RCTs compared PFMT alone to PFMT assisted with BF (70, 73, 74, 79-81). In these RCTs, the comparison groups were similar according to the amount of supervision and the intensity of training; they differed only with regard to the addition of biofeedback.

Two RCTs investigated clinic-based BF using pressure perineometry (79) and ultrasound imaging (70). Prudencio *et al*. (79) included women with SUI while Galea *et al*. (70) also evaluated women with UUI. Duration of treatment varied from 10 weeks (70) to 3 months (79).

Four RCTs evaluated home-based biofeedback using a Vibrance device (73), EMG BF (74) and pressure BF (80, 81). Of these, three were conducted in women with SUI (73, 74, 81) and one did not specify the type of UI of women included (80). In all RCTs, the same PFMT program was used in the comparison groups and differed only with regards to the addition of BF. Treatment duration varied from 12 weeks (74), 16 weeks (73, 81) and 6 months (80).

Self-reported cure: There was no statistically significant difference in terms of the number of women who indicated they were 'cured' between PFMT alone or combined with home-based (73) or clinic-based BF (79).

Improvement: Galea *et al*. (70) reported a non-significant benefit of adding clinic-based BF as assessed with the King's health questionnaire. Using the same questionnaire, Prudencio *et al*. (79) conversely reported a significant difference between groups but did not reveal which of the three treatment arms differed. With regard to home-based BF, three of the four RCTs reported a non-significant difference between PFMT combined or not with BF. Shin *et al*. (44) did not conduct any inter-group comparisons but reported a significant reduction of incontinence only in the group which received BF.

Leakage episodes: Galea *et al*. (70) found a non-significant difference in leakage episodes in women receiving or not clinic-based BF. Likewise, non-significant benefits were found when adding home-based BF to PFMT (74).

Pad and paper towel tests: Galea *et al*. (70) reported a non-significant benefit of adding clinic-based BF to PFMT as assessed with pad-testing measurements. Also, Hirakawa *et al*. (74) found a non-significant difference between women receiving or not home-based BF.

Summary

Based on current evidence, PFMT with regular (e.g. weekly) supervision is better than PFMT with little or no supervision **(Level of Evidence: 1)**. However, data were unclear as to whether supervision was more effective in individual or group settings. Sufficiently powered studies using appropriate design should be undertaken to investigate this comparison.

Based on limited evidence (6 previous RCTs and 2 new RCTs), 'indirect' methods of PFMT (e.g. the 'Paula method' or 'Sapsford' approach) are not better than direct PFMT, However, some data were confounded by differences in the amount of contact time with health professionals or the small sample size, which made it difficult to detect clinically significant differences **(Level of Evidence 2: *unchanged*).**

No robust recommendation can be made with regard to the type or specification of training (i.e. generic versus individualized exercises, submaximal versus near maximal contractions, daily versus three times per week, addition of upright exercise position).

There remains insufficient evidence as to whether the combination of PFMT with other treatment modalities (i.e. motor learning, abdominal- or hip-muscle training, intra-vaginal resistance device) could increase its efficacy.

With regard to clinic-based BF, new evidence (2 studies) reported no statistically significant differences between BF-assisted and non-BF groups for self-reported cure, improvement, or frequency of leakage episodes **(Level of Evidence: 1)**.

Likewise, there is no statistically significant differences between home BF and non-BF groups for self-reported cure, improvement, frequency of leakage episodes and pad-test measures in women with SUI **(Level of Evidence: 2).**

Recommendations

Clinicians should offer and provide the most intensive health professional-led PFMT programme possible within service constraints. **(Grade of Recommendation: A).**

Although studies are limited, there does not appear to be clear benefit for adding other modalities (i.e. motor learning, abdominal- or hip-muscle training, intra-vaginal resistance device) to PFMT **(Grade of Recommendation: B)**

There is no clear benefit from adding clinic- **(Grade of Recommendation: A)** or home-based BF (**Grade of Recommendation: B)** to a PFMT program.

Implications for research

Comparisons of PFMT approaches are, *de facto*, comparisons of two active treatments. It is therefore difficult to determine which approach is best unless (a) the differences in outcome are large or (b) the RCTs are designed with sufficient sample size to find small to moderate differences. Finding the best approach to PFMT remains among the highest research priorities. Future studies should be sufficiently powered to detect clinically important differences.

2.3.3 Is PFMT Better than Other Treatments?

Trials were considered for inclusion in this section if they compared PFMT with another stand-alone intervention, e.g. vaginal cones, bladder training, drug therapy. The 2013 ICI review concluded that PFMT is better than EStim, BT, or vaginal cones for women with SUI and better than duloxetine because of its side-effects. PFMT and surgery were both effective, but PFMT was recommended as first-line therapy because it is less invasive. For women with UUI or MUI, PFMT and BT were both deemed effective, with some evidence to suggest an advantage for PFMT. Evidence was sparse for a comparison between PFMT and drug therapies

Seven new trials were found that compared PFMT to another stand-alone treatment.

PFMT was compared to vaginal cones (92-94), surgery (95), continence pessary, (96, 97), drug therapy (98), and bladder training (98). One trial was a head-to-head comparison of PFMT to surgery (95). The other trials had more than two arms. They included PFMT alone and another treatment alone, but were also designed to evaluate combinations of treatments (See Tables 10 and 13).

Trials addressed the following comparisons:

i) PFMT versus vaginal cones (VC):

One recent Cochrane review compared PFMT to VC (92). This review considered the eleven studies included in this consultation along with two other RCTs (93, 94). Moreover, our literature search revealed the study of Golmakani *et al*. (60). Details of these new trials are presented in Table 13.

ii) PFMT versus EStim:

No new trials have been published.

iii) PFMT versus Bladder training (BT):

The Kafri trial examined the effects of PFMT alone and BT alone in the context of its 4-arm design (98). All groups had significant improvement at 3 and 12 months on all parameters, including UUI episodes. But, no significant time X group interactions were found that would indicate a difference between PFMT and BT (Table 10).

iv) PFMT versus drug therapy:

The trial by Kafri and colleagues examined the effects of PFMT alone compared to anticholinergic drug therapy alone in the context of a 4-arm design (98). All groups had significant improvement at 3 and 12 months on all parameters, including UUI episodes but, no significant time X group interactions were found that would indicate a difference between PFMT and drug therapy (Table 10).

v) PFMT versus surgery:

The single trial of surgery compared PFMT to mid-urethral sling in women with stress predominant UI (95). It was a multi-site trial involving 23 medical centres and 83 physiotherapists (Table 10).

vi) PFMT vs continence pessary:

A single new trial compared PFMT to continence pessary in women with stress predominant UI (96, 97). It was a multi-site trial conducted by the Pelvic Floor Disorders Network of the National Institute on Child Health and Human Development (NICHD) (Table 10).

Quality of data

i) PFMT versus VC:

Randomization and adequate allocation concealment were reported in the three new RCTs (93, 94, 99). Of these, two indicated that outcome assessors were blinded (93, 99). In the third study, the evaluator was unblinded (94). Sample sizes were small ranging from 15 to 30 women with SUI per group (93, 94, 99). Dropout rates were higher in the VC groups in two studies (93, 99); no loss to follow up was reported in the study of Pereira *et al*. (94). Substantial attrition occurred in the study of Harvey *et al*. (93) with drop-outs reaching 41% in the PFMT group and 72% in the VC group. Follow-up beyond the post-treatment evaluation was reported by Pereira *et al*. (94) in a subsequent publication with a 12-month post-treatment assessment (100).

ii) PFMT versus EStim: Not applicable.

iii) PFMT versus BT:

Risk of Bias - This trial was not a head-to-head comparison of PFMT and drug therapy, but rather a comparison of four treatment approaches including BT and combined therapy. Randomization method and allocation concealment were described. Analysis was conducted by ITT. It was not clear whether assessors were blinded.

iv) PFMT versus drug therapy:

This trial was not a head-to-head comparison of PFMT and drug therapy, but rather a comparison of four treatment approaches including BT and combined therapy. Randomization method and allocation concealment were described. Analysis was conducted by ITT. It was not clear whether assessors were blinded.

v) PFMT versus surgery:

Randomization method and allocation concealment were reported. Analysis included ITT and other approaches. It was not clear whether assessors were blinded. Fifteen women in the surgery group and 28 in the PFMT group did not start treatment after randomization. The ITT analyses did not include these individuals. Nineteen women in the surgery group and 28 in the PFMT group were lost to follow-up after starting treatment.

vi) PFMT vs continence pessary:

Randomization method and allocation concealment were reported. Analyses were performed by ITT.

Results and Summary

i) PFMT versus VCs:

As underlined in Herbison *et al*.'s meta-analysis (92) comprising 13 RCTs, most studies had a small sample size and differed according to the PFMT regimen (92). There was also limited overlap between outcomes. No statistically significant differences between PFMT and VC were found in subjective improvement or cure (reported in six RCTs) (Risk ratio (RR) for failure 0.97, 95% CI 0.75 to 1.24) (92). There were no significant differences in subjective cure (reported in five RCTs) (RR for failure 1.01, 95% CI 0.91 to 1.13) (92). Pooled data from these RCTs showed substantial heterogeneity. Likewise, inconsistency between RCTs was noted in relation to leakage episodes whereas a non-significant difference between treatments was observed (mean difference 0.00, 95% CI -0.20 to 0.20) (92). With regard to improvement in pad test, non-significant differences were found in the meta-analysis based on six RCTs (RR for failure 1.00, 95% CI 0.76 to 1.31). However, the new study of Golmakani *et al*. (60) favoured PFMT when using the 1-h pad test and the leakage index. With regard to quality of life improvement, the three new RCTs found a non-significant difference between PFMT and VC treatments (93, 94, 99). Three RCTs included in the Herbison review as well as the study of Golmakani *et al*. (60) reported the inability for some women to use VCs and adverse effects such as pain, vaginitis, bleeding and a sense of unpleasantness or inconvenience.

In the 14 RCTs (13 from the new Cochrane review, 11 of which were discussed in the previous ICI chapter edition and 1 additional RCT) that compared PFMT with VC in women with SUI, limited evidence suggests that VC appear to have similar effects or are not superior to PFMT **(Level of Evidence: 1)**. There were no statistically significant differences between interventions in subjective improvement or cure (reported in six RCTs), subjective cure (reported in five RCTs), or leakage episodes per day (reported in four RCTs), and no improvement in the pad test (reported in six RCTs). The additional RCT favoured PFMT using both the 1-h pad test and the leakage index. VC treatment may be inappropriate in some cases due to the inability to use and potential side effects as reported in four RCTs (i.e. pain, vaginitis, bleeding and a sense of unpleasantness or inconvenience)**.**

ii) PFMT versus EStim:

No new trials were found. Previous pooled data demonstrated that self-reported cure and cure/improvement were more likely in PFMT than in EStim groups **(Level of Evidence: 1).**

iii) PFMT versus BT:

There is evidence for an advantage of PFMT over BT for women with SUI **(Level of Evidence: 2).**

There does not appear to be a significant difference between PFMT and BT in UUI and MUI women **(Level of Evidence: 2).**

iv) PFMT versus drug therapy:

There is weak evidence that PFMT is more beneficial than drug therapy, but not enough evidence to change previous recommendations **(Level of Evidence: 2).**

v) PFMT versus surgery:

On the primary outcome, PGI-I at 12 months, perceived improvement was significantly greater in the surgery group compared to the PFMT group: 90.8% of women in the surgery group reported being "much better" or "very much better" compared to 64.6% in the PFMT group. Change in the UDI UI domain and OAB domain were also significantly greater with surgery and a higher proportion of women in the surgery group had subjective and objective cure.

The one new trial of PFMT compared to surgery appeared well-designed and adequately powered, providing evidence that mid-urethral sling may be more effective than PFMT for treatment of SUI in women **(Level of Evidence: 2)**.

vi) PFMT vs continence pessary:

The PFMT/behavioural group had better outcomes on the PFDI SUI subscale and greater patient satisfaction. The groups were not significantly different on the PGI-I, UI episode frequency, or outcome measures, including domains of the PFDI and PFIQ.

There may be some benefit for PFMT over continence pessary alone, the evidence is not strong enough to recommend one treatment over the other **(Level of Evidence: 2; Grade of Recommendation: D).**

Recommendations

For women with SUI:

- PFMT and VC are both effective as conservative therapy, although PFMT is better because inability of use and side effects are experienced with VC in some women **(Grade of Recommendation: B).**
- PFMT is better than EStim as first line conservative therapy **(Grade of Recommendation: B).**
- PFMT is better than BT as first line conservative therapy **(Grade of Recommendation: B).**
- PFMT and drug therapy are both effective as first line therapy, although PFMT is better because of side effects experienced with drug therapy **(Grade of Recommendation: B).**
- Surgery is more effective than PFMT, but potential benefit should be weighed against potential adverse events. PFMT should be offered as first line therapy due to its being less invasive. **(Grade of Recommendation: B New).**
- PFMT and continence pessary are both effective in first line conservative therapy **(Grade of Recommendation: B New).**

For women with SUI or MUI:

- VC do not appear to be better than PFMT in the treatment of UI. PFMT should be recommended as first-line conservative therapy **(Grade of Recommendation: B).**

VC with supervised training sessions by a trained health professional can be offered to women who can and are prepared to use them **(Grade of Recommendation: B).**

VC may be inappropriate for some women due to inability to insert or retain the cone or because of side effects and discomfort.

For women with UUI or MUI:

- PFMT and BT are effective first-line conservative therapy **(Grade of Recommendation: B).**
- PFMT is better than oxybutynin as first line therapy **(Grade of Recommendation: B).**

For women with UUI

- PFMT and BT are effective first line conservative therapy **(Grade of Recommendation: B).**

Research recommendation

Larger, good quality trials are needed to address each of the above comparisons if these are of interest to women. In planning comparisons researchers should consider carefully the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies.

Table 10 Summary of data on PFMT vs other treatments

Author, year	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Kafri 2013 (1)	Drug therapy (anticholinergic) BT	N=164 DT: 42 BT: 41 PFMT: 40 Conbined: 41	Women with UUI, No SUI (45-75 years)	PFMT based on National Institute for Health and Clinical Excellence (NICE) recommendations. Included behavioral guidance 3 sets of 8-12 slow maximal contractions sustained for 6-8 s in different positons. Daily home-based exercise prescribed.	Number of voids and UUI episodes, QOL-ruI, Urogyn VAS. All groups had significant improvement at 3 and 12 months on all parameters ($p<0.001$). No significant timeXgroup interactions (except favoring combination group)	Comparison was in the context of 4-arm trial, including arm for combined Tx. Randomization method and allocation concealment described. ITT analysis Not clear whether assessors were blinded
Richter 2010 (2) Kenton 2012 (3)	Intravaginal pessary	N=446 PFMT: 146 Pessary: 149 Combined: 151	Women with predominant SUI (18+ years)	12 weeks of supervised PFMT and behavioral strategies (PFM pre-contraction for SUI; urge suppression for concomitant UUI). Implemented in 4 visits at 2-week intervals. Home exercise: written prescriptions X3 daily exercise between visits.	Primary: PGI-I and SUI subscale of the PFDI at 3 months (FU 6 & 12 months) Secondary: Satisfaction, PFDI, PFIQ PFMT/behavioral group had better outcomes on the PFDI SUI subscale (49% vs 33% reporting no bothersome SUI symptoms, $p=0.006$) and greater satisfaction (75% vs 63%, $p=0.02$). Groups not significantly different on the PGI-I (49% vs 40% “much better” or “very much better,” ($p=0.09$), UI episodes on bladder diary, or other outcome measures including other domains of the PFDI and PFIQ.	Comparison was in context of 3-arm trial, including arm for combined Tx Multi-site trial Randomization method and allocation concealment reported ITT analysis

Author, year	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Labrie 2013 (4)	Mid-urethral sling	N=460 PFMT: 230 Surgery: 230	Women with predominant SUI (35-80 years)	Supervised, somewhat individualized program conducted by 83 PTs according to Dutch guidelines. Treatments given at 1-week or 2-week intervals with an intended 9 sessions in 9-18 weeks. Goal to build up to 8 to 12 maximal contractions X3 per day. Use of touch, tapping, massage, BF, or functional electrical stimulation allowed to increase muscle awareness as needed.	Assessed at 12 months Primary: PGI-I, 90.8% in surgery group were “much better” or “very much better” vs 64.4% in PFMT. Secondary: UDI, IIQ, PGI-S Both groups had significant improvement in UDI and IIQ domain scores. Change in UDI greater for surgery than PFMT on UI and OAB domains (P<0.001, .02) Subjective cure: (single question) 85.2% in surgery vs 53.4% in PFMT Objective cure: (cough test) 76.5% in surgery vs 58.8% in PFMT After 12 months, 99 women (49.0%) had crossed over to surgery after a mean 31.7 weeks.	Multi-site trial (23) Randomization computerized on central server Allocation not concealed Not clear whether assessors were blinded. 65 adverse events reported - all in surgery group. Analysis included modified ITT and other approaches. 15 in surgery group and 28 in PFMT group did not start treatment after randomization. 19 in surgery group and 28 in PFMT group were lost to follow-up after starting Tx.

2. Richter HE, Burgio KL, Brubaker L, Nygaard IE, Ye W, Weidner A, *et al*. Continence pessary compared with behavioral therapy or combined therapy for stress incontinence: a randomized controlled trial. Obstet Gynecol. 2010;115(3):609-17.

3. Kenton K, Barber M, Wang L, Hsu Y, Rahn D, Whitcomb E, *et al*. Pelvic floor symptoms improve similarly after pessary and behavioral treatment for stress incontinence. Female Pelvic Med Reconstr Surg. 2012;18(2):118-21.

4. Labrie J, Berghmans BL, Fischer K, Milani AL, van der Wijk I, Smalbraak DJ, *et al*. Surgery versus physiotherapy for stress urinary incontinence. N Engl J Med. 2013;369(12):1124-33.

2.3.4 Does the Addition of PFMT to Other Treatments Add Benefit?

Six trials addressed the following comparisons (Table 11):

i) PFMT+VC vs VC: Both the Herbison *et al.* meta-analysis (92) and the ICI 5th edition (2) included two studies comparing combined PFMT/VC versus VC. No new RCTs with the same comparators were identified.

ii) PFMT + EStim vs EStim: A single trial examined the effects of adding PFMT to vaginal EStim in 48 women with SUI (101). No significant differences were found between the groups.

iii) PFMT+ BT vs BT: Two trials examined the effects of adding PFMT to BT, one in 108 women with SUI, UUI, or MUI (102), the other in 164 women with UUI (no SUI) (98). In the first, significantly more patients in the combined therapy group reported cure or improvement and greater improvements on several secondary outcomes. In the second trial, all groups had significant improvement, but there were no significant interactions indicating differential group effects.

iv) PFMT + drug therapy vs drug therapy alone: A single trial examined the effects of adding PFMT to intravaginal oestriol in 206 postmenopausal women with SUI and vaginal atrophy (103). Combined therapy resulted in significantly greater improvement than oestriol only.

v) PFMT + continence pessary vs continence pessary:

A single trial examined combined pessary + PFMT to pessary alone in 446 women with stress predominant UI (97). The combined therapy group had significantly better outcomes on the PGI-I and the PFDI and reported greater satisfaction with treatment.

vi) PFMT + surgery vs surgery:

A single, multi-centre trial examined the effects of perioperative behavioural and pelvic floor muscle training (BPMT) in 374 women undergoing surgery to treat both apical prolapse and SUI (104). The group receiving BPMT resulted in no greater improvements in urinary symptoms compared to usual peri-operative care at 6 or 24-month follow up.

Summary

The literature on the effect of adding PFMT to another stand-alone therapy remains relatively small.

There is no evidence of benefit in adding PFMT to VC in women with SUI **(Level of Evidence: 2).**

There may be some benefit for adding PFMT when using a continence pessary **(Level of Evidence: 2)**.

PFMT may add benefit in terms of reducing SUI over intravaginal estrogen alone when treating women with vaginal atrophy **(Level of Evidence: 2)**.

There is some evidence that there may be benefit in adding PFMT to BT **(Level of Evidence: 2)**.

There is no evidence of improved outcomes with perioperative PFMT for women undergoing surgery for apical prolapse and SUI, or for adding PFMT to EStim in women with SUI **(Level of Evidence: 2).**

Recommendation

In women using VC, it does not appear to help to add PFMT **(Grade of Recommendation: C)**.

For the treatment of SUI, UUI, or MUI in women, consider a combination of PFMT and BT rather then BT alone **(Grade of Recommendation: C)**.

For treatment of UUI (tolterodine) but not for SUI (duloxetine), consider adding PFMT to drug therapy **(Grade of Recommendation: B),**

When treating women with SUI and vaginal atrophy, consider combining PFMT and intravaginal oestrogen over estrogen alone **(Grade of Recommendation: C New)**.

Note, many of these recommendations are based on single RCTs of variable quality. Larger, good-quality RCTs are needed to address each of the above comparisons. Furthermore, these studies examine the effects of combining therapies as an initial approach. Less is known about the effects of combining therapies in a stepped fashion when women do not achieve the desired outcomes with a single therapy (i.e. active PFMT than resisted PFMT with cones such as in progressive muscle training overload).

Table 11 Summary of data on PFMT + another treatment vs the other treatment

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
Richter 2010 (1)	Continence pessary alone	N=446	Women with stress predominant UI	Pessary + behavioral training Behavioral training program - supervised PFMT + behavioral strategies: PFMT pre-contraction for SUI and urge suppression for concomitant UUI. Treatment implemented in 4 visits at 2-week intervals and included written prescriptions for home exercise X3 daily between visits.	Primary: PGI-I and SUI subscale of UDI at 3 months Results - Combined therapy group had significantly better outcomes on the PGI-I (53.3% vs 39.6% reporting “much better” or “very much better,” p=.02) and the PFDI (44.0% vs 32.9% reporting no bothersome SUI symptoms (p=.05). Combined group also reported greater satisfaction with treatment (78.7% vs 63.1%, p=.003). The groups were not significantly different on number of UI episodes on bladder diary. Group differences not sustained to the 12-month follow up.	Multi-site trial conducted by the NICHD Pelvic Floor Disorders Network with randomization to 3 arms: pessary alone, behavioral training alone, combined Tx Data quality – Randomization method and allocation concealment were reported. Analysis conducted by ITT
Barber 2014 (2)	Surgery alone for prolapse and SUI	N=374	Women undergoing surgery to treat both apical vaginal prolapse and SUI	Surgery + perioperative behavioral and pelvic floor muscle training (BPMT) PFMT program - Single session 2-4 weeks prior to surgery; 4 postoperative visits (2, 4-6, 8, & 12 weeks) Individualized, supervised program of progressive home PFME, education on healthy bladder and bowel habits, and behavioral strategies to reduce UI episodes (PFM pre-contraction for SUI, urge suppression for UUI) Home PFME prescribed for X3 daily with duration increasing to 10 sec.	Primary: UDI at 6 months Results – Perioperative BPMT not associated with greater improvements in urinary symptoms at 6 months or 24-month follow-up	Multi-center 2X2 factorial trial with 2 distinct randomizations: First: to perioperative BPMT or usual care Second: to one of 2 surgical approaches for prolapse, each with concomitant retropubic midurethral sling for SUI. Data quality – Randomization method and allocation concealment reported.
Capobianco 2012 (3)	Intravaginal estrogen alone (estriol ovules, 1m daily for 2	N=206	Postmenopausal women with SUI and vaginal atrophy, no DO	Estrogen + PFMT with EStim (per Castro, 25) PFMT was for 6 months and included EStim. Further details lacking, but per	Outcome based on change in patient rating of SUI as none, mild, moderate, or severe before and after 6 months of treatment.	Data quality - Randomization method not described. Group allocation was concealed. Analysis was by ITT AEs were reported

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
	wks, then 2.wk for 6 months)			reference to a previous article, PFMT was conducted in 45-minute group sessions X3 per week under the supervision of a physiotherapist.	Results - Combined therapy resulted in significantly greater improvement than estriol only. 73.5% (61/83) of treated and 9.7% (10/103) showed improvement in UI (p<.01)	Not clear all women actually had SUI.
Kafri 2013 (4)	BT alone	N=164	Women with UUI, no SUI (ages 45-75)	Bladder training + PF rehab and behavioral. PFMT program based on the National Institute for Health and Clinical Excellence (NICE) recommendations. Women practiced 3 sets of 8-12 slow maximal contractions sustained for 6-8 s in different positons. Daily home-based exercise was prescribed, and urge suppression using PFM contraction was taught.	Number of voids and UUI episodes, voids/24 hours, QoL-rUI, Urogyn VAS, number of pads Results - analysis was by repeated measures ANOVA with all four groups, including tests for main effects and group X time interactions. However, statistical analysis did not include comparisons between individual groups. All groups had significant improvement at 3 and 12 months on all parameters, (p<.001) but there were no significant interactions. UI episodes decreased by 1.7/day in BT and 4.0/day in combined therapy, but a test of this difference was not conducted. Only CPFR showed significant reduction in voids/24 hours.	Comparison was in context of 4-arm trial: BT alone, PFMT alone, drug therapy alone, and combined Tx. Data quality –Randomization method and allocation concealment described. Analysis conducted by ITT. Not clear whether assessors were blinded.
Kaya 2015 (5)	BT alone	N=108	Women with SUI, UUI, MUI	BT + PFMT for 6 weeks High-intensity PFMT program conducted in 4 visits across 6 weeks by an experienced physical therapist. Home-based exercise regimen initiated with 5 sets of exercises per day and progressed to 30 sets per day (600 PFM contractions).	Primary: global rating of improvement on a 4-point scale (worse, unchanged, improved, cured). Secondary: UI severity, symptom distress, QOL, UI episodes, voids/day. Results – Significantly more patients in the combined therapy group reported cure or improvement (100% vs 82.7%, p=.001). Greater improvements observed for combined therapy on secondary outcomes, including severity of UI (ISI; p=.001),	Data quality –Randomization method and allocation concealment described. Analysis conducted by ITT. Not clear whether assessors were blinded.

Study	Comparator	N	Study Population	Intervention	Outcomes/Results	Notes
					UDI-6 (p=.001), IIQ-7 (p=.005), and incontinent episode frequency per bladder diary (p=.024).	
Furst 2014 (6)	EStim alone Vaginal probe; two 30-min sessions per week; frequencies of 4Hz and 50Hz; fixed intensity (20mA); 4 s stimulation/rest cycles	N=48	Women with SUI (Mean age 49.6)	EStim + PFMT for 3 months PFMT program – individually designed by PT, 2 30-min sessions per week. PFMT and EStim conducted on alternate days. No home PFME program	Improvements in urinary symptoms, IEF per bladder diary, satisfaction (perception of need or not to repeat or change Tx); assessments at 3, 12 and 96 months. Results – Both groups showed improvement in leakage episodes and voiding intervals. No significant between group differences.	Data quality – Randomization method described; allocation concealed. Analysis not conducted by ITT (only included patients who had not received any additional therapy)

3. WEIGHTED VAGINAL CONES (VC)

Weighted vaginal cones (VC) were developed as a method for testing PFM function and to provide progressive muscular overload during PFM strengthening exercises (105). In theory, when a cone is inserted into the vagina, the sensation of 'losing the cone' provides strong sensory feedback that prompts the PFM to contract to prevent the cone from slipping out. Women start in a standing position with a weighted cone held inside the vagina for at least one minute, incrementally adding time and increased cone weight whilst standing or walking. The goal is to walk around for 20 minutes without losing the cone; the gradual increase in cone weight maintains muscle overload over the course of the exercise programme.

There are various cone weights and sizes (Figure 1). However, the effectiveness of the VC training method is unclear. Because orientation of the vagina is not completely vertical, some women can retain the cone without actually contracting the pelvic floor. Radiology has also demonstrated that the cones can rest in a transverse position (106). Depending on the axis of the vagina, women need to produce different force intensities to retain the cone. Thus, using VC as a measure of PFM function may not be a valid method. Finally, some women may find it impossible to insert the cones due to a narrowed vaginal opening or, conversely, to retain it due to an enlarged vaginal opening, prolapse, or an insufficient PFM contraction, one incapable of holding even the lightest cone.

This section examines the evidence for VC in the prevention and treatment of UI in women. Questions addressed:

- Are VC better than no treatment, placebo or control for the prevention of UI?
- Are VC better than no treatment, placebo or control for the treatment of UI?
- Are VC as effective as other treatments for the treatment of UI?
- Are VC combined with PFMT better than PFMT alone for the treatment of UI?

Figure 1 Weighted vaginal cones

3.1. Prevention

No previous (prior to last Consultation) or new RCT investigating either the primary or secondary prevention effects of training with VC for women with UI were found.

3.2. Treatment

A Cochrane review specifically addressing the effectiveness of VC in the treatment of UI was updated in March 2013 (92) This meta-analysis and four new studies form the basis of this subsection (79, 99, 107, 108). Table 12 illustrates the number of studies included in the 5th ICI and in the Cochrane review of Herbison *et al*. (92) as well as the new studies identified in the current update. Characteristics of each RCT not included in the previous ICI are presented in Table 13.

3.2.1 Are VC Better than No Treatment, Placebo or Control Treatments?

The meta-analysis published by Herbison *et al. (92)* comprised 5 RCTs comparing VC to a control treatment. Except for Pereira *et al*. (94) (presented in Table 13), these studies were part of the ICI previous edition. Our literature search identified no further RCT.

Quality of data

In the study of Pereira *et al.* (94), adequate allocation concealment and randomisation was reported. The evaluator was however not blinded to patient assignation. No attrition was reported in the VC group while 13% dropped out from the control group. No adverse effects were reported in this RCT.

Results

As discussed in Herbison *et al*.'s meta-analysis (92), women in the VC groups were more likely to report they were *cured* than the controls (RR for failure 0.84, 95%CI 0.76 to 0.94). VCs were also better than control treatment in the *subjective reporting of cure or improvement* (RR for failure 0.72, 95%CI 0.52 to 0.99). Further, Pereira *et al.* (94) reported better incontinence-related QOL and a significant reduction in the 1-h pad test for women in the VC group compared to the control treatment.

Summary

VCs with supervised training sessions by a trained health professional are better than control treatments for subjective reporting of *cure* or *cure/improvement* and the QOL impact on the treatment of SUI **(Level of Evidence: 1).**

However, VC treatment may be inappropriate in some cases due to potential reported side effects (92).

Recommendations

For women with SUI, VCs with supervised training sessions by a trained health professional may be offered as a first-line conservative therapy to those who can and are prepared to use them **(Grade of Recommendation: B)**

Trained health professional assessment is recommended. VC may be inappropriate in some cases due to inability to insert or retain the cone or because of side effects and discomfort. **(Grade of Recommendation: D)**.

3.2.2 Are VC As Effective as Other Treatments?

VC have been compared with PFMT and EStim, but not with other therapies such as drug treatment, BT or surgery.

i) VC versus PFMT

This comparison is addressed in Section II.2.3.3. Details of the VC and PFMT programs for each trial are presented in Table 13.

ii) VC versus EStim

Since the last ICI edition, a meta-analysis update was published. (92) It comprised the same trials as in the ICI 5th edition as well as the study of Santos *et al*. (109) (presented in Table 13). Our literature search revealed no further trials.

Quality of data

i) VC versus PFMT: See Section II.2.3.3.

ii) VC versus EStim

In the study of Santos *et al.* (109), participants were randomly assigned to treatments while blinding of assessors and allocation concealment were not clearly reported. No losses to follow-up were reported (109).

Results

i) VC versus PFMT: See Section II.2.3.3.

ii) VC versus EStim

As reported in the Herbison *et al*. meta-analysis (92), there was no statistically significant difference between VC and EStim in the pooled data of three trials with regard to self-reported *cure* (RR for failure 1.26 95% CI 0.85 to 1.87). Non-significant differences also emerged from the pooled data of three RCTs with respect to improvement in pad test (RR 1.21 95%CI 0.90 to 1.63) and leakage episodes (Mean difference -0.05 95% CI -0.27 to 0.17). Herbison *et al*. (92) reported discomfort or side effects associated to both EStim and VC (VC: abdominal pain, vaginitis, bleeding, motivational problems and difficulties using the VC. EStim: tenderness and bleeding, discomfort or motivational and other difficulties in using the EStim).

Summary

The meta-analysis of Herbison *et al*. (92) including six RCTs revealed no significant difference between VCs and EStim in terms of *self-reported cure, cure/improvement*, improvement in pad test or the number of leakage episodes; both the VC and EStim groups reported adverse events.

VC and EStim seem equally effective in the treatment of SUI and MUI. **(Level of Evidence: 1).** Side effects and discomfort appear to limit their utility in clinical practice. **(Grade of Recommendation: D)**.

3.2.3 Are VC Combined with PFMT Better than PFMT Alone?

Both Herbison *et al*.'s meta-analysis(92) and the ICI 5th edition relied on two RCTs comparing combined PFMT/VC to PFMT alone. Our search revealed three additional studies presented as published abstracts (79, 107, 108). Details of the PFMT/VC and PFMT are presented in Table 13.

Quality of data

Limited information on method and results were available from these published abstracts (79, 107, 108). Although participants were randomly assigned, no information on allocation concealment and blinding of assessors was provided. The sample sizes were relatively small with no more than 39 patients per treatment arm. Dropouts ranged from 0 (79) to 13% (108) in the PFMT group and 0% (79, 108) to 5% (107) in the combined treatment.

Results

Including two RCTs, Herbison's meta-analysis reported no significant differences between PFMT/VC and PFMT alone for either *cure* or *cure/improvement*. Likewise, the results from the three additional RCT failed to show any significant difference between treatments in terms of *subjective cure* (79, 108) and *subjective cure/improvement* (107). Porta Roda *et al*. reported that improvement occurred earlier in the combined group (after 3 months of treatment) but this was not maintained at the end of the treatment (6 months of treatment) (107).

Summary

Limited evidence suggests no benefit from adding VCs to PFMT for women with SUI **(Level of Evidence: 2).**

Recommendations

No recommendation is possible for combination intervention. Adequately powered studies are needed to confirm or refute the advantages of adding VCs to PFMT (No Recommendation).

3.3. Other Lower Urinary Tract Symptoms (LUTS)

In the previous ICI, two RCTs reported data on the efficacy of VC on urgency and nocturia (Williams *et al*. 2006) and nocturia (Gameiro *et al*. 2010). Our search revealed no new RCTs on other lower urinary tract symptoms.

3.4. Factors Affecting Outcome

None of the RCTs above addressed the effect of age or other factors on the outcome of VC training. Nonetheless, in the 22 RCTs included here, on average, 22% of the women being treated with VCs (range 0 to 63%) withdrew from the study or dropped out. Although few RCTs examined the causes of attrition, among those that reported causal factors low compliance, motivational problems, unpleasantness, aesthetic dislike, discomfort, and bleeding were implicated although no one reason predominated.

4. ELECTRICAL STIMULATION (ESTIM)

The theoretical basis of neuromuscular electrical stimulation (EStim) interventions has emerged with increasing understanding of the neuroanatomy and physiology of the central and peripheral nervous systems. The mechanisms of action vary depending on the cause(s) of UI and the structure(s) being targeted e.g. PFM or detrusor, peripheral or central nervous system. In general, the aim of EStim for SUI appears to be to increase proprioception and/or to improve the muscle function of an atrophied or weak PFM, while for UUI the objective seems to be to inhibit detrusor overactivity (DO) (1).

EStim is provided by clinic-based mains powered machines or portable battery powered stimulators (Figure 2) with a seemingly infinite combination of current types, waveforms, frequencies, intensities, electrode types and placements (Figure 3). Without a clear biological rationale, it is difficult to make choices about different ways of delivering EStim. Additional confusion is created by the relatively rapid developments in the area of EStim, and a wide variety of stimulation devices and protocols that have been developed even for the same condition.

Figure 2 Neuromuscular electrical stimulation equipment

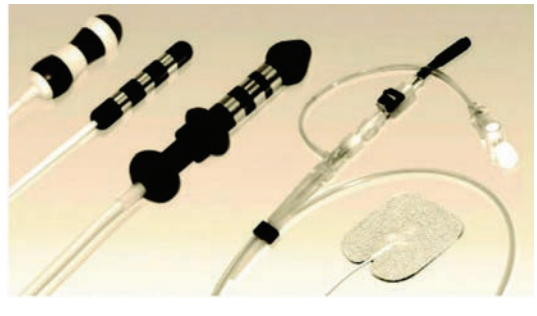

Figure 3 Neuromuscular electrical stimulation electrodes

Finally, the nomenclature used to describe EStim remains inconsistent. EStim has not only been described based on the type of current being used (e.g. faradic, interferential), but also on the structures targeted (e.g. neuromuscular), the current intensity (e.g. low-intensity, or maximal stimulation), and the proposed mechanism of action (e.g. neuromodulation). In this section, EStim type and parameters are reported in line with International Continence Society definitions (1).

This section presents the evidence for the use of EStim in the prevention and treatment of UI in women. Questions addressed are:

- Is EStim effective in the prevention of UI?
- Is EStim better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?
- Is one type of EStim better than another in the treatment of UI?
- Is EStim better than other treatments in the treatment of UI?
- Does the addition of EStim to other treatments add any benefit in the treatment of UI?
- What is the effect of EStim on other LUTS?
- What factors might affect the outcome of EStim in the treatment of UI?

Eligible interventions were non-invasive EStim without implanted electrodes. (Magnetic stimulation and posterior tibial nerve stimulation are described in Sections II.5 and II.6). Other criteria for inclusion were (1) randomised or quasi-randomised (alternate allocation) trial design, (2) women with UI or other LUTS, (3) no participants with incontinence due to neurological or cognitive impairment and (4) no pregnant or postpartum women (within 12 months of childbirth). Trial data reported in conference abstracts as well as full-text papers were included. EStim compared with PFMT and vaginal cones are covered in previous sections (sections II.2.3.3 and II.3.2.2). This section focuses on EStim compared with no active treatment or other conservative treatments.

The primary outcomes were cure rates (the number of women with no urinary incontinence episode at time of assessment) and improvement rates (the number of women improved, including cure). There was considerable variability in the way these outcomes were measured. Women's self-report was given priority but for studies in which it was not reported, the rate based on diaries was used as a proxy; where diary data were also not reported, the rate based on pad tests or any other definitions chosen by the trialists was used (110). Data on health-related quality of life and adverse effects were also extracted. Data at the end of the prescribed treatment phase, or at the first outcome measurement, if later, were used in the analysis. Any treatment effects shown are likely to reflect maximum effect of each intervention. Data from further follow-up were also recorded.

Due to the small number of available studies per intervention, data were sub-grouped by dominant type or pattern of incontinence: (1) studies with all or at least 50% of participants having SUI alone or a predominant symptom of SUI (as defined by trial investigators), (2) studies with all or >50% of participants having UUI alone or a predominant symptom of UUI (as defined by trial investigators), (3) other studies of participants with UI in which neither stress- or urgency-UI represented a predominant symptom in the study population ('UI all types' hereafter), and (4) studies of overactive bladder (OAB) or DO in which it was unclear whether all participants had UI.

Single EStimates with 95% confidence intervals (CI) were derived for each study comparison using odds ratios (OR) for dichotomous variables or mean difference (MD) for continuous variables. Summary EStimates were calculated using random effects models if there was more than one study reporting the same outcome (meta-analysis).

'Risk of bias' in the included studies was assessed for allocation concealment (selection bias) and completeness of outcome data (attrition bias), using relevant items in a standard tool developed by the Cochrane Urinary Incontinence Group (111). Risk of bias regarding blinding to the allocated intervention was high in most included studies: blinding of participants and care providers is not always feasible (other than the use of sham EStim), and blinding of outcome assessors is equally difficult for self-reported outcomes such as cure, improvement and quality of life.

Description of intervention in included studies of EStim

Nine new trials were identified for this update, making a total of 42 trials included in this section. All new trials targeted women with SUI or predominant SUI. No new studies for predominant UUI, DO or OAB (incontinent or not) were found for this update. Findings for UUI, UI all types, DO and OAB are therefore unchanged from 5th ICI. The number of included studies by dominant type or pattern of incontinence is summarised in Table 14.

In addition, there was one study, published in Portuguese, which was a three-arm trial comparing EStim and PFMT (N = 24), PFMT (N = 25) and control (N = 22) (112). This trial could not be incorporated here, as an English translation was not available.

The EStim parameters and protocols in this section are summarised in Table 15. Some approaches to treatment are now less common, such as the use of interferential current or external electrodes. There was considerable variation in the intervention protocol. Although the biological rationale and purpose of EStim might be different depending on diagnosis, there was no consistency in the EStim protocols used for women with SUI, UUI, UI all types, or DO.

4.1. Prevention

No published trials were found.

Table 14 Studies of EStim included in the previous review (5th ICI) and current update (6th ICI)

	Studies included in the previous review (5th ICI)	New studies identified in this update (6th ICI)	Total
EStim vs No active treatment

4.2. Treatment

4.2.1 Is EStim Better than No Active Treatment (Placebo, Sham, Control or No Treatment) for Treatment of UI?

Four new studies including 267 women with SUI or predominant SUI (113-116). Participants in one of these studies were women who had responded positively to physiotherapy treatment for their UI (10-15 sessions), with EStim used to maintain the benefit of initial physiotherapy (114). One study (115) was a pilot study for a newly identified study (113).

Characteristics of the new studies comparing EStim with no active treatment are presented in Table 16. No active treatment consisted of no treatment (113, 115), sham EStim (116) or usual care (114). One study was a three-arm trial. Two of the arms using surface and intravaginal EStim (N = 31) were combined and compared with the 'no treatment' arm (N = 17) (113).

Quality of data

Three studies reported adequate methods of allocation concealment, namely third party involvement (113, 116) or opaque (and sealed) envelopes with third party involvement (115) in the allocation procedure. One study did not describe methods used for allocation concealment (116). Trial results were reported for everyone who entered the trial in one study (115) but this was not done in the others. One study is funded by the manufacturer of the study stimulator (114).

Results

SUI or predominant SUI. When adding new studies to those previously reported, pooled data suggest that cure rates were, on average, higher for EStim compared with no active treatment but the difference was not statistically significant (N = 434, 22% vs 5%, OR 2.43, 95% CI 0.89 to 6.60) (116-123). Improvement rates were statistically significantly higher for EStim compared with no active treatment (N = 613, 53% vs 30%, OR 3.64, 95% CI 1.82 to 7.27) (114, 116-118, 120-124), although there was some evidence of statistical heterogeneity for the improvement rate (I-squared = 45%). The result of this meta-analysis using additional data from newly identified studies remains similar to the analysis performed in the 5th ICI, except that effect size was larger and confidence interval for cure was wider, and effect size was smaller and confidence interval was narrower for improvement.

Quality of life was reported in seven studies, using diverse measures. Six studies, including 4 new studies, found statistically significant differences favouring EStim compared with no active treatment (113-116, 118, 119), and one previous study found no significant differences between the groups (125). All new studies that reported this outcome favoured EStim: one (114) used the International Consultation on Incontinence Questionnaire (ICIQ), one (116) used the Incontinence Quality of life (I-QoL) questionnaire, and two used the King's Health Questionnaire (KHQ) (113, 115).

Adverse effects appeared uncommon. One new study reported bleeding in one and discomfort in three of 64 participants using the active EStim device and none of 29 participants in the sham EStim device (116). This is in line with two previous studies that reported tenderness and bleeding (118), and vaginal irritation, pain or infection (123) associated with the device. Another study reported that one participant each in the treatment (N = 78) and control (usual care; N = 86) groups was lost to follow-up due to adverse effects (no further detail was provided) (114).

Summary

A total of 21 studies assessed the effect of EStim compared with no active treatment, including 13 in women with SUI or predominant SUI, three in UUI or predominant UUI, two in all types of UI, and three in DO/OAB (incontinent or no).

Findings from update analysis using the additional data from newly identified studies were broadly similar to those from the 5th ICI. Included studies were generally assessed as having a high risk of bias.

EStim might be more effective than no treatment in improving symptoms and quality of life in women with SUI and improving symptoms in women with UUI, although this may not result in cure **(Level of Evidence: 2).**

Information on quality of life was sparsely reported particularly for UUI or DO, and the limited data that were available were not consistent. Adverse effects appear uncommon but some women experienced discomfort with the treatment device. Scant data were available on long-term performance.

Recommendations

EStim might be better than no treatment to improve symptoms and quality of life in SUI women **(Grade of Recommendation: B)**.

EStim may be considered for treatment to improve symptoms for UUI **(Grade of Recommendation: B).**

However, this recommendation should be viewed with caution until the findings are supported or refuted in further trials; it would be particularly useful if further trials used validated and reliable quality life measures as a primary outcome indicator particularly for UUI.

4.2.2 Is One Type of EStim Better than Another in the Treatment of UI?

Four new studies including 145 women with SUI and predominant SUI (113, 126-128) were found. The characteristics of the new studies comparing one type of EStim with another are presented in Table 17. Different variants of EStim were assessed, either alone

(113, 126, 128) or as an adjunct to PFMT and biofeedback (127).

Table 17 Summary of data on different types of EStim comparisons

Author, year	Comparator	N randomised	Study population	Duration (months)	Outcome**
SUI or predominantly SUI					
Alves 2011 (1)	Medium frequency ES vs Low frequency ES (number per group not reported)	24	SUI alone	1.5	Cure based on pad test: 10/10 vs 10/10 Improvement: NR QoL: NR Adverse effects: NR
Correia 2014 (2)	Surface ES (15) vs Vaginal ES (16)	31	SUI alone	1.5	Cure: NR Improvement: NR QoL via KHQ: N = 30, mean difference 2.22 higher, 95% 6.95 lower to 11.39 higher Adverse effects: NR
Huebner 2011 (3)	Dynamic ES + PFMT + BF† (36) vs Conventional ES + PFMT + BF† (36)	72	SUI or SUI-predominant MUI	3	Cure: NR Improvement: NR QoL via KHQ: N = 61, mean difference in change from baseline 4.10 lower, 95% CI 6.77 to 1.43 lower Adverse effects: allergic reaction to lubricant
Maher 2009* (4) (ongoing)	External ES vs Vaginal ES (number per group not reported)	18	SUI alone	2 (outcome measured at 1 month)	Cure: NR Improvement: NR QoL: NR Adverse effects: NR

Note: For modality details or parameters, see Table 14.

NR = not reported; KHQ = King's Health Questionnaire (higher scores indicate greater impairment);

* abstract only;

**Source of cure and improvement outcomes: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.

† Electromyography-assisted biofeedback

2. Correia GN, Pereira VS, Hirakawa HS, Driusso P. Effects of surface and intravaginal electrical stimulation in the treatment of women with stress urinary incontinence: randomized controlled trial. European Journal of Obstetrics and Gynecology and Reproductive Biology. 2014;173(1):113-8.
3. Huebner M, Riegel K, Hinninghofen H, Wallwiener D, Tunn R, Reisenauer C. Pelvic floor muscle training for stress urinary incontinence: a randomized, controlled trial comparing different conservative therapies. Physiother Res Int. 2011;16(3):133-40.
4. Maher RM, Crowe L, Caulfield B. Comparison of two methods of electrical muscle stimulation training of pelvic floor musculature in the treatment of stress urinary incontinence (Abstract). Journal of Women's Health Physical Therapy. 2009;33(1):24.

One study comparing external and vaginal EStim for women with SUI, available only as an abstract, did not report any of the specified outcomes and thus did not contribute to the analysis (128). Since there is little duplication of EStim interventions, it was not thought appropriate to combine study findings.

Quality of data

Allocation concealment was adequate in one study which involved a third party in the allocation procedure (113). The other three studies did not mention allocation concealment (126-128). Data were reported only for those who completed the trial in two studies (126, 127) but it was unclear in the other two studies if trial results were reported for everyone who entered the trial (113, 128).

Results

SUI or predominant SUI. One new small study comparing medium and low frequency EStim found no difference for cure rates (126). The results for improvement rates are as reported in two previous studies (129, 130).

While no information was available on quality of life and adverse effects in the 5th ICI, two new studies reported quality of life using the KHQ. The first study comparing 'dynamic' EStim (contract pelvic floor muscles, and then add stimulation at maximal contraction) with 'conventional' EStim (perform stimulation, rest, and contract pelvic floor muscles) found a statistically significant difference favouring 'dynamic' ES, although study authors considered the difference to be small and not clinically important (127). The second study comparing surface and vaginal EStim found no statistically significant difference between the groups (113).

One new study in which EStim was performed as an adjunct to PFMT and biofeedback reported that one of 72 participants had an allergic reaction to biofeedback lubricant and withdrew from the study, although it was unclear in which group these adverse effects occurred (127).

Summary

A total of eight studies assessed the effect of one approach of EStim compared with another, with six in women with SUI and predominant SUI and two in women with DO. No study focusing on UUI or predominant UUI was identified.

Findings from an updated analysis using the additional data from newly identified studies were broadly similar to those from the 5th ICI. Included studies generally had a high risk of bias. There were eight small trials comparing different EStim protocols; the clinical heterogeneity between studies meant it was not appropriate to pool the data.

Based on a single trial (130) for women with SUI, maximal clinic-based stimulation may be more effective than low-intensity home-based stimulation in improving symptoms, although no data were available on cure rates, quality of life and adverse effects **(Level of Evidence: 2).**

The other studies did not find clinically important differences between stimulation groups for the specified outcomes; the studies were small and may have been underpowered. Further comparisons of EStim protocols are needed.

Recommendations

For women with SUI maximal clinic-based EStim might be better than daily low-intensity home-based EStim in improving symptoms **(Grade of Recommendation: B).**

There is a need for studies to elucidate the purpose and biological rationale for EStim in different diagnostic groups, so these can then be tested and compared in clinical trials.

4.2.3 Is EStim Better than Other Treatments for UI?

No new study was found that investigated whether EStim is better than other treatments for UI. The level of evidence and recommendations remains unchanged from the previous review (5th ICI) formed on the basis of six studies (124, 131-135).

Summary

The 5th ICI included six studies, including one in women with SUI, one in women with predominant UUI, and four in women with OAB/DO (wet or dry).

Included studies were generally assessed as having a high risk of bias. With small numbers per comparison group available, there is insufficient evidence to determine if EStim is better than vaginal oestrogens in women with SUI, propantheline bromide in women with UUI, or oxybutynin and tolterodine for DO **(Level of Evidence: 2).**

Recommendation

Based on current limited evidence, EStim could be considered as an alternative to medical treatment. Medical treatments (drugs) appear to be no more effective than EStim **(Grade of Recommendation: B)**. These findings need to be investigated further with high quality trials, if it is a clinical question of interest to women.

4.2.4 Does the Addition of EStim to Other Treatments Add Any Benefit in the Treatment of UI?

Three new studies including 52 women including women with SUI and predominant SUI were found (127, 136, 137). The characteristics of these new

studies are presented in Table 18. Two studies (136, 137) combined EStim with PFMT (EStim + PFMT vs PFMT), while the other (127) combined EStim with PFMT and biofeedback (EStim + PFMT + BF vs PFMT + BF)..

Table 18 Summary of data on EStim + another treatment vs the other treatment

Author	Comparator	N randomised	Study population	Duration (months)	Outcome**
SUI or predominantly SUI					
Jeyaseelan 2003* (1)	ES + PFMT (6?) vs PFMT (7?)	13?	SUI alone	2	Cure: NR Improvement: NR QoL via IIQ (% change from baseline): N = 6, median -27%, range -63 to 0, vs. N = 7, median 0%, range -67 to 200 QoL via UDI (% change from baseline): N = 6, median -32%, range -50 to -18, vs. N = 7, median 0%, range -43 to 180 Adverse effects: NR
Patil 2010 (2)	ES + PFMT (55) vs PFMT (55)	13	USI alone	1	Cure: NR Improvement: NR QoL via IIQ: N = 102, mean difference 12.53 lower, 95% CI 19.45 to 5.61 lower Adverse effects: NR
Huebner 2011 (3)	ES + PFMT + BF† (72) vs PFMT + BF† (36)	26	SUI or SUI-predominant MUI	3	Cure: NR Improvement: NR QoL via KHQ Dynamic ES+PFMT+BF vs PFMT+BF: N = 55, mean difference in change from baseline 4.60 lower, 95% CI 7.43 to 1.77 lower; Conventional ES+PFMT+BF vs PFMT+BF: N = 60, mean difference in change from baseline 0.50 lower, 95% CI 3.22 lower to 2.22 higher Adverse effects: allergic reaction to lubricant

Note: For modality details or parameters, see Table 14.

NR = not reported; IIQ = Incontinence Impact Questionnaire (lower scores indicate better QoL); KHQ = King's Health Questionnaire (higher scores indicate greater impairment); UDI = Urogenital Distress Inventory (higher scores indicate greater discomfort);

† Electromyography-assisted biofeedback

1. Jeyaseelan S, Oldham JA. Can the effects of pelvic floor muscle exercises be enhanced with a new pattern of electrical stimulation in women with stress incontinence (Abstract). Proceedings of the World Confederation for Physical Therapy (WCPT), 14th International Congress, 7-12 June, Barcelona. 2003.

2. Patil SP, Nagrale AV, Ganvir SD. Additive effect of interferential therapy over pelvic floor exercises. International Journal of Therapy & Rehabilitation. 2010;17(11):596-602.

3. Huebner M, Riegel K, Hinninghofen H, Wallwiener D, Tunn R, Reisenauer C. Pelvic floor muscle training for stress urinary incontinence: a randomized, controlled trial comparing different conservative therapies. Physiother Res Int. 2011;16(3):133-40.

One study was a three-arm trial that included both 'dynamic' EStim (stimulation added at maximum contraction of pelvic floor muscles) and 'conventional' EStim (stimulation followed by rest and pelvic floor muscle contraction) as two of the study arms (127). These arms were combined in the analysis. One study is a pilot study, available only as abstract, with limited information (136).

Quality of data

Allocation concealment was inadequate in one study which used opaque sealed envelopes but with no indication of third party involvement in the allocation procedure (137). The other two studies did not mention allocation concealment (127, 136). In two studies, data were reported only for those who completed the trial (127, 137) and it was unclear in the other study if trial results were reported for everyone who entered the trial (136).

Results

i) EStim + PFMT vs PFMT

SUI or predominant SUI. Two new studies assessing EStim as an adjunct to PFMT compared with PFMT alone, contributed no additional data in terms of cure, improvement and adverse effects. The 5th ICI previous analysis for these outcomes therefore remains unchanged.

Three studies reported data on quality of life with inconsistent results. One previous study found no statistically significant differences between the group (138), whereas one new study using the Incontinence Impact Questionnaire (IIQ) found a statistically significant difference favouring the group which combined EStim with PFMT (137). The results from another new study based on either the IIQ or the Urogenital Distress Inventory were inconclusive, due to the pilot nature of the study and small sample size (N = 13) (136).

ii) EStim + PFMT with biofeedback vs PFMT with biofeedback

SUI. One new study assessed EStim as an adjunct to PFMT and biofeedback compared with PFMT and biofeedback alone. This was a three-arm trial, assessing a combination of either 'dynamic' or 'conventional' EStim with PFMT and biofeedback, compared with PFMT and biofeedback alone (127).

This study did not provide any data on cure and improvement rates (127). Thus, the 5th ICI analysis of improvement rates based on two studies (129, 130) remains unchanged, with no available information on cure rates.

While no information was available on quality of life and adverse effects for this comparison in the 5th ICI, the new study (127) reported that quality of life scores based on the King's Health Questionnaire improved statistically significantly for the group which combined 'dynamic' EStim with PFMT and biofeedback, compared with PFMT and biofeedback alone, although study authors did not consider the difference to be clinically important. No significant difference was found for the group combining 'conventional' EStim with PFMT and biofeedback, compared with PFMT and biofeedback alone.

In the same study (127), one of 72 participants had an allergic reaction to biofeedback lubricant and withdrew from the study, although it was unclear in which group this occurred.

Summary

A total of 15 studies assessed the effect of EStim as an adjunct to another treatment, compared with the other treatment alone. All but two studies included women with SUI or predominant SUI. No study focusing on UUI or predominant UUI was identified.

Findings from update analysis using the additional data from newly identified studies were broadly similar to those from the 5th ICI. For comparisons of EStim with PFMT versus PFMT alone, there was no clear evidence of a difference between the groups in women with SUI or predominantly SUI in terms of cure and improvement. Evidence for quality of life outcomes was not consistent across studies **(Level of Evidence: 2).** There was also no evidence to suggest that the addition of EStim to a BF-assisted PFMT was more effective than BF-assisted PFMT in women with SUI **(Level of Evidence: 2).** A few women experienced adverse effects with EStim. There is no evidence to draw any conclusion about the effect of adding EStim to PFMT for women with UUI.

Recommendations

The addition of EStim to PFMT or BF-assisted PFMT programmes does not appear to add benefit **(Grade of Recommendation: B);** combinations of techniques need to be investigated further with high quality trials if this is a clinical/research question of interest to women.

4.3. Other LUTS

In the 5th ICI, there were no trials that analysed the effect of EStim in women with other LUTS alone.No new published trials were found.

4.4. Factors Affecting Outcome

None of the included trials addressed the effect of age, or any other factor, on outcomes of EStim. There was no clear indication from the included trials that EStim could not be tolerated by elderly. There is no reason, therefore, to either exclude older women from studies of EStim, or not to offer EStim as part of a conservative management programme, except where recognised precaution with use of intra-vaginal electrodes in women with vaginal atrophy and contraindications such as a cardiac pacemaker are present.

One newly identified study including elderly women (over 60 years old) highlighted the potential embarrassment perceived by the elderly with regard to conventional intra-vaginal stimulation and suggested that surface EStim may be a more acceptable method for this population (115).

Of note, in a prospective cohort of 3,198 women treated with home-managed EStim in Norway during 1992-1994, there was no association between self-reported improvement and age (139). In the same cohort, success rates as defined by clinicians were higher in younger individuals but this effect was not significant after controlling for other factors.

Aside from age, other factors may have the potential to mitigate treatment outcome. On the basis of trial reports to date, it appeared that there was considerable variation in EStim protocols with no consistent pattern emerging. EStim protocols are also often poorly reported, lacking detail of stimulation parameters, devices and methods of delivery. The wide range of protocols that have been tested may have affected the effect EStimates reported in this section. ICS/IUGA has produced a physiotherapy interventions terminology paper in the last year, and authors are encouraged to refer to this paper when reporting EStim parameters in a publication (1).

It is not clear whether one diagnostic group may benefit more than another from EStim. It has been hypothesised that, in women with SUI who cannot voluntarily contract the PFM to begin a PFMT programme, EStim might help initiate or substitute for a voluntary contraction. However, most studies focusing on the efficacy of EStim do use EStim to initiate or substitute for a voluntary PFM contraction (140). To date, there has been no trial addressing this hypothesis.

As with all conservative therapy modalities, one of the key factors to the success or failure of EStim is treatment adherence. Some authors commented on adherence or reported adherence data. Of the new studies identified for this 6th ICI update, one study reported that adherence to EStim was satisfactory (116) and another reported that the EStim regimen was adhered to by over >75% of participants (114). However, adherence measures were highly variable, making comparison across studies difficult.

5. POSTERIOR TIBIAL NERVE STIMULATION (PTNS)

Posterior tibial nerve stimulation (PTNS) is a form of peripheral neurostimulation targeted towards symptom relief of OAB and UUI (141). Indirect access to the sacral plexus is achieved by intermittent, electrical stimulation of the posterior tibial nerve, which lies behind the medial malleolus. PTNS may be minimally invasive, involving insertion of a fine needle close to the nerve (Percutaneous PTNS), or non-invasive, using skin surface electrodes applied to the medial malleolar area (Transcutaneous PTNS)(141).

PTNS aims to stimulate the sacral nerve plexus through the afferent fibres of the posterior tibial nerve, a mixed nerve containing L5-S3 fibres (142). The S3 nerve root contains sensory fibres from the pelvic floor and parasympathetic motor efferent fibres to the detrusor as well as the pelvic sphincters and the pelvic floor muscles. Afferent nerve stimulation can therefore lead to activation of inhibitory sympathetic neurons and suppression of detrusor contraction through a direct sacral route. Urodynamic studies have shown that electrical stimulation of the posterior tibial nerve increases cystometric capacity and suppresses detrusor contraction (143-145). The full mechanism of action of treatment effect for PTNS is not yet understood, however it is thought that the observed effects may be related to a neuroplastic reorganisation of sacral spinal reflexes and regulation of cortical excitability (146, 147).

Percutaneous PTNS is performed as an outpatient procedure. It involves inserting a 34-gauge needle 3–5 cm cephalad to the medial malleolus. The needle is connected to a low-voltage stimulator device, and a grounding pad is placed on the bottom of the foot just below the smallest toe. Transcutaneous PTNS may be delivered either in clinic or self-administered at home. Self-adhesive electrodes are placed behind the medial malleolus and 10cm proximal to this. The positive lead is connected to the proximal electrode and the negative to the distal electrode and both are connected to a portable battery-powered stimulator. The intensity level of the stimulation current for percutaneous PTNS and transcutaneous PTNS is determined once correct positioning has been established by noting sensory and motor (hallux) reaction (Figure 4).

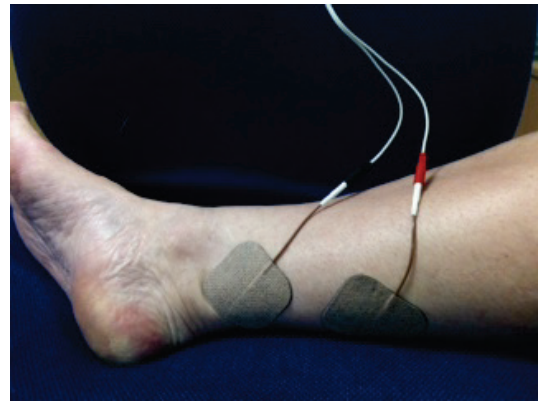

Figure 4 PTNS equipment

This section presents the evidence for the use of PTNS in the prevention and treatment of UI in women. Since this is a new section for the Conservative Management chapter, the same search strategy as EStim section was used although no date restrictions have been applied to the literature search.

Table 19 Summary of PTNS protocols

Author, year	Current	Current Intensity	Pulse Shape & Duration	Frequency (Hz)	Duty Cycle	Electrodes	Treatment Duration	Target UI
Bellette 2009 (1)	NR	NR	NR	NR	NR	NR	2 months	OAB

Questions addressed are:

- Is PTNS effective in the prevention of UI?
- Is PTNS better than no active treatment (placebo, sham, control or no treatment) for treatment of UI?
- Is one type of PTNS better than another in the treatment of UI?
- Is PTNS better than other treatments in the treatment of UI?
- Does the addition of PTNS to other treatments add any benefit in the treatment of UI?
- What is the effect of PTNS on other LUTS?
- What factors might affect the outcome of PTNS in the treatment of UI?

Eligible interventions were PTNS/neurostimulation/ neuromodulation, percutaneous or transcutaneous. Eligibility criteria for study participants and outcomes, as well as criteria used to assess 'risk of bias' in the included studies, were identical to those used in the previous section on EStim (Section II.4).

Description of intervention in included studies of PTNS

A total of 11 studies were eligible and are summarised in Table 19 (148-158).

5.1. Prevention

No studies that investigated either primary or secondary prevention of UI or LUTS were identified.

5.2. Treatment

5.2.1 Is PTNS Better than No Active Treatment (Placebo, Sham, Control or No Treatment) for Treatment of UI?

Three studies compared PTNS with no active treatment (Table 20) (148, 149, 151). One study included women with UUI (149) and two included women with OAB where some but not all participants had UI. No study focusing on SUI or predominant SUI was found.

A placebo or a sham procedure was employed as a comparator in all three studies. In two studies, the sham procedure was described as having electrodes placed without turning on the electrical generator (148, 151). In another study (149), the electrical generator was turned on only for a few seconds to allow the patient to experience a mild sensation; prior to treatment, patients in both groups had been counselled that the subsequent absence of the sensation was due to adaptation. The choice of a different needle position in the sham group was to eliminate any presumed response that could arise from the acupuncture effect from piercing the skin cephalad to the medial malleolus (149).

Quality of data

One study described using a computer generated randomisation list (149); other studies did not report randomisation techniques (148, 151). No study reported information on allocation concealment. Results were reported for everyone who entered the trial in one study (148), and another study reported 5% attrition rate from PTNS group and 13% from the sham group and that the reasons for drop out from each group were unrelated to the treatment (149), however it was unclear whether the other study had missing data (151).

Results

(a) UUI. No included studies reported information on cure rates. One study (149) reported that improvement rates were significantly higher for PTNS compared with no active treatment (reported p value <0.001). I-QoI scores found a significant difference between the groups which was due to a lack of significant change after the sham procedure and to the significant increase (improved quality of life) after PTNS (149). No serious adverse effects were reported in either group but patients in both groups reported occasional transient pain at the stimulation site (149).

(b) DO/OAB. There was no information on cure rates.

Summary

The three included studies were small (35-43 participants). All were generally assessed as having a high risk of bias. Data pooling was not possible. Data available from two studies on women with UUI or OAB suggests PTNS may be more effective than no active treatment in improving symptoms and quality of life, although no data were available on cure **(Level of Evidence: 2).** The included studies reported no serious adverse effects associated with either active or sham treatment **(Level of Evidence: 2).** No evidence was available for women with SUI or predominant SUI.

Recommendations

For women with UUI or OAB, PTNS may be more effective than no active treatment in symptom control **(Grade of Recommendation: C New).**

More studies with larger sample sizes and consistent and clear reporting of core outcomes would be beneficial in reaching a conclusion on the effectiveness of PTNS over no active treatment.

5.2.2 Is One Type of PTNS Better than Another in the Treatment of UI?

No study was found for this comparison.

5.2.3 Is PTNS Better than Other Treatments for Treatment of UI?

Five studies compared PTNS with drug treatment (Table 21).

Table 21 Summary of data on PTNS vs other treatments

Author, year	Comparator	N random-ised	Study popula-tion	Duration (months)	Source of outcome**
UUI					
Preyer 2007* (1)	Percutaneous PTNS (16) vs Tolterodine (15)	31	UUI	3	Cure: NR Improvement: NR QoL via unspecified tool (higher scores indicate improvement): mean 4.4 higher, 95% CI 1.7 to 7.1 higher vs mean 4.6 higher, 95% CI 2.1 to 7.0 higher, reported p value = 0.93 Adverse effects: unspecified events noted
DO/OAB					
Manriquez 2013* (2)	Transcutaneous PTNS vs Oxybutynin (number per group not reported)	56	OAB	3	Cure: NR Improvement: NR QoL via OAB-q: no significant difference, no data Adverse effects: NR
Preyer 2015 (3)	Percutaneous PTNS (18) vs Tolterodine (18)	36	OAB (wet or dry)	3	Cure: NR Improvement: NR QoL via VAS, change from baseline, median [range]: N = 18, 1.9 [0 to 8] vs N = 18, 2.7 [0 to 8.5], reported p-value = 0.07 Adverse effects: pain, dry mouth, dizziness
Souto 2014 (4)	Transcutaneous PTNS (25) vs Oxybutynin (25)	50	OAB	3	Cure: NR Improvement: NR QoL via ICIQ-SF, mean [range]: 7.2 [0 to 18] vs 9.8 [0 to 18] at 3 months (treatment end), 8.3 [0 to 20] vs 13.3 [8 to 20] at 6 months (i.e. 3 month after treatment) QoL via ICIQ-OAB, mean [range]: 5.9 [1 to 11] vs 4.6 [0 to 10] at 3 months, 6.1 [1 to 20] vs 9.2 [4 to 13] at 6 months Adverse effects: NR
Vecchioli-Scaldazza 2013† (5)	Percutaneous PTNS (20) vs Solifenacin Succinate (SS) (20)	40	OAB (some had UUI)	1.5	Cure: NR Improvement: NR QoL via PGI-I (Wilcoxon test for paired sample, mean, SD): Group A (SS→PTNS): post SS 2.9 (1.1), post PTNS 2.1 (0.7); Group B (PTNS→SS): post SS 3.1 (1.0), post PTNS 2.3 (0.7) QoL via OAB-q: significant improvement in all groups both with SS and PTNS Adverse effects: NR

Note: For modality details or parameters, see Table 19.

NR = not reported; ICIQ-SF = International Consultation on Incontinence-Short Form (higher scores indicate increased severity); ICIQ-OAB = International Consultation on Incontinence-OAB (higher scores indicate increased severity); OAB-q = Overactive Bladder Questionnaire (higher scores indicating worse condition); PGI-I = Patient Global Impression of Improvement Questionnaire (lower scores indicate greater improvement); VAS = Global response assessment on visual analogue scale (higher scores indicate greater impact on QoL);

4. Souto SC, Reis LO, Palma T, Palma P, Denardi F. Prospective and randomized comparison of electrical stimulation of the posterior tibial nerve versus oxybutynin versus their combination for treatment of women with overactive bladder syndrome. World Journal of Urology. 2014;32(1):179-84.
5. Vecchioli-Scaldazza C, Morosetti C, Berouz A, Giannubilo W, Ferrara V. Solifenacin Succinate versus Percutaneous Tibial Nerve Stimulation in Women with Overactive Bladder Syndrome: Results of a Randomized Controlled Crossover Study. Gynecologic & Obstetric Investigation. 2013;75(4):230-4.

PTNS was compared with solifenacin succinate in one (158), tolterodine in two (153, 154) and oxybutynin in two (150, 157). The target population had OAB (with UI in some but not all of the participants) except for one study (153) where it was UUI. No study focusing on SUI or predominant SUI was found. One study used a cross-over design (158). Another study was a three-arm trial comparing PTNS versus oxybutynin versus PTNS and oxybutynin; only the findings for PTNS vs oxybutynin are reported here (157).

Quality of data

One study described using a computer generated sequence using adaptive randomisation, where allocation was centralised using telephone (154). Permutated blocks were used in one study but it was unclear whether there was allocation concealment (150). Other studies did not report such information on allocation concealment nor provided details on the randomisation process (153, 157, 158). In one study there was a dropout rate of 11% in both groups (154). In another study (158), a two-arm crossover trial of PTNS and Solifenacin where group A had Solifenacin then PTNS after a washout period and group B had PTNS then Solifenacin, there was a dropout rate of 30% from the group A and 20% from group B; the reasons were refusal of further treatment (10% vs 5%), no indication for starting treatment (10% vs 15%). A further 10% dropped out from group A as a result of adverse effects of treatment. Twenty-six percent of participants were excluded from analysis in one study (157) because they failed to comply with 12 weeks of treatment and/or did not attend follow up at six months; the reasons for non-compliance or missing data were not reported. In one study (150), it was unclear whether results were reported for everyone who entered the trial, while in another (153) the authors did not account for all drop-outs.

Results

(a) UUI. There was no information on cure and improvement (153). Quality of life outcomes, measured using an unspecified tool, improved in both groups, although there was no statistically significant difference between them (153). One study reported unspecified adverse events in one of 16 participants and six of 15 participants in the PTNS and Tolterodine groups respectively; authors did not specify the nature of these adverse events (153).

(b) OAB. Data on cure or improvement were not reported. Quality of life outcomes were reported in four studies. Three of these found no significant difference between the groups, based on the Overactive Bladder Questionnaire in one study (150), OAB-q and the Patient Global Impression of Improvement (PGI-I) in another (158) and a visual analogue scale in the third (154). One study using ICIQ-SF and ICIQ-OAB reported that post-treatment scores decreased (indicating symptom reduction) in both groups at 12 weeks of treatment, although the score increased (indicating symptoms worsened) significantly for the oxybutynin group in contrast to the PTNS group. The PTNS group maintained their scores at 6 months follow-up (12 weeks after the cessation of treatment) (157). One study reported that adverse events were observed in three of 18 (17%) participants in the PTNS group (mainly pain at the puncture site) and nine of 18 (50%) participants in the tolterodine group (mainly dry mouth and dizziness) (154).

Summary

Five studies were included. These were small (36-56 participants) and generally assessed as having a high risk of bias. There were limited and widely heterogeneous data. Two studies (one for UUI, one for OAB) reported that quality of life improved over time for both PTNS and drug treatment groups with no significant difference between them, while two other studies (for OAB) found no significant difference in quality of life between PTNS and drug treatment post-intervention **(Level of Evidence: 2).** However, one study on women with OAB found that the improvement in quality of life was longer lasting following the cessation of treatment with PTNS than after tolterodine **(Level of Evidence: 2).** Data available from two studies on women with UUI or OAB suggests that PTNS is associated with a lower rate of adverse events than tolterodine and when they occurred, there were not as bothersome as those associated with tolterodine **(Level of Evidence: 2).** No evidence was available for women with SUI or predominant SUI.

Recommendations

There is no significant difference between PTNS and tolterodine in terms of quality of life, however PTNS may be considered as both may improve quality of life **(Grade of Recommendation: B New).**

PTNS may considered for women as it is associated with fewer and less bothersome adverse effects than those from drug treatment **(Grade of Recommendation: B New).**

Recommendations

More randomised controlled trials with large sample sizes and clear and consistent reporting of core outcome data would be beneficial in reaching a firm conclusion on the effectiveness of PTNS over other treatments.

5.2.4 Does the Addition of PTNS to Other Treatments Add Any Benefit in the Treatment of UI?

Three studies assessed the effect of PTNS as an adjunct to another treatment, compared with the other treatment alone or with PTNS alone (Table 22). One study included women with UUI (reported as OAB incontinent) and combined PTNS with PFMT and bladder training (PTNS plus PFMT plus bladder training vs PFMT plus bladder training) (156). Two other studies included women with OAB (where some but not all participants had UI) and combined PTNS with a drug. One study combined PTNS using the Stoller afferent neuro-stimulation (SANS) protocol with Tolterodine (PTNS plus Tolterodine vs Tolterodine) (155). The other study was a three-arm trial of PTNS versus Oxybutynin versus PTNS plus Oxybutynin; only the findings for PTNS plus Oxybutynin versus Oxybutynin are reported here (157). No study focusing on SUI or predominant SUI was found.

Quality of data

All studies reported adequate methods of randomisation, including the use of a list of random numbers (155), simple random number generator (156) and online randomisation (157). Allocation concealment was not mentioned in any of the study reports. In one study, there was 10% missing data from the group who had tolterodine alone, while there were no missing data in the combination therapy group (155). In another study, there was 5% missing data from the PTNS group only; the reported reason for the attrition was due to health problems unrelated to therapy (156). In the third study, 24% dropped out of the oxybutynin group while 16% were excluded from the analysis in the combination therapy group. The reasons patients failed to complete the trial were not reported and it is unclear whether they were related to treatment (157).

Results

(a) UUI. No information was available on cure rates. One study reported that improvement rates were statistically significantly higher for the group combining PTNS with PFMT and bladder training compared with PFMT and bladder training alone (156). None of the participants reported significant adverse effects (156). ICIQ-SF scores improved for both groups but the combination treatment group had a significantly greater improvement (156). Similar results were found for KHQ; the combination treatment group showed a significantly greater improvement (156).

(b) OAB. No information was available on cure and improvement. Two studies reported quality of life outcomes. One study using the short form of Incontinence Impact Questionnaire (IIQ-7) reported that post-treatment scores decreased (indicating less impact of UI on daily living) in both groups but this decrease in the group combining PTNS and drug was greater that the group using drug alone (155). Another study reported that ICIQ-SF scores decreased (indicating symptom reduction) in both groups at 12 weeks of treatment, although the score increased (indicating symptoms worsened) significantly for the group using drug alone compared with the group combining PTNS and drug at 6 month follow-up (12 weeks after the cessation of treatment) (157). ICIQ-OAB results from the same study found that the combination treatment group had a greater improvement in OAB symptoms compared with the group using drug alone at 12 weeks of treatment; ICIQ-OAB scores increased (worsening in symptoms) for the group using drug alone in contrast to the other group that maintained their scores at 6-month follow-up (157). No information was available on cure and improvement.

Table 22 Summary of data on PTNS + another treatment vs the other treatment

Author, year	Comparator	N randomised	Study population	Duration (months)	Outcome**
UUI					
Schreiner 2010 (1)	Transcutaneous PTNS + PFMT + bladder training (26) vs PFMT + bladder training (26)	52	UUI	3	Cure: NR Improvement based on diary: 19/25 vs 7/26 QoL via ICIQ-SF, change from baseline, mean (SD): 7.2 (4.3) vs. 2.6 (3.3), reported p-value <0.001 QoL via KHQ: reported p-value <0.05 favouring the combination treatment group; no data Adverse effects: no events noted
OAB					
Sancaktar 2010 (2)	SANS (Percutaneous) + Tolterodine (20) vs Tolterodine (20)	40	OAB (some had UUI)	3	Cure: NR Improvement: NR QoL via IIQ-7, mean (SD): SANS + Tolterodine, change from pre 19.0 (2.0) to post 9.0 (0.8), p <0.001; Tolterodine, change from pre 18.1 (2.5) to post 11.2 (2.7), p <0.001 Adverse effects: dry mouth, constipation, headache, local irritation of puncture site
Souto 2014 (3)	TENS (Transcutaneous) + Oxybutynin (25) vs Oxybutynin (25)	50	OAB	3	Cure: NR Improvement: NR QoL via ICIQ-SF, mean [range]: 7.9 [0 to 14] vs 9.8 [0 to 18] at 3 months (treatment end), 7.4 [0 to 14] vs 13.3 [8 to 20] at 6 months (i.e. 3 month after treatment) QoL via ICIQ-OAB, mean [range]: 2.9 [0 to 5] vs 4.6 [0 to 10] at 3 months, 3.0 [0 to 5] vs 9.2 [4 to 13] at 6 months Adverse effects: NR

Note: For modality details or parameters, see Table 19.

NR = not reported; ICIQ-SF = International Consultation on Incontinence-Short Form (higher scores indicate increased severity); ICIQ-OAB = International Consultation on Incontinence-OAB (higher scores indicate increased severity); IIQ-7 = short form of Incontinence Impact Questionnaire (lower scores indicate better QoL); KHQ = King's Health Questionnaire (higher scores indicate greater impairment);

SANS = Stoller Afferent Nerve Stimulation of the posterior tibial nerve;

TENS = Transcutaneous Electrical Nerve Stimulation of the posterior tibial nerve;

TTNS = Transcutaneous Tibial Nerve Stimulation;

**Source of cure and improvement outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.

2. Sancaktar M, Ceyhan ST, Akyol I, Muhcu M, Alanbay I, Mutlu EC, *et al*. The outcome of adding peripheral neuromodulation (stoller afferent neuro-stimulation) to anti-muscarinic therapy in women with severe overactive bladder. Gynecological Endocrinology. 2010;26(10):729-32.

3. Souto SC, Reis LO, Palma T, Palma P, Denardi F. Prospective and randomized comparison of electrical stimulation of the posterior tibial nerve versus oxybutynin versus their combination for treatment of women with overactive bladder syndrome. World Journal of Urology. 2014;32(1):179-84.

Adverse events were reported by one study comparing PTNS plus tolterodine with tolterodine alone (155). In this study, severe dry mouth, severe constipation, headache and local irritation at puncture site were reported in both treatment groups, and skin irritation for the group using PTNS. Two of 18 participants (11%) experienced more than one adverse event in the tolterodine group compared with one of 20 participants (5%) in the group combining PTNS with tolterodine.

Summary

Three small studies were included (40-52 participants). The included studies were assessed as having a high risk of bias. No data were available on cure and improvement rates for this comparison. Data from one study suggests that the addition of PTNS to PFMT and bladder training was more effective in improving symptoms and quality of life than PFMT and bladder training alone in women with UUI **(Level of Evidence: 2).**

Data from two studies suggest that adding PTNS to drug treatment resulted in a greater improvement in quality of life than the drug treatment alone in women with OAB, and this effect was sustained for a longer term (6 months) for the treatment with PTNS than the treatment without PTNS **(Level of Evidence: 2).** Adverse events appear uncommon for either group in the same study. No evidence was available for women with SUI or predominant SUI.

Recommendations

PTNS may be considered for symptom control when chosen in combination interventions by women with UUI or OAB **(Grade of Recommendation: B New).**

This recommendation should be viewed with caution until these findings are supported or refuted in further trials.

5.3. Other LUTS

No trials were identified that analysed the effect of PTNS in women with other LUTS alone, e.g. frequency of voiding, urgency and/or nocturia.

5.4. Factors Affecting Outcome

The included studies did not address the effect of factors that could potentially affect the response to treatment with PTNS. A greater discussion of the factors that affect outcome is provided in the section on urinary incontinence in men and women (see section V.1.4).

6. MAGNETIC STIMULATION (MSTIM)

MStim has been developed for “non-invasive” stimulation of both central and peripheral nervous systems (159). MStim for the treatment of UI was reported for the first time in 1999 by Galloway (160). In contrast to EStim, extracorporeal magnetic innervation (more commonly called magnetic stimulation) stimulates the PFM and sacral nerve roots without insertion of an anal or vaginal probe (161). For treatment, the individual is positioned in a chair. Within the seat is a magnetic field generator (therapy head) that is powered and controlled by an external power unit (Figure 5). A concentrated steep gradient magnetic field is directed vertically through the seat of the chair. When seated, the individual’s perineum is centred in the middle of the seat, which places the PFM and sphincters directly on the primary axis of the pulsing magnetic field (Figure 6). Because of their anatomical location, it is thought that all tissues of the perineum can be penetrated by the magnetic field. According to Galloway (1999) no electricity, but only magnetic flux enters the body from the device. Goldberg (2000) has suggested that, in contrast to electrical current, the conduction of magnetic energy is unaffected by tissue

Figure 5 MStim machine

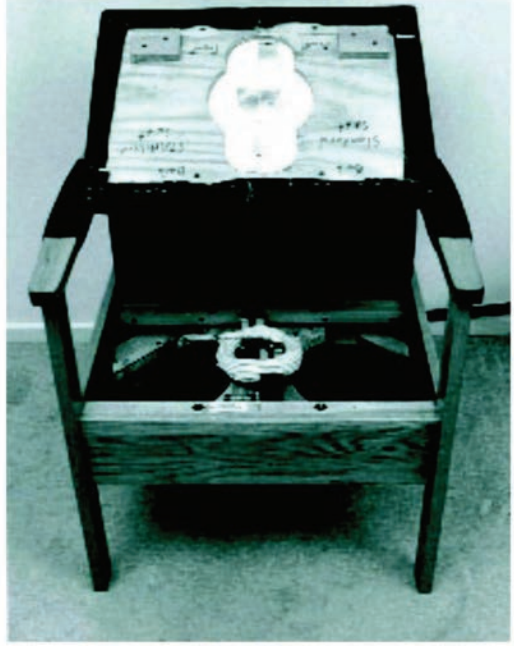

Figure 6 Pulsing magnetic field

impedance, creating a theoretical advantage in its clinical application compared to EStim. Conventional magnetic stimulators deliver, at frequencies of 10 to 50 Hz, repetitive pulses of current lasting less than 100 μsec (161) and 275 Φs (160) in duration. Size and strength of the magnetic field is determined by adjustments of this amplitude by the therapist (160).

Possible advantages of MStim are that it is performed through clothing, needs no probes, skin preparation, or contact with the skin surface. On the other hand, the need for repeated clinic based treatment sessions is a potential disadvantage. In contrast to EStim, MStim lacks portability, although a study by But in 2003 (162) reported the development of a portable small electromagnetic device (Pulsegen) for home use that fit into the underwear and was designed for continuous use for up to 8 weeks.

The mechanism of action of MStim is not fully understood (163). Some authors have suggested that in SUI stimulation of the PFM causes external sphincter contraction (164), acts as a passive PFMT exercise (165), and increases maximal urethral closure pressure (162). In UUI, MStim might suppress DO through activation of pudendal nerve afferents blocking parasympathetic detrusor motor fibres at the spinal reflex arc, activation of inhibitory hypogastric sympathetic neurons, or a combination of both mechanisms (166). Stimulation of sympathetic fibres maintaining smooth muscle tone within the intrinsic urethral sphincter and modulation of pudendal nerve afferent branches stimulating an inhibitory spinal reflex at the S3 nerve root, are also suggested to play a role in this mechanism of action (166).

In this section the evidence is considered for the use of MStim for the prevention and treatment of UI in women. Questions addressed are:

- Is MStim effective in the prevention of UI?
- Is MStim better than no active treatment (placebo, sham, control or no treatment) for the treatment of UI?
- Is one type of MStim better than another in the treatment of UI?
- Is MStim better than other treatments in the treatment of UI?
- Does the addition of MStim to other treatments add any benefit in the treatment of UI?
- What is the effect of MStim on other LUTS?
- What factors might affect the outcome of MStim in the treatment of UI?

Eligible interventions were non-invasive magnetic stimulations. Eligibility criteria for study participants and outcomes, as well as criteria used to assess 'risk of bias' in the included studies, were identical to those described in the previous sections on EStim and PTNS (Sections II.4 and II.5).

Description of intervention

In addition to eleven studies included in the 5th ICI, two new trials were identified for this update. The number of included studies by dominant type or pattern of incontinence is summarised in Table 23. Table 24 illustrates the intervention characteristics of the two new trials.

6.1. Prevention

In the last ICI chapter, there were no trials on prevention of UI or LUTS. No new published trials were found.

6.2. Treatment

6.2.1 Is MStim Better Than no Active Treatment (Placebo, Control or no Treatment)?

Two new studies including 162 women were identified (167, 168). In one study the majority of female participants had SUI (refractory to first-line management) (167). The other study included all types of UI (168).

Characteristics of the two new studies comparing magnetic stimulation with no active treatment are presented in Table 25. In both studies the no active treatment consisted of sham treatment.One study assessed the efficacy of a magnetic stimulator developed for home use (168), whereas in the other study treatment was provided in the outpatient clinic setting (167). Since there was little duplication of MStim interventions, or sample populations, in the eleven trials, it was inappropriate to combine study findings.

Quality of data

Allocation concealment was considered to be adequate in one study that used an independent research assistant in the randomisation process (168). The other study did not describe methods used for allocation concealment (167). In both studies, data were reported only for those participants who completed the study (167, 168). In particular, in the study by Wallis (2012), 19% (12/62) of participants from the intervention group and 15% (9/60) in the control group withdrew from the study (168).

Results

i) SUI. No additional data on cure and improvement were available for this update. The results for cure and improvement rates are as reported in two previous studies (169, 170).

Information on quality of life was provided in three studies, including one new study (167), but the results were not consistent. Two previously reported studies found no significant differences between the groups (169, 170), whereas the new study reported better quality of life at 18 weeks after active treatment compared with sham treatment, based on the Urge-Urinary Distress Inventory and the Overactive Bladder Questionnaire (167).

Table 23 Studies of MStim included in the previous review (5th ICI) and current update (6th ICI)

	Studies included in the previous review (5th ICI)	New studies identified in this update (6th ICI)	Total
MStim vs No active treatment			
SUI or predominant SUI	3	1	4

Table 24 Summary of data on MStim

Study	Intervention description
Tsai 2014 (1)	A Magstim Rapid2 with a 70-mm figure-8 coil. Treatment administered over the bilateral third sacral roots, with the maximal tolerable intensity, which was typically 70% to 80% of the maximal stimulator output, for 20 minutes each day for 12 consecutive weekdays. The stimulation frequency and the stimulation-on time and -off time were fixed at 5Hz, 10 seconds, and 20 seconds, respectively.
Wallis 2012 (2)	A commercially available undergarment incorporating 15 static magnets of 800-1200 Gauss arranged anterior, posterior, and inferior to the pelvis. Women were asked to wear it for a minimum of 6 consecutive hours during the day and at least 6 hours overnight for 3 months.

1. Tsai PY, Wang CP, Hsieh CY, Tsai YA, Yeh SC, Chuang TY. Long-term sacral magnetic stimulation for refractory stress urinary incontinence. Archives of Physical Medicine & Rehabilitation. 2014;95(12):2231-8.

2. Wallis MC, Davies EA, Thalib L, Griffiths S. Pelvic static magnetic stimulation to control urinary incontinence in older women: a randomized controlled trial. Clinical Medicine & Research. 2012;10(1):7-14

Two studies (one new) reported no adverse effects (167, 169).

ii) All types of UI. One new study that provided stimulation using an undergarment with embedded magnets reported that improvement rates were statistically significantly higher for active compared with no treatment, although the result did not hold in sensitivity analysis (168). No information was available regarding cure rates.

With respect to quality of life measures, no statistically significant difference was found based on the Bristol Female Lower Urinary Tract Symptoms (BFLUTS) questionnaire (168).

In the same study, participants reported problems with comfort and wearability of the garment, which were considered by study authors to have contributed to a relatively high attrition rate of 20%. Commonly cited problems include the attraction to metal objects; embedded magnets sticking to each other and making it difficult to put on; and also the garment being bulky and very warm to wear, especially in the subtropical climate of the study area (168).

Summary

A total of 11 studies assessed the effect of MStim compared with no active treatment, including four focusing on SUI or predominant SUI, one on UUI, one on MUI, two on all types of UI, and three on OAB/DO (where only some but not all had UI).

Findings, using the additional data from newly identified studies were broadly similar to those in the 5th ICI.

For women with SUI, MStim might be more effective than sham in improving (not necessarily curing) symptoms **(Level of Evidence: 2),**

Data from two small trials of MStim (12 and 6 sessions) examining the effect on quality of life were conflicting **(Level of Evidence: 2).**

For women with UUI, evidence from a small trial (171) suggests that active MStim might result in better quality of life than sham **(Level of Evidence: 2),** although there is some uncertainty surrounding this, as data was limited and no statistical test was performed.

Active MStim was associated with higher cure rates than sham in a small trial (172) with women with MUI **(Level of Evidence: 2),** and also higher cure and improvement rates in another small trial (162) with women with all types of UI **(Level of Evidence: 2)** but no such difference was observed for women with DO (wet or dry) **(Level of Evidence: 2).** In general, adverse effects appear uncommon.

Recommendations

No recommendation is possible based on current conflicting evidence **(Grade of recommendation D).**

6.2.2 Is One Approach to MStim Better than Another?

No new study comparing one approach of MStim with another was found for this update. The level of evidence and recommendations remains unchanged from the 5th ICI.

Summary and Recommendation

The 5th ICI included one study with women presenting UI symptoms (173). There is insufficient evidence to determine if one type of MStim is better than another **(Level of Evidence: 2)**. No recommendation is possible **(Grade of Recommendation: D).**

6.2.3 Is MStim Better than Other Treatments?

There were no trials for this comparison in the 5th ICI chapter. No new published trials were found for this update.

6.2.4 Does the Addition of MStim to Other Treatments Add Any Benefit in the Treatment of UI?

No new study was found investigating the effect of adding MStim to other treatments compared with the other treatments alone. The level of evidence and recommendations remains unchanged.

Summary and Recommendation

The previous 5th ICI included one study in women with SUI (174). The addition of MStim to PFMT does not appear to be beneficial **(Level of Evidence: 2)**.

Adding MStim to PFMT does not appear to be beneficial **(Grade of Recommendation: C).** This hypothesis needs to be investigated further with high quality trials, if it is a clinical question of interest to women.

6.3. Other LUTS

No trials were identified that analysed the effect of MStim in women with other LUTS alone, i.e., frequency of voiding, urgency and/or nocturia.

6.4. Factors Affecting Outcome

None of the included trials addressed the effect of age, or any other factor, on outcome of MStim. In one early prospective multi-centre study, factors predicting success of MStim were included (160). Treatment success was associated with no prior hysterectomy, no prior anti-incontinence operations, UI symptoms for fewer than 10 years, and no use of medications known to cause UI. Brodak has suggested that detrusor response to MStim might be better in 'thin' individuals (presumably due to a shorter distance between the stimulating coil and the sacral nerve roots) and at low bladder volumes (175). Overall, little is known about the factors affecting the outcome of MStim.

7. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens

This section examines the evidence on use of scheduled voiding regimens in cognitively intact, non-institutionalized women with UUI, SUI, and MUI and provides recommendations for their use in clinical practice. A summary of the search strategy and inclusion/exclusion criteria for selecting studies for review is provided (see section I). The chapters on the Frail Elderly and Neurogenic Incontinence provide detailed review of scheduled voiding regimens that are used in those with cognitive impairment, or UI secondary to central nervous system or spinal cord disease (see chapter 11).

Types of Scheduled Voiding Regimens

Bladder training is a broad term often used to describe any type of a scheduled toileting intervention. This has created conceptual confusion in interpreting research reports where few details are provided other than the statement that bladder training was used. The types of scheduled voiding regimens can be categorised as: bladder training, timed voiding, habit training, and prompted voiding (176). Although these regimens share a common feature of a toileting schedule, they differ on the basis of adjustments to the voiding schedule, the active or passive involvement of the patient, the nature of patient education including the teaching of strategies to control urgency and prevent stress leakage, the use of reinforcement techniques, and the nature of the interactions between clinicians and patients. In practice, however, scheduled voiding regimens may share aspects of one or more of these features.

Table 25 Summary of data on MStim vs no active treatment

Author	Comparator	N random-ised	Study population	Duration (months)	Outcome**
Predominantly SUI					
Tsai 2014 (1)	MStim (20) vs Sham MStim (20)	40	>50% of study sample had SUI alone	outcome measured at 4.5 months	Cure: NR Improvement: NR QoL: OQB-q: N = 30, mean difference 23.80 lower, 95% CI 36.28 to 11.32 lower QoL via Urge-UDI: N = 30, mean difference 1.80 lower, 95% CI 2.64 to 0.96 lowerAdverse effects: no events observed
All types of UI					
Wallis 2012 (2)	MStim (62) vs Sham MStim (60)	122	SUI, UUI or MUI	3	Cure: NR Self-reported improvement: 26/46 vs 18/50 QoL via BFLUTS (median change in score, IQR): UI symptoms, N = 101, 1.5 (3.0) vs 1.5 (3.0), p = 0.80; Sexual function, N = 101, 0 (0.75) vs 0 (0), p = 0.80; Quality of life, N = 101, 1.0 (5.0) vs 0 (5.0), p = 0.28 Adverse effects: discomfort of the garment

Note: For modality details or parameters, see Table 24.

NR = not reported; BFLUTS = Bristol Female Lower Urinary Tract Symptoms (higher scores indicate more severe comlaints); OAB-q = Overactive Bladder Questionnaire (higher scores indicating worse condition); Urge-UDI = Urge-Urinary Distress Inventory (higher scores indicate worse condition);

**Source of cure and improvement outcome: women's self-report was given priority but for studies in which it was not reported, quantification of outcomes based on diaries, pad tests or any other definitions chosen by trialists was used as a proxy.

1. Tsai PY, Wang CP, Hsieh CY, Tsai YA, Yeh SC, Chuang TY. Long-term sacral magnetic stimulation for refractory stress urinary incontinence. Archives of Physical Medicine & Rehabilitation. 2014;95(12):2231-8.

2. Wallis MC, Davies EA, Thalib L, Griffiths S. Pelvic static magnetic stimulation to control urinary incontinence in older women: a randomized controlled trial. Clinical Medicine & Research. 2012;10(1):7-14.

Bladder training

Bladder training (also referred to as bladder drill, bladder discipline, bladder re-education, and bladder retraining) involves a programme of patient education along with a scheduled voiding regimen with gradually progressive voiding intervals. Specific goals of bladder training are to correct faulty habit patterns of frequent urination (if present), improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient confidence in controlling bladder function. The underlying mechanism of how bladder training achieves its effect is poorly understood. Several hypotheses have been proposed including improved cortical inhibition over detrusor contractions; improved cortical facilitation over urethral closure during bladder filling; improved central modulation of afferent sensory impulses; altered behaviour resulting from better individual awareness of the lower urinary tract function and circumstances that cause UI, and increasing the "reserve capacity" of the lower urinary tract system (177-179).

Timed voiding

Timed voiding is a fixed voiding schedule that remains unchanged over the course of treatment (176). The goal is to prevent UI by providing regular opportunities for bladder emptying prior to exceeding bladder capacity. Timed voiding has been recommended for patients who cannot participate in independent toileting (180). It also has applicability for use in outpatient settings with incontinent women who have infrequent or irregular voiding patterns (181) and men who are independent in their voiding function (182).

Habit training

Habit training is a toileting schedule matched to the individual's voiding pattern based on their voiding diary. The toileting schedule is assigned to fit a time interval that is shorter than the person's normal voiding

pattern and precedes the time when incontinent episodes are expected. Thus, the voiding interval may be lengthened or shortened throughout the day depending on the patient's voiding pattern with the goal to pre-empt UI. Habit training is usually implemented by caregivers in institutional settings with cognitively and/or physically impaired adults, but it has also been tested in homebound older adults (183). It is potentially useful for adults without cognitive or physical impairment, who have a consistent pattern of UI (181).

Prompted voiding

Prompted voiding refers to a caregiver education programme in combination with a scheduled voiding regimen, typically every two hours. It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so (184). It has been used primarily in institutionalized settings with cognitively and physically impaired older adults.

Section Overview

This section examines evidence for the use of bladder training and timed voiding for the prevention and treatment of UI in non-institutionalised women of all ages without cognitive or mobility impairment. However, the majority of evidence available pertains to the effects of bladder training, thus this is the focus of this section.

Previously, no trials were identified that tested habit training or prompted voiding for UI in independent-living women without cognitive or physical impairment, and no new trials meeting these criteria were identified in this update. Therefore, evidence for use of habit training and prompted voiding is not included in this section.

Questions addressed in this section include:

- Can scheduled voiding regimens prevent UI?
- What is the most appropriate bladder training protocol?
- Is bladder training better than no treatment, placebo or control treatments?
- Is bladder training better than other treatments?
- Can any other treatment be added to bladder training to add benefit?
- Does the addition of bladder training to other treatments add any benefit?
- Is timed voiding effective at treating UI?
- What is the effect of bladder training on other LUTS?
- What factors might affect the outcome of bladder training?

7.1. Prevention

Previously no trials had examined scheduled voiding regimens as a sole intervention in the prevention of UI. In this update, no further trial was identified.

7.2. Treatment

Previous recommendations related to bladder training as treatment for UI were based on review of individual published trials and three systematic reviews that provided descriptive synthesis with evidence grading (180, 185, 186), including a published Cochrane review last updated in 2006 (185). In this ICI update, 5 additional trials were identified and are described in the relevant sections below (98, 102, 156, 187, 188).

7.2.1 What Is the Most Appropriate Bladder Training (BT) Protocol?

Previously no trials were identified that compared two or more methods of bladder training (BT), and none were identified for this update. In the absence of trials comparing two or more approaches, a content analysis was performed looking at the protocols used in trials investigating the effects of BT. It has been updated for this edition. Twenty-two trials on BT involving a total of 3194 women have been identified, including 5 trials involving 732 women added since the last update (98, 102, 156, 187, 188). Several of the trials previously reviewed (189-194) and 2 of the new trials identified for this update (156, 187) provided no or minimal details regarding the specific BT protocol used. In trials that did provide some description, BT protocols were implemented in differing ways. In the following review of BT protocols, information from studies added in this update are integrated with information from previously reviewed studies.

All protocols involved some type of patient education, namely:

- Brief verbal (191, 192) or written instructions (195, 196)
- Verbal, written, and audio-visual instruction (177, 179, 197)
- Introduction to an individual who successfully completed BT (193)

If specified, the education was provided by nurses (177, 179, 189, 190, 198, 199), general practitioners (200), or physiotherapists (98, 102, 188).

Scheduling of voids varied in the following ways:

- Assignment of the initial voiding interval varied from 30 minutes to two hours, with one hour being the most common interval based upon the participant's voiding pattern or 30 minutes beyond the participant's average (195, 201) or longest (102) voiding interval.

- Adjustments to the voiding interval varied from 15 to 30 minutes, with 30 minutes the most common interval. Increases were made daily for inpatient regimens (193), after 48 hours of dryness (202), every four to five days (201), or weekly if schedule was well-tolerated (102, 177, 179).
- Goals for optimal voiding interval varied from three to four hours.
- Voiding was 'mandatory' with restriction of voiding in between assigned toileting times even if UI occurred (193), a scheduled voiding regimen that allowed interruptions in the schedule if urgency became unbearable (177, 179, 199), or self-scheduling of voiding with a target goal to reach (195).
- Voids were not scheduled (allowed) during sleeping hours (193); none of the other protocols identified how voids were handled during sleeping hours.

In some protocols the scheduled voiding regimen was supplemented by specific strategies to control urgency and/or stress leakage, including distraction and relaxation (102, 177, 179, 188, 195, 199), and pelvic floor muscle contraction (102, 177, 190, 196). In other studies there was encouragement to suppress urge but it was not clear what strategies were used (192, 200, 203). Feedback techniques included self-monitoring (177, 179, 191, 194, 199), goal setting with feedback of progress (198), and positive reinforcement (177, 179, 201).

Several protocols included use of adjunctive treatments:

- Fluid and caffeine adjustments (197, 199, 203)
- Fluids allowed up to a certain level (1,500 ml) (202)
- No fluid modifications (102, 177, 179, 195, 200)
- Advice on constipation prevention (199)

Both in and outpatient BT programmes have been used. Early inpatient BT programmes involved five to 13 days of hospitalisation to ensure strict protocol adherence (193). Outpatient programmes are more commonly described and the amount of health professional contact ranged from weekly visits for six weeks with fortnightly telephone calls for six additional weeks (177), to weekly visits (179, 188, 189), fortnightly visits (102, 201), and monthly visits (202). A "simplified" BT treatment with minimal to no health professional contact (instructions given to patients on a one page instruction sheet) has also been tested (195, 196).

Overall, there is a lack of consistency in BT protocols. Based on the protocols described, a reasonable outpatient BT protocol, based on expert opinion is shown in Figure 7.

Typical Bladder Training Regimen

- An initial voiding interval typically beginning at one hour during waking hours, which is increased by 15 to 30 minutes per week depending on tolerance of the schedule (such as fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the patient's feeling of control over urgency and confidence to expand the voiding interval), until a two to three hour voiding interval is achieved. A shorter initial voiding interval, e.g. 30 minutes or less, may be necessary for patient whose baseline micturition patterns reveal an average daytime voiding interval of less than one hour.
- Education about normal bladder control and methods to control urgency such as distraction and relaxation techniques and PFM contraction.
- Self-monitoring of voiding behaviour using diaries or logs in order to determine adherence to the schedule, enhance self-awareness, evaluate progress, and determine whether the voiding interval should be changed (for example, see Figure 7).
- A supervising health care professional to monitor progress, suggest adjustments to the voiding interval, and provide positive reinforcement to patient undergoing BT at least weekly during the training period.
- If there is no improvement after three weeks of BT, re-evaluation is warranted and other treatment options would be considered. Inpatient BT programmes may follow a more rigid scheduling regimen with progression of the voiding interval on a daily basis.

Summary

There is still no trial evidence to suggest the most effective method or specific BT parameters. For those undertaking BT it is likely that more health professional contact will be better than less, based on the developing evidence for PFMT, which like BT, requires behavioural change **(Level of Evidence: 4).** The literature suggests several areas that could be investigated in future trials, including the instructional approach, supervisory intensity, strategies for controlling urgency, scheduling parameters, frequency of schedule adjustments, length of treatment, and use of adjunctive treatments.

Recommendations

Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of their approach to BT. The ICS Consensus statement and review pa-

pers on Adherence and PFMT could be useful to clinicians and researchers (24-27). **(Grade of Recommendation: D).**

Clinicians should provide the most intensive BT supervision that is possible within service constraints **(Grade of Recommendation: D).**

More research is needed to investigate which BT parameters, supervisory intensity, and adjunctive treatments are most effective. Future trials should include outcomes that matter to patients, including the length and frequency of supervisory contact.

7.2.2 Is BT Better than No Treatment, Placebo or Control Treatments?

BT as sole therapy has been used in the treatment of DO, urodynamic SUI, MUI, UUI, UUI with a stable bladder, and OAB (also called urgency-frequency syndrome).

No new trials were identified that addressed this question. Previously 5 RCTs reporting on 515 women were identified that compared the effect of BT to no treatment or control (179, 189, 194, 199, 200). Of 4 trials with relevant analysable data (179, 189, 194, 200), 3 reported improvements in the BT group compared to the control group (179, 194, 200). The trial quality and detailed results were presented in previous editions of this chapter.

Summary

The few available trials (reviewed previously) were small and of variable quality. No new trials were identified in this update.

There is limited **Level 1** evidence that BT may be an effective treatment for women with UUI, SUI, and MUI **(Level of Evidence: 1)**.

Recommendations

BT should be recommended as first line conservative therapy for UI in women **(Grade of Recommendation: A)**.

Additional high quality studies are needed that examine the effect of BT versus no treatment in treatment of women with UUI, SUI, and MUI.

7.2.3 Is BT Better than Other Treatments?

This section, considered trials which compared BT alone versus another active therapy.

For the comparison of BT versus PFMT see II.2.3.3.

The only other comparison for which trials were found was BT versus drug therapy. One additional trial was identified for this update (98). Previously, two small trials were identified that randomized 131 women with UUI to BT or drug treatment (193, 201).

Kafri *et al.* (98) randomized 184 women with UUI to one of four groups: BT, PFMT, tolterodine extended release 4 mg or combined behavioural therapy (BT and PFMT). Results from the BT and drug treatment group comparison are included here, while results of

Figure 7 Bladder diary

the BT vs PFMT comparison are included in section II.2.3.3.

Quality of data

Kafri *et al.* (98, 201) was a single-blinded trial in which 83 women were randomized to drug treatment or BT and followed up for 12 months. A power calculation and adequate random allocation concealment were reported. Drug tolerability and adverse events were assessed, but side effects were reported in a composite outcome only. Intent-to-treat principles were followed. Drop out at 3 months was higher in the drug treatment compared to BT group (36% vs 5%) (98).

Results

In Kafri (98), the number of self-reported UUI episodes in the past week significantly decreased at 3 and 12 months in both the BT and drug treatment groups. Between group comparisons suggested no difference in outcomes. Differential dropout suggested drug treatment was associated with more adverse effects, but this was not clearly reported. These results were similar to one previously reviewed trial in short-term outcomes (201), but in that trial symptoms recurred more often after drug treatment than after BT at 6 months follow-up. Another older trial found BT superior to drug treatment at 3 months follow-up (193). Both previously reviewed trials found adverse effects common in the drug treatment groups, but not in BT groups.

Summary

Despite an additional trial, it remains unclear whether BT or drug therapy is more effective for women with DO or UUI **(Level of Evidence: 1)**.

This result is consistent with the findings of the Cochrane review (185), which concluded that there was not enough evidence to determine whether first line therapy should be BT or anticholinergic drugs.

Recommendations

When considering BT and anticholinergic drug for women with DO or UUI, either may be effective **(Grade of Recommendation: B)**.

BT may be preferred by women and clinicians because it is not associated with the drug related side effects **(Grade of Recommendation: D)**.

7.2.4 Can Any Other Treatment Be Added to BT to Add Benefit?

To be included here, trials needed to investigate the effects of BT versus BT plus therapy A to address the additive benefit of therapy Three new trials were identified that tested the additional benefit of PFMT, drug therapy and tibial nerve transcutaneous electrical stimulation when added to BT (102, 156, 187). One trial addressed the added benefit of PFMT to BT (102) and is considered in the section on PFMT (II.2.3.4). A 2010 randomized trial tested the additive effects of tibial nerve transcutaneous electrical stimulation in 51 older women undergoing "routines of care" which included BT and Kegel exercises (156). As BT was combined with pelvic floor exercise treatment in both groups and no details were provided about the BT protocol, it was not possible to determine the effects of BT alone, and it is not considered further here. The third trial tested the addition of oxybutynin, imipramine or placebo to BT in 282 men and women with DO who had failed at least 8 weeks treatment of BT alone (187). However, very limited information is available on the methods and results (abstract only). This trial was also not considered further.

Prior editions of this chapter identified trials addressing the additional benefit of caffeine reduction, PFMT, and drug therapy when combined with BT. The caffeine reduction trial was included in the Lifestyle Interventions (II.1) section (203), and the trial addressing additional benefit of PFMT when added to BT was included in the PFMT section (II.2.3.4) (177). Three trials previously identified tested the added benefit of drug therapy to BT treatment. One of these tested a drug that is no longer available (terodiline), and is not considered further (192). The remaining trials included one that randomized 34 women and men with DO to BT or BT plus imipramine therapy (202), and another that randomized 60 women and men to BT and placebo or BT plus immediate release oxybutynin (191). No difference was seen in incontinence outcomes between the groups in either trial, although subjective improvement was greater with addition of a drug in one (191). Data quality and detailed results from these trials were reviewed in past editions of this chapter.

Summary

No new trials contributed evidence in this area. In two small trials (reviewed in previous editions) comparing BT (or BT plus placebo) versus BT plus drug in DO, there was a suggestion that the effect of BT might be enhanced by active drug **(Level of Evidence: 2)**. However, both trials were small, conducted in gender-mixed sample populations, and outcomes were not common to both trials. Thus, there is insufficient evidence to derive a conclusion related to the effectiveness of augmenting BT with drug therapy.

Recommendations

Direct comparisons of BT versus BT with drug for UI treatment are needed to address the question of whether the effect of BT can be augmented by drug therapy. No recommendation is possible **(Grade of recommendation D).**

7.2.5 Does the Addition of BT to Other Treatment Add Benefit?

To be included here, trials needed to investigate the effects of Therapy A versus Therapy A plus BT to assess the added benefit of BT over Therapy A alone. A search for trials that investigated the effects of PFMT alone versus PFMT plus BT, and drug therapy

alone versus drug therapy plus BT was performed. No new trials focused on this question were identified.

Three trials were reviewed in previous editions of this chapter, including one older study that compared BT, PFMT and combination therapy in 204 community-dwelling women with SUI and/or DO (177). Two larger RCTs compared a "simplified" BT (administered by providing participants with a 1 page written instructions on BT) plus drug therapy (tolterodine (2mg twice daily) (190, 195) and solifenacin (5/10mg daily)(195)) to drug therapy alone in women and men with OAB with or without UUI. UI outcomes were secondary endpoints in these trials.

Summary

A single trial found combining BT with PFMT improved short-term outcomes compared to PFMT alone, but the added benefit did not persist three months later **(Level of Evidence: 2)**.

There is no evidence for an added benefit of combining brief written BT instructions with tolterodine (2mg twice daily) or solifenacin (5/10mg daily) compared to drug therapy alone for urgency incontinence **(Level of Evidence: 2)**, although these trials were likely underpowered to study UI outcomes.

Recommendations

With no new trials contributing evidence in this update, the available evidence (single trial) supports the use of BT as a supplement to PFMT in improving short-term outcomes, but not longer-term results **(Grade of Recommendation: C)**.

Limited evidence suggests the addition of written information on BT for women with OAB taking an antimuscarinic drug does not further improve UI **(Grade of Recommendation: B)**.

More research is needed using an appropriately supervised BT programme combined with drug therapy versus drug alone.

7.2.6 Is Timed Voiding Effective at Treating UI?

The Cochrane review on timed voiding for management of UI in adults was last updated in 2010 (204). Ostaszkiewicz (2010) considered randomized and quasi-randomised trials only and identified two trials comparing timed voiding combined with additional interventions (including medications) to usual care. Both trials were conducted in nursing homes and most participants were elderly women with cognitive impairment. Neither study recruited participants that met criteria for inclusion here.

No new trials were identified that tested timed voiding for UI in women without cognitive or physical disability. Previously, two older non-randomised studies, excluded from the Cochrane review, reported findings on the effects of timed voiding in women with UUI, stable bladders with UUI, and MUI (205, 206). One of these, a small, double-blind crossover study compared timed voiding plus anticholinergic drug therapy (terodiline) to timed voiding plus placebo (205). As terodiline is no longer available, this study was not considered further. The second study was a small case series of 20 women with mild UI treated with timed voiding and followed from 6 weeks to 8 months after treatment (206). A successful outcome (not objectively quantified) was reported in 79% of participants.

Summary

There are no RCTs, or high quality observational studies, providing evidence on the effects of timed voiding for UI in cognitively intact, community-dwelling women, and no new trials considering this were identified. Based upon the data from one small uncontrolled study, it seems a two-hour timed voiding schedule may be beneficial in treating women with mild UI, infrequent voiding patterns, and stable bladder function **(Level of Evidence: 3)**.

Recommendations

Timed voiding with a two-hour voiding interval may be considered as a sole intervention for women with mild UI or infrequent voiding patterns **(Grade of Recommendation: C)** Timed voiding may also be considered as an adjunct to other treatment.

7.3. Other LUTS

Two new trials were identified that reported frequency outcomes. Kafri *et al.* (98) compared BT to drug treatment and reported on frequency outcomes (others reviewed in section II.7.2 above). A second trial addressed the added benefit of PFMT to BT (102) and reported frequency as a secondary outcome. This trial is considered in the section on PFMT (II.2.3.4).

Older trials (from past editions of this chapter), which also contributed evidence related to other LUTS outcomes, compared BT to drug therapy (190, 193, 201), BT to no treatment (179, 189, 194), BT plus placebo to BT and drug treatment (191), and additive effects of a simplified BT program to drug treatment (195, 196).

Quality of data

The quality of data in the new trial that tested BT vs drug treatment was described earlier (II.VII.2c).

Results

i) Urgency: No new trials reported on urgency outcomes. In previously reviewed trials, urgency results were conflicting. An older trial suggested BT was superior to drug treatment (193), but another reported greater improvement in urgency after drug treatment or combined drug and BT treatment compared to BT alone (190). Two larger trials found no additional improvement in urgency when a simplified BT treatment was added to drug treatment for OAB (195, 196).

ii) Daytime (diurnal) frequency:

A newly identified trial found frequency improved at 3 and 12 months after treatment with BT, drug treatment (tolterodine extended release 4 mg), or a combined BT and PFMT group (98). On average, subjects reported 2 to 4 fewer voids per 24 hours after treatment. Between group differences were not reported.

In previously reviewed trials, frequency improved to a greater extent in BT groups compared to no treatment (179, 189, 194). In trials testing BT compared to drug treatment, frequency improved in both groups similarly (190, 201), or to a greater extent in the BT group (193). In one trial testing the additive effect of drug treatment to BT, a greater reduction in frequency was reported in the BT plus drug treatment group compared to BT plus placebo group (191). Lastly, two trials found that "simplified" BT significantly augmented the effect of drug alone. BT with tolterodine had greater improvement in voiding frequency compared to drug alone (33% versus 25% improvement, respectively; $p<0.001$) and BT with solifenacin reduced the number of voids in 24 hours to a greater extent compared to drug alone (2.8 versus 2.1 fewer voids in 24 hours; $p<0.001$) (195, 196).

iii) Nocturia: No new trials were identified reporting on nocturia. Three previously reviewed trials reported data in comparisons of BT with no treatment, and found reductions in nocturia after BT but not in the control group (179, 189, 194). Four previously reviewed trials compared BT with drug therapy. Two smaller trials found BT superior compared to drug treatment in treating nocturia (193, 201). Another trial compared BT plus placebo versus BT plus drug (191) and found no difference in nocturnal micturition frequency. Song (2006) reported that nocturia improved similarly in women with OAB treated with BT (56.1%), tolterodine (65.4%), and combined treatment (66.3%) (190).

Summary

No trials were identified which tested the effectiveness of BT compared to no treatment or a control for urgency. It remains unclear whether BT or drug treatment is more effective in treating urgency **(Level of Evidence: 2).**

Several trials, including one newer study, suggest BT is effective at improving frequency, (**Level of Evidence: 1),** but it is unclear whether BT or drug treatment is more effective **(Level of Evidence: 2)**. Two larger, higher quality trials show that the addition of "simplified" BT to drug treatment does not provide additional benefit in treating urgency, but does improve frequency **(Level of Evidence: 1).** A few small, randomized trials of variable quality suggest BT is effective at treating nocturia **(Level of Evidence: 2).** Additional small trials do not find that BT (or BT added to drug treatment) is more effective at treatment of nocturia than drug treatment, but evidence is limited **(Level of Evidence: 2).**

Recommendations

Insufficient evidence exists to support either the use of BT to treat urgency in women with UI and/or OAB, or to guide the choice of BT vs drug treatment as initial treatment aimed at urgency **(Grade of Recommendation: D)**.

Routine addition of a "simplified" BT to drug therapy does not provide additional improvement in urgency, but should be considered in treatment of voiding frequency in women with UI and OAB **(Grade of Recommendation: B)**.

BT should be offered as treatment for urinary frequency and nocturia **(Grade of recommendation: B)**, but in choosing between BT and an anticholinergic drug for women with frequency, either may be effective **(Grade of Recommendation: B)**.

7.4. Factors Affecting Outcome

Few trials on BT have examined predictors of treatment response. New trials reviewed for this update did not contribute additional information related to predictors of timed voiding or BT treatment response.

8. COMPLEMENTARY AND ALTERNATIVE MEDICINES

There is limited, but growing evidence that complementary and alternative medicines (CAMs) may influence physiological function and/or health outcomes. CAMs include those therapies that are not part of the traditional biomedical model, such as meditation, imagery, hypnosis, acupuncture and naturopathic and herbal remedies.

This section reviews the current evidence for the effects of CAMs on UI in cognitively intact, community-dwelling women. Studies focused on UI in women with neurogenic aetiologies (for example, UI associated with stroke or multiple sclerosis) have been excluded. A summary of the search strategy used for selecting studies for review is provided in section I.

In the 5th ICI, a single RCT focused on hand acupuncture therapy was reviewed here. Given the lack of evidence, no recommendations related to CAMs were made for women with UI. Since then, additional RCTs and a Cochrane review have been published. Many of these trials tested various acupuncture techniques for UI; these are reviewed and summarized below.

Small individual trials testing other types of CAM therapy (for example, meditation and relaxation therapies and natural supplements) for UI were identified in the current search, many labelled as pilot trials. As recommendations cannot be made based on the minimal evidence available for any individual type of CAM therapy, these are not formally reviewed here. As interest in CAM therapies grows and more evidence accrues, additional types of non-traditional therapies may be reviewed in future editions.

Acupuncture and UI

Acupuncture and related techniques have been performed as part of Eastern medicine for thousands of years. Related therapies may include body acupuncture, hand acupuncture, electroacupuncture and acupressure, amongst others. Their mechanisms of action are not fully understood, but discussions of these mechanisms related to treatment of UI from traditional Chinese medicine and other perspectives are available (207, 208).

8.1. Prevention

In the 5th ICI, no trials examined acupuncture for the prevention of UI. In this update, no new trials were identified.

8.2. Treatment

8.2.1 Acupuncture for Treatment of SUI

Previously, one low-quality RCT that studied the effect of hand acupuncture vs control (no treatment) for female SUI in 52 women (209) was identified. In this update, a recently-published Cochrane review of acupuncture and SUI was reviewed (207), which included one trial of acupuncture vs drug treatment for SUI (210). An additional trial of acupressure for the treatment of is included in this update (211).

The 2013 Cochrane review considered evidence for acupuncture interventions from traditional Chinese medicine (body acupuncture, scalp acupuncture, electroacupuncture, warm acupuncture, fire needle and elongated needle), and did not consider trials of other interventions, such as hand acupuncture and acupressure (207). The authors searched and reviewed English and Chinese language publications. Only 1 trial was included (many were excluded because they combined acupuncture with other treatments or compared different types of acupuncture). The single eligible trial randomized 60 women to acupuncture vs a drug treatment (midrodine) and reported subjective improvement and cure and adverse effects at 6 to 12 weeks (207).

Chang *et al.* completed an RCT of 81 women with urodynamic SUI, randomized to 3 groups including acupressure, sham acupressure and "usual care" including PFMT (taught at baseline) (211). The treatment and sham groups underwent 3 weekly treatment sessions for 10 weeks. No information was provided on performance of PMFT (or other treatments) in the "usual care" group (or the other treatment groups). Outcomes were assessed after the 10-week treatment period. The primary outcome was pelvic floor muscle strength. Numbers of urine leak episodes from a 4-day diary and a subjective assessment of urine incontinence severity were also assessed.

Quality of data

Randomization concealment was inadequate in both trials (207, 211). No blinding or partial blinding was performed. Few participants withdrew from the trials (<5%). Adverse effects were reported in 1 reviewed trial (207).

Results

More women reported improvement in the acupuncture group (73% vs 33%; risk ratio 2.2 (95% CI 1.3-3.8)) compared to drug treatment (207). Cure rates were low and not different between the groups (13% vs 7%; risk ratio 2.0 (95% CI 0.4, 10.1)). Adverse effects were reported in the drug group only (including headache, dizziness, and thirst).

In the trial comparing acupressure, sham acupressure vs PFMT alone, numbers of incontinence episodes were unchanged and did not differ between groups, although self-reported severity of leakage improved to a greater extent in the acupressure compared to the sham acupressure group (p=0.04) and to PFMT alone (p=0.01) (211). Adverse effects were not reported.

Summary

A single trial suggests acupuncture may be better than drug treatment in SUI **(Level of Evidence: 2),** but the low quality and atypical comparator group limits the impact of these results.

A single trial suggests mixed results for acupressure compared to sham treatment or usual care in treatment of SUI **(Level of Evidence: 2),** but the low quality and small numbers limit these findings. There is inadequate evidence to know if acupuncture or acupressure treatments are effective for SUI in women.

Recommendations

No recommendations can be made regarding the use of acupuncture or acupressure for SUI in women. High-quality RCTs are needed.

8.2.2 Acupuncture for Treatment of OAB, UUI and Mixed UI

In this update, two recently-published reviews were identified which focused on acupuncture for women with OAB, UUI or Mixed UI, as well as an additional trial (not included in the reviews) (208, 212, 213).

Paik *et al.* (208) performed a systematic review of RCTs published in English or Korean language journals testing acupuncture and acupressure treatments for UI. Four small RCTs were found eligible for that review. One of these studied acupressure for SUI and is discussed in the section above (211), but 3 are considered in this section, all published before 2010 (214-216). A second review focused on acupuncture and OAB in non-comparative and comparative trials (212). This review identified 4 RCTs relevant to this section (comparative trials of acupuncture for women with UI), 3 of which were also included in the review by Paik *et al.* (214-217). Thus, in total 5 RCTs (four included in the recently published reviews and 1 additional trial) are included in this edition. Study populations included women with OAB and UUI (214,

215), OAB with or without UUI (217), MUI and UUI (216) and MUI (213).

Two trials compared acupuncture to sham or placebo acupuncture (215, 216). One was a pilot RCT which tested acupuncture vs sham acupuncture (sham needles which did'nt puncture the skin were used) in 9 women with mixed or urgency UI (216). The second trial randomised 74 women with OAB including UUI to acupuncture vs acupuncture performed at relaxation points (215). Two trials compared acupuncture to drug treatment, including an older trial that tested acupuncture vs oxybutynin 5 mg twice daily in 39 women with OAB with UUI (214). A recent, larger trial randomized 272 women with OAB with or without UUI to acupuncture or tolterodine 2 mg twice daily (217). Last, Jin *et al.* studied combination therapy with electroacupuncture plus tolterodine 2 mg twice daily versus electroacupuncture alone in 71 women with MUI (213).

Acupuncture techniques and regimens differed widely among the studies, including different acupuncture points treated. Treatments occurred 1 to 3 times weekly, lasted 4 to 8 weeks and outcomes were assessed immediately after treatment or 2 to 12 weeks later.

Quality of data

Randomization concealment was considered adequate in 2 of 5 trials (215, 217), one testing acupuncture vs placebo acupuncture and one comparing acupuncture to drug treatment (tolterodine). Blinding of participants and assessors was done in the trials testing acupuncture with a sham or placebo treatment (215, 216). Participants were not blinded in the 3 trials involving acupuncture and drug treatments (213, 214, 217), and assessors were blinded in only 1 of these (217). Sample size calculations were reported in only one trial (215). Adverse effects were described in 4 of 5 trials (214-217).

Results

Overall, no differences were seen in primary outcomes when comparing acupuncture with sham or placebo treatment and when comparing acupuncture with drug treatment. One small trial comparing acupuncture vs sham acupuncture in women with MUI reported greater reductions in overall incontinence episodes and urgency incontinence episodes in the acupuncture group after 4 weeks of treatment (67.5% vs 16.7% and 75.2% vs 24.9%, respectively), but statistical significance was not reached (216). Another trial of acupuncture vs sham acupuncture (relaxation points) in women with OAB and with UUI found a non-significant reduction in incontinence episodes (59 and 40% in the treatment and placebo groups) (215). For acupuncture treatment compared to drug therapy (oxybutynin or tolterodine) in women with OAB, no difference was seen in improvement in UUI episodes between treatment groups (214, 217). In one, frequency and urgency improved but UUI was unchanged and in the other, frequency, urgency and UUI improved, but no between group differences were reported (214). In the trial comparing combination treatment with electroacupuncture and tolterodine to electroacupuncture alone for MUI, both groups had significant reductions in overall UI episodes and in urine leakage volume on pad test, but these outcomes did not differ between groups. Significantly more women in the combination treatment group had a more than 50% improvement in number of UI episodes (76 vs 59%, $p<0.05$) (213).

No serious adverse effects occurred. Minor bruising and bleeding as well as some discomfort with needle placement were described (214-217).

Summary

Two trials (small to medium size) of varying quality found no or limited benefit in testing acupuncture to various sham treatments for MUI and OAB\UUI in women **(Level of Evidence: 2).**

Several factors limit these results, including small sample size, risk of bias and heterogeneity of active and sham treatments. Two trials comparing acupuncture to drug therapy in women with OAB, UUI and MUI found no difference between treatments **(Level of Evidence: 2).** One low quality trial suggested combination therapy of electroacupuncture plus drug for MUI was superior to electroacupuncture alone **(Level of Evidence: 2).**

Recommendations

When choosing between acupuncture and anticholinergic drug for women with OAB, UUI and MUI, either may be effective **(Grade of Recommendation: B)**.

There is insufficient evidence to make a recommendation related to the effectiveness of augmenting electroacupuncture with drug therapy **(Grade of recommendation: D).** High-quality RCTs are needed, including standardized acupuncture treatment regimens.

Conclusions

Limited evidence is available for the use of acupuncture techniques for the treatment of UI in women. Challenges in this area (in performing research as well as in interpreting the literature) include a lack of consistency in acupuncture techniques and regimens and controversy regarding the best comparator (sham or placebo acupuncture) (218). Also, much of the literature is not published in English language journals. Given the limitations to the quality and the heterogeneous nature of evidence available, few formal recommendations are possible related to use of acupuncture for SUI, UUI, MUI or overall UI in women. More rigorously-conducted RCTs are needed in this area.

9. FUTURE RESEARCH DIRECTIONS

9.1. Summary

Even with the number of reasonable trials on conservative management of UI in women, the standards of trial conduct and reporting varied considerably. It is strongly recommended that future RCTs on conservative management include power and sample size calculation, account for potential risk of bias, intervention content and intensity, and choice of outcome measures prior to conducting the trial.

9.2. Recommendations for practice

While some recommendations are underpinned by good and consistent evidence of effects, there remains a need for further testing because of **insufficient Level 1 and Level 2 evidence.**

9.2.1 Lifestyle Intervention

Treatment:

Nonsurgical weight loss should be considered a first line treatment to reduce UI in obese and overweight women **(Grade of Recommendation: A).**

Moderate exercise may help in decreasing the incidence of UI: this effect may be mediated by weight control **(Grade of Recommendation: C).**

Caffeine reduction may help in improving incontinence symptoms **(Grade of Recommendation: B).**

Minor decrease of fluid intake (by 25%) may be recommended provided baseline consumption is not less than 30 ml/Kg a day **(Grade of Recommendation: B).**

9.2.2 PFMT (Principal Recommendation)

PFMT in the prevention of UI in childbearing women: Continent, pregnant women should be offered a supervised (including regular health professional contact) and intensive strengthening antepartum PFMT programme to prevent antepartum and postpartum UI **(Grade of Recommendation: A).**

PFMT in the treatment of UI in childbearing women: PFMT should be offered as first line conservative therapy to women with persistent UI symptoms three months after delivery **(Grade of Recommendation: A)**.

An 'intensive' PFMT programme (in terms of supervision and exercise content) is likely to increase the treatment effect **(Grade of Recommendation: B).**

PFMT in the prevention/treatment of UI in childbearing women: Health providers should carefully consider the cost/benefit of population based approaches to health professional taught antepartum or postpartum PFMT, that is, health professional instruction to all pregnant or postpartum women regardless of their current or prior continence status **(Grade of Recommendation antepartum PFMT: A). (Grade of Recommendation postpartum PFMT: B).**

Where a population approach is used, the 'best' evidence to date suggests the following: (a) an intervention comprising of a daily home PFMT and weekly physiotherapist-led exercise classes for 12 weeks, starting at 16-24 weeks' gestation for pregnant women, and (b) an individually taught strengthening PFMT programme that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000g or more) **(Grade of recommendation: C).**

i) Other women PFMT

Prevention:

There is preliminary evidence that PFMT may help prevent UI in older women. **(Grade of Recommendation: C New).**

Treatment:

Supervised PFMT should be offered as first line conservative therapy to women urinary incontinence **(Grade of Recommendation: A).**

Clinicians should provide the most intensive health professional-led PFMT program possible within service constraints because programs that are thaught and supervised by health-professionals are better than those with little or no supervision **(Grade of Recommendation A)**.

Although studies are limited, there does not appear to be clear benefit for adding other modalities (i.e. motor learning, abdominal- or hip-muscle training, intra-vaginal resistance device) to PFMT **(Grade of Recommendation: B)**

There is no clear benefit from adding clinic- **(Grade of Recommendation B)** or home-based BF **(Grade of Recommendation B)** to a PFMT program. The use of clinic or home-based BF should remain a therapist/individual decision based on individual's needs and service constraints.

ii) Other women PFMT vs other intervention

For women with SUI:

- PFMT and VC are both effective as conservative therapy, although PFMT is superior **(Grade of Recommendation: B).**
- PFMT is better than EStim as first line conservative therapy **(Grade of Recommendation: B).**
- PFMT is better than BT as first line conservative therapy **(Grade of Recommendation: B).**
- PFMT and drug therapy are both effective as first line therapy, PFMT avoids the adverse effects experienced with drug therapy **(Grade of Recommendation: B).**
- Surgery is more effective than PFMT, but potential benefit should be weighed against potential

adverse events. PFMT should be offered as first line conservative therapy **(Grade of Recommendation: B New).**

- PFMT and continence pessary are both effective as first line conservative therapy **(Grade of Recommendation: B New).**

For women with SUI or MUI:

- VC does not appear to be better than PFMT in the treatment of UI. PFMT should be recommended as first-line conservative therapy **(Grade of Recommendation: B)**.

VCs with supervised training sessions by a trained health professional can be offered to women who can and are prepared to use them **(Grade of Recommendation: B)**

VC may be inappropriate for some women due to inability to insert or retain the cone or because of side effects and discomfort.

For women with UUI or MUI:

- PFMT and BT should be offered as effective first-line conservative therapies **(Grade of Recommendation: B).**
- PFMT is better than oxybutynin as first line therapy **(Grade of Recommendation: B).**

For women with UUI

PFMT and BT should be offered as effective first line conservative therapy **(Grade of Recommendation: B).**

iii) Other women PFMT + other intervention vs PFMT

In women using VC, it does not appear to help to add PFMT **(Grade of Recommendation: C)**.

For the treatment of SUI, UUI, or MUI in women, consider a combination of PFMT and BT rather then BT alone **(Grade of Recommendation: C)**.

For treatment of UUI (tolterodine) but not for SUI (duloxetine), consider adding PFMT to drug therapy **(Grade of Recommendation: B),**

When treating women with SUI and vaginal atrophy, consider combining PFMT and intravaginal oestrogen over estrogen alone may be better than estrogen alone **(Grade of Recommendation: C New)**.

9.2.3 Cones

For women with SUI, VC with supervised training sessions by a trained health professional may be offered as a first-line conservative therapy to those who can and are prepared to use them **(Grade of Recommendation: B)**.

VC may be inappropriate in some cases due to inability to insert or retain the cone or because of side effects and discomfort. Trained health professional assessment is recommended **(Grade of Recommendation: D)**.

VC and EStim seem equally effective in the treatment of SUI and MUI. Side effects and discomfort caused by both VC and EStim appears to limit their utility in clinical practice **(Grade of Recommendation: B).**

If this combined intervention proves to be of interest to women, then adequately powered studies are needed to confirm or refute the advantages of adding VCs to PFMT **(No Recommendation).**

9.2.4 EStim

EStim might be better than no treatment to improve symptoms and quality of life in SUI women **(Grade of Recommendation: B)**.

EStim may be considered for treatment to improve symptoms for UUI **(Grade of Recommendation: B).**

For women with SUI maximal clinic-based EStim might be better than daily low-intensity home-based EStim in improving symptoms **(Grade of Recommendation: B).**

Based on current limited evidence, EStim could be considered as an alternative to medical treatment. **(Grade of Recommendation: B)**.

The addition of EStim to PFMT or BF-assisted PFMT programmes does not appear to add benefit **(Grade of Recommendation: B)**

9.2.5 PTNS

For women with UUI or OAB, PTNS may be more effective than no active treatment in symptom control **(Grade of Recommendation: C New).**

There is no significant difference between PTNS and tolterodine in terms of quality of life, however PTNS may be considered as both may improve quality of life and PTNS is less invasive **(Grade of Recommendation: B New).**

PTNS may be considered for women as it is associated with fewer and less bothersome adverse effects than those from drug treatment **(Grade of Recommendation: B New).**

PTNS may be considered for symptom control when chosen in combination interventions such as with PFMT plus bladder training, or drug treatment by women with UUI or OAB **(Grade of Recommendation: B New).**

9.2.6 Magnetic Stimulation

No recommendation is possible based on current conflicting evidence **(Grade of recommendation: D).**

No recommendation is possible regarding optimum type of MStim **(Grade of Recommendation: D).**

The addition of MStim to PFMT in treatment of SUI does not appear to be beneficial **(Grade of Recommendation: C).**

9.2.7 Bladder Training

BT should be recommended as first line conservative therapy for UI in women **(Grade of Recommendation: A)**.

Clinicians should provide the most intensive BT supervision that is possible within service constraints **(Grade of Recommendation: D).**

Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of their approach to BT. **(Grade of Recommendation: D).**

When considering BT and anticholinergic drug for women with DO or UUI, either may be effective **(Grade of Recommendation: B)**.

BT may be preferred by women and clinicians because it is not associated with the drug related side effects **(Grade of Recommendation: D)**.

The available evidence (single trial) supports the use of BT as a supplement to PFMT in improving short-term outcomes, but not longer-term results **(Grade of Recommendation: C)**.

Limited evidence suggests the addition of written information on BT for women with OAB taking an antimuscarinic drug does not further improve UI **(Grade of Recommendation: B)**.

Timed voiding with a two-hour voiding interval may be considered as a sole intervention for women with mild UI or infrequent voiding patterns **(Grade of Recommendation: C)** Timed voiding may also be considered as an adjunct to other treatment.

Insufficient evidence exists to support the use of BT to treat urgency in women with UI and/or OAB, or to guide the choice of BT vs, drug treatment as initial treatment aimed at urgency **(Grade of Recommendation: D)**.

Routine addition of a "simplified" BT to drug therapy does not provide additional improvement in urgency, but should be considered in treatment of voiding frequency in women with UI and OAB **(Grade of Recommendation: B)**.

BT should be offered as treatment for urinary frequency and nocturia **(Grade of recommendation: B)**, but in choosing between BT and an anticholinergic drug for women with frequency, either may be effective **(Grade of Recommendation: B)**.

9.2.8 Complementary and Alternative Medicine

Acupuncture:

The limited evidence available to date does not support the use of acupuncture when compared to sham or placebo treatment for women with OAB, UUI and MUI.

When choosing between acupuncture and anticholinergic drug for women with OAB, UUI and MUI, either may be effective **(Grade of Recommendation: B)**.

There is insufficient evidence to make a recommendation related to the effectiveness of augmenting electroacupuncture with drug therapy **(Grade of recommendation: D).**

High-quality RCTs are needed, including standardized acupuncture treatment regimens.

9.3. Future Research Direction

All future trials must be designed, implemented and reported in ways that maximise their usefulness in practice; this includes being well powered, with longer term follow up, with evaluation of cost-effectiveness and planned secondary analysis of trial data to investigate predictors of effectiveness. Readers are referred to the revised CONSORT statement for guidance (219).

9.3.1 Lifestyle Modification Intervention

Prevention should be an area for future research investment and comprise robust economic evaluation to determine the benefits of lifestyle modification strategies in women with UI.

With limited new data on the effects of physical activity (moderate or strenuous), smoking cessation, diet modification and constipation, their association with UI development or symptom reduction should be investigated further.

Separate investigation of the impact of lifestyle modification interventions on nocturia, diurnal frequency, urgency and UI should be undertaken.

9.3.2 PFMT in Antenatal and Postnatal women

- Additional trials with longer-term follow-up (greater than 12 months postnatal) are needed to determine long-term benefits of antenatal PFMT.
- Large and good-quality RCTs are needed to investigate the effect of antepartum PFMT on preventing postpartum UI in multiparous women.
- Large and good-quality RCTs are needed to investigate the effect of intensive post-partum PFMT on preventing postpartum UI in women. Attention must be given to high risk subgroups.
- There is a need for at least one large, pragmatic, well-conducted and explicitly reported trial with long term follow-up (five plus years) of postpartum PFMT that investigates the long term effect of 'intensive' PFMT for persistent postnatal UI.

9.3.3 PFMT in Women (Others)

The effect of PFMT in the prevention of UI in women should be studied further.

Larger, good quality trials are needed to address comparisons between PFMT regimens, PFMT and other modalities or PFMT + another modality and PFMT alone, if these are of interest to women. In planning comparisons, researchers should consider carefully power calculation, intervention intensity and the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies.

9.3.4 Vaginal Cones

Larger, good quality trials are needed to address comparisons between VC and other modalities, and VC+ other modalities compared to VC, if these are of interest to women. In planning comparisons researchers should consider carefully power calculation, intervention intensity and the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies.

9.3.5 EStim/PTNS/MStim

Larger, good quality trials are needed to address comparisons between EStim/PTNS/MStim and no treatment, EStim/PTNS/MStim and other modalities, EStim/PTNS/MStim + other modalities and EStim/PTNS/MStim, if these are of interest to women. In planning comparisons researchers should consider carefully power calculation, intervention intensity and the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies.

9.3.6 Scheduled Voiding Regimen

Larger, good quality trials are needed to address comparisons between BT and no treatment, BT and other modalities, BT + other modalities and BT, if these are of interest to women. In planning comparisons researchers should consider carefully power calculation, intervention intensity and the potential impact of different levels of supervisory intensity between groups, particularly in comparisons of conservative therapies.

III. PELVIC ORGAN PROLAPSE (POP)

Pelvic organ prolapse (POP) refers to the loss of support for the uterus, bladder, colon or rectum leading to prolapse of one or more of these organs into the vagina. Prolapse is characterised by a variety of pelvic floor symptoms (2), the most commonly reported being a sensation of bulging into the vagina. Treatment depends on the severity of the prolapse and its symptoms, and the woman's general health (2). Conservative treatment is generally considered for those with a lesser degree of prolapse, those who wish to have more children, those with frailty or those unwilling to undergo surgery. Conservative management, defined here as lifestyle modification interventions, PFMT and pessaries, was first reviewed in the 3rd ICI and in the 5th was recommended as first-line treatment for prolapse.

The aims of conservative treatment in the management of POP include:

- preventing the prolapse becoming worse;
- decreasing the frequency or severity of symptoms caused by prolapse (pelvic pressure, vaginal bulging, backache, urinary, bowel and sexual dysfunction);
- aversion or delaying of the need for surgery.

In this section the evidence is presented for the use of conservative management of POP, utilising information from Cochrane systematic reviews (220-222), and literature identified via a search strategy summarised in Section I. For included trials, risk of bias (RoB) was assessed using the Cochrane Collaborations RoB tool (223). For other types of study, bias was assessed using the Critical Appraisal Skills Programme (CASP) (224) checklist item relating to adjustment in analysis for potential confounding risk factors.

1. LIFESTYLE MODIFICATION INTERVENTION

Lifestyle modification interventions include weight loss, reducing exacerbating activities (e.g. lifting, coughing) and treating constipation, and are intended to avoid worsening of the prolapse by decreasing intra-abdominal pressure.

1.1. Prevention

1.1.1 Quality of Data

No trials of lifestyle modification interventions to prevent prolapse were identified in this update. However, 12 observational studies (retrospective reviews, prospective surveys and case-control studies) that examined the association between modifiable lifestyle factors such as occupation (involving heavy lifting/strenuous physical activity), bodyweight, smoking, constipation, nutrition and the development of prolapse have been published since last review, which add to the 33 previously described (9 in 5th edition, 15 in 4th edition and 9 in 3rd edition). These are reported and summarised in Table 26. Studies often examined multiple risk factors and contribute evidence to more than one section below. If modifiable lifestyle factors are established as risk factors for prolapse these could be targeted with a view to prevention.

1.1.1.1 Association Between POP and Occupation and Physical Activity

To date, the potential relationship between occupation and physical activity on prolapse has received scant attention (5 studies in 3rd edition (225), 5 in 4th edition(226), 3 in 5th edition(2)). A recent narrative lit-

erature review (227) investigated the effect of physical activity and occupation on the development of prolapse. The review authors identified 10 studies, all of which have been reviewed in–depth in previous editions of this chapter. They concluded that the evidence linking physical activity and occupation with an increased risk for POP was weak and inconclusive.

Our systematic search identified a further 5 additional studies, included (228-232). The key characteristics of these studies are described in Table 26.

Akmel *et al.* (2012) conducted a retrospective study of women in one Ethiopian hospital treated surgically for prolapse over three years (230). Medical interns extracted data from the women's medical records on demographics, medical, surgical and obstetric history, symptoms and risk factors. Only univariate analysis was performed and therefore the study was judged to be at high risk of bias (Table 26).

Bathla *et al.* 2014 (232) carried out a retrospective review of case notes for women who presented with prolapse at mobile surgical camps in a remote village of Himachal Pradesh between 2009- 2013. Women underwent POP-Q assessment prior to surgery. The aim was to study the epidemiological risk factors for prolapse, including occupation and nutrition (see below). The analysis was mainly descriptive although the authors report they did "correlation regression", but it was not clear what this was, and therefore the results were difficult to interpret and at high risk of bias (Table 26).

Gumanga *et al.* (2014) undertook a prospective study of women presenting with prolapse at gynaecological outpatients at a hospital in Ghana over two years (2010-2011), describing occupational, socio-cultural practices and obstetric characteristics and how they related to severity of prolapse (231). Data collected included demographics, reproductive history and pelvic examination findings. Women were included if they complained of a mass in the vagina and had demonstrable descent on pelvic examination. There was no control group so analysis of risk factors was not possible, thus the study was at high risk of bias (Table 26).

Lonnée-Hoffmann *et al.* (2015) recently reported on a cross sectional study they undertook in women 30 years or older in one Nordic county in the Nord-Trøndelag Health Study (228). Outcome measures examined were self-reported prolapse surgery, age at survey, socio-demographic factors, and information on risk factors for prolapse (smoking, chronic obstructive pulmonary disease, asthma, constipation a decade previously, and measured body mass index) (see Table 26). Multivariable logistic regression was used for analysis thus the study was judged to be at low risk of bias.

Nygaard *et al.* (2014) conducted a retrospective case-control study of women with prolapse (descent ≥ 1 cm beyond the hymen) and without prolapse (descent ≤ 1 cm above the hymen), age and site matched, to assess the impact of lifetime physical activity on the risk of prolapse (229). Women were recruited from primary care or community advertisements, and were not seeking treatment for prolapse. Physical activity was measured using the Lifetime Physical Activity Questionnaire (LPAQ), which assesses physical activity over four periods (start of menstruation to age 21, 22-34, 35-50, and 51-65 years), and includes leisure activity, outdoor work, and housework. The Occupation Questionnaire (OQ), part of the LPAQ, was also used. Multivariable models were fitted to assess the effect of physical activity on prolapse indicating a low risk of bias for this study (Table 26).

1.1.1.2 Association Between POP and Body Weight

There has been little agreement on whether an increase in weight (or increased waist circumference or higher BMI) is linked with an increased risk of POP. Seventeen studies have evaluated the effects of bodyweight on POP since the previous editions (4 in 5th edition, 5 in 4th edition, 6 in 3rd edition) (228, 233-248). In addition, two reviews have recently been published on this topic (249, 250) (Table 26). The former literature review included a study by Kudish and colleagues (2009) – which had not previously been included in earlier editions of this chapter – it is therefore included here (251).

1.1.1.3 Association Between POP and Smoking

Three studies on the relationship between smoking and prolapse were identified (228, 232, 252). In addition, Kudish (2009) investigated smoking as a risk factor (251).

Estanol and colleagues (252) studied female smokers and non-smokers with and without prolapse in a cross-sectional study in one centre. Smokers and non-smokers without prolapse were age matched to smokers and non-smokers with prolapse. The aim was to examine the impact of smoking on collagen markers (MMP-9) and vitamin C, in those with and without prolapse. Women with prolapse had a bulge at or beyond the hymen on examination, and answered positively to two Pelvic Floor Distress Inventory (PFDI) questions on the feeling of a bulge or a visible bulge in the last 12 months. A univariate analysis of the associations was carried out, thus a high risk of bias was assumed (Table 26).

A significant association between POP and smoking has also been reported in 2 studies above (228, 251). Bathla *et al*., (2014) also noted that 30-57% of their sample were smokers; collectively these studies suggest that smoking is a risk factor for POP.

Table 26 Summary of data on lifestyle factors and POP

Author, year	Study design/ Comparator	N	Study population	Modality details/methods employed	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
POP and Occupation/Physical activity							
Akmel 2012 (1)	Retrospective descriptive case note analysis	129	Patients who were admitted and operated on in the gynaecology ward in one hospital in Ethopia. All the women with POP who were admitted and treated during the study period were included; no sampling technique was employed	Demographic and medical characteristics were extracted based on the initial medical history and physical examination documentation in the case records	Type of occupation was strongly associated with stage of prolapse. Housewives were more likely to have stage IV (vs stage III) prolapse compared to farmers.	None	Data was available for 129 out of a possible 143 women. No multivariate analysis to allow for other confounding variables.
Bathla 2014(2)	Retrospective descriptive case note analysis	157	157 women who had POP surgery conducted in 5 mobile surgical camps in Shillai, Himachal Pradesh from 2009 to 2013 (“Project Prolapse”).	Epidemiological data and POP-Q data were collected.	Factors contributing to POP believed to be “poor nutritional status (mean weight 41.1 kg), multiparity (mean 3.5), early marriage (mean age 18.2 years), unassisted home deliveries (100%), premature bearing down (23.8%), early postpartum resumption of strenuous activity (54.7%) and smoking (33%)” This was not based on statistical analysis.	None	“Statistical analysis was performed using correlation regression analysis”, but limited data presented. No multivariable analysis performed.
Gumanga 2014 (3)	Prospective observational study	118	POP cases, out-patients seen over 2-year study period at a teaching hospital in Ghana.	Questionnaires and physical exam in patients whose main complaints included “a mass falling from the vagina” or “bulging mass” or “sensation of mass in the vagina”.	Main occupations were trading of produce 66/118 (55.9%) and farming 44/118 (37.3%)	None	Authors report that occupational factors might contribute to the severity of POP in this sample. Analysis undertaken is unclear but appears not to be multivariable analysis.

Author, year	Study design/ Comparator	N	Study population	Modality details/methods employed	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Lonnee-Hoffmann 2015 (4)	Cross-sectional survey	20,285	All women aged ≥ 30 years in one Nordic county invited to take part	Women were sent questionnaires and attended screening stations. Risk factors assessed: smoking, chronic obstructive pulmonary disease, asthma, constipation a decade previously, and measured BMI	POP surgery was reported by 1,123 (5.3 %). Only women reporting more lifting in addition to walking had significantly higher odds of reporting POP surgery compared with women with sedentary occupation in the age-adjusted model	None	Authors also report that constipation reported a decade prior, above-normal BMI, and COPD were significant non-obstetric risks for prolapse surgery. Multivariable analysis performed.
Nygaard 2014 (5)	Retrospective case-control study	382	191 POP cases and 191 age and recruitment-site matched controls, aged between 39-65 years, not seeking prolapse treatment	Women were asked to complete Lifetime Physical Activity and Occupation Questionnaires based on self-reported activities	No associations between odds of POP and overall lifetime physical activity, lifetime leisure activity, or lifetime strenuous activity	None	Authors suggest that strenuous activity during teenage years may have an association with POP, and recommend further prospective research in this area Multivariable analysis??
POP and Smoking (see also entries for Bathla 2014, Kudish 2009 and Lonnee-Hoffmann 2015)							
Estanol 2015 (6)	Cross-sectional study	96	4 groups of women: smokers with POP (n=16), non-smokers with POP (n=16), smokers without POP (n=32) and non-smokers without POP (n=32)	Fasting blood panel, including plasma procollagen 1-N propeptide (P1NP), matrix metalloproteinase 9 (MMP-9), and vitamin C. These are markers of collagen metabolism. Smokers were defined as smoking 1 pack or more a day for at least 1 year; non-smokers were defined as not having smoked for at least 7 years	Comparing women with POP and without, there were no significant differences in vitamin C, P1NP and MMP-9 levels, independent of smoking status. MMP-9 levels were higher and vitamin C lower in smokers compared to non-smokers.	None	Small sample size; was not sufficiently large to detect a true difference, particularly in those with prolapse. No multivariable analysis

Author, year	Study design/ Comparator	N	Study population	Modality details/methods employed	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
POP and Bowel function (see also entries for Kudish 2009 and Lonnee-Hoffmann 2015)							
Bezerra 2014 (7)	Cross-sectional survey	172	Participants referred to one tertiary urogynecology outpatient clinic with self-reported symptoms of PFD: POP [POP-Q ≥ stage II and/or UI]	Medical history, series of questionnaires (ICIQ-SF; KHQ; PISQ-12), Cleveland Constipation Scale and physical exam using the PERFECT scheme.	No differences in prolapse status between patients with and without anal incontinence and/or bowel disorders.	None	No multivariable analysis
Elbiss 2015 (8)	Cross-sectional	429	Women attending family development centres in United Arab Emirates, 29.6% reported POP symptoms	Questionnaire included items for details of socio-demographic, obstetrics, medical and surgical history. Presence of a lump in/out of vagina was taken as presence of POP.	Chronic constipation and chest disease, level of education, occupation birth weight and BMI were independent risk factors for having POP symptoms.	None	Multivariable analysis was performed. Authors recommended additional healthcare campaigns to raise awareness about risk factors for POP
POP and Nutrition (see also entries for Estanol, 2015)							
Navaneethan 2015 (9)	Prospective case-control study	120	Women with (n=51) or without (n=69) PFD on examination when attending outpatient clinic at one tertiary care centre in South India	Medical history and clinical examination (POP-Q) were performed. Serum 25-hydroxy vitamin D levels were measured in all participants	23/51 had POP alone, 9/51 had POP+SUI; vitamin D levels were not significantly associated with POP	None	Multivariable analysis performed to adjust for age.
Parker-Autrey 2012 (10)	Retrospective chart review	394	Women over 19 years old attending a Urogynecology Care Clinic from 2008 to 2010 who had vitamin D measured.	Diagnosis categorized as PDF (SUI, UUI, FI, POP) (n=268) or general GYN (n=126). Demographic and medical characteristics were extracted. PFDI-SF 20, IIQ-7, Medical, Epidemiologic, and Social Aspects of Aging (MESA) questionnaire.	Only higher IIQ-7 scores were significantly related to having insufficient vitamin D.	None	Multivariable logistic regression model used to adjust for age, BMI, ethnicity, and use of vit. D supplementation

Author, year	Study design/ Comparator	N	Study population	Modality details/methods employed	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
POP and body weight							
Myers *et al*., 2012(11)	Secondary data analysis of RCT	338	Overweight and obese women with UI	Women were randomised either into an intensive 6-month weight loss or to the control group (educational program) Symptomatic prolapse was defined as a positive response to at least 1 prolapse subscale question of the UDI. "Bother" was defined as responses of slight, moderate, or great.	Increasing BMI was associated with only "feeling" a vaginal bulge. (13% of obese women reported feeling vaginal bulging compared with overweight women (0%).	Evaluated for prolapse symptoms at baseline and 6 months	At 6 months, there were no significant differences in improvement of self-reported bothersome prolapse symptoms in women in the weight loss or the control group Multivariable analysis was performed.
Kudish 2009 (12)	Secondary analysis of a 5-yr clinical trial	16608	Post-menopausal women aged 50-79 yrs	Degree of prolapse assessed using the WHI Prolapse Classification System	Prolapse risk in overweight and obese women (compared with the women with healthy BMI) increased by 32% and 48% for cystocele, by 37% and 58% for rectocele, and by 43% and 69% for uterine prolapse, respectively	Annual pelvic exam over a 5 year interval	Being overweight or obese is associated with progression of POP. Authors reported that “weight loss was not significantly associated with regression of POP”, and argued that pelvic floor damage related to weight gain could be irreversible Multivariable analysis was performed.

Abbreviations: PFDI-20: pelvic floor distress inventory short form 20, PFIQ-7: pelvic floor impact questionnaire short form; PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; POP-Q; Pelvic Organ Prolapse Quantification system; PISQ-12: Pelvic organ prolapse/urinary incontinence sexual questionnaire’ POP-SS: pelvic organ prolapse symptom score; QoL: quality of life; RCT: randomized controlled trial; sEMG: surface electromyography; SR: systematic review; UI: urinary incontinence

1.1.1.4 Association Between POP and Bowel Function

Previously there were 8 studies that had examined the potential impact of bowel disorders/ or bowel dysfunction on prolapse (4 in 5th edition, 4 in 4th edition). This update adds a further 4 studies. Two are described below; two have been described above (Lonnee-Hoffman *et al.*, 2012; Kudish *et al.*, 2009).

Bezerra *et al.* (2014) undertook a cross-sectional study of women with pelvic floor disorders (POP-Q ≥ stage II and/or urinary incontinence) presenting at a tertiary urogynaecology clinic in Brazil (253). The aim was to report the prevalence, bother, and impact on quality of life (QoL) of unreported bowel symptoms, to improve the patient care. Those with and without defaecatory or anal continence problems were compared. A number of measures were used depending on the presence/absence of bowel and urinary incontinence symptoms: ICIQ-SF, King's Health Questionnaire, PISQ-12, the Wexner score, Cleveland Clinic Florida Incontinence Scale, Cleveland Clinic Florida Constipation Scale (mild, moderate or severe). All women completed the SF-36 and had their pelvic floor assessed by a physiotherapist using the PERFECT scheme. Only univariate analysis was performed, putting the study at a high risk of bias (Table 26).

Elbiss and colleagues (238) carried out a cross-sectional study of parous Emirati women 30 years or older attending three family development centres in Al-Ain in one year. The objective was to EStimate the prevalence of prolapse and its risk factors. The study used a self-developed questionnaire, which was piloted and revised before use. The questionnaire covered demographic, obstetrics, and medical history, prolapse symptoms (lump coming down in the vagina, lump coming out of vagina or lump felt or seen outside vagina), other vaginal symptoms and the need to digitate to empty bladder or bowel. Following univariate analysis, multivariable binary logistic regression analysis (prolapse symptoms versus no prolapse symptoms) was performed including all significant variables to determine which were independent risk factors for prolapse (Table 26). This study was judged as having a low risk of bias.

1.1.1.5 Association Between POP and Nutrition

Two studies were identified in previous editions of the chapter that examined the effects of anaemia (4th edition) and vitamin D (5th edition) on prolapse. A further 2 studies relating to vitamin D are included in this update (Table 26).

Navaneethan *et al* (2015) conducted a case-control study of postmenopausal women with and without pelvic floor disorders, in particular, symptoms of urinary incontinence or prolapse. It was not clear how the women were selected but the study took place in a department of obstetrics and gynaecology in South India. A clinical and obstetric history was taken, examination performed (POP-Q and stress test) and vitamin D measured in all women. A multivariable logistic regression analysis was undertaken to assess the relationship between vitamin D and PFD adjusting for other variables (254). A low risk of bias was assumed (Table 26).

Parker-Autry *et al.* (2012) in Alabama, US, undertook a retrospective review of women who were new urogynaecology outpatients presenting over a two-year period (2008 to 2010) and who then had vitamin D measured within one year of that visit. 25(OH)D < 15 ng/ml was defined as being deficient in vitamin D, and 15 to 29 ng/ml as having insufficient vitamin D. Women were classified into two groups, either PFD (having SUI, UUI, FI or POP) or general gynaecology (no PFD) (Table 26). Demographic, medical, and laboratory data were extracted from the initial history and physical examination notes. Questionnaire responses from the clinic visit were also available (PFDI-SF 20 (including the UDI, CRADI, POPDI) and IIQ-7). Multivariable logistic regression was used to examine the association between vitamin D status and pelvic floor disorder symptoms, with adjustment for age, BMI, race/ethnicity, and the use of vitamin D supplementation. This study was judged to be at low risk of bias.

1.1.2 Results

1.1.2.1 Association Between POP and Occupation and Physical Activity

In the Akmel *et al.* (2012) study, 143 prolapse cases were examined and complete data retrieved for 129 cases. The mean age of the women was 42 years (range 22 to 72 years), mean parity was 6.5 (range 1 to 14) and all had stage III (56%) or IV (44%) prolapse. Significant univariate associations were found between age, parity and rurality and stage of prolapse. Occupation was significantly associated with prolapse stage in that farmers were more likely to have a lower stage and housewives a higher stage of prolapse (230).

In the retrospective case analysis described by Bathla *et al*. (2014), 192/490 surgical case presentations were gynaecological and 82% of these were prolapse (99% involving the anterior compartment). These women were aged between 30 and 70 (mean 47 years), had mean parity of 3.5, and all had unassisted home deliveries. Premature bearing down during delivery was reported for 24%. Women on average resumed strenuous physical work and sexual activity 20 days after giving birth. 33% were smokers and 55% lifted heavy weights uphill. The authors reported non-significant correlations between POP-Q stage and parity, resumption of physical activity and weight (232).

Out of 4403 outpatients, 118 cases (2.7%) of prolapse were seen over the study period in the Gumanga (2014) paper, with a mean age of 46 years (SD 15 years) and mean parity 4.4 (SD 1.7). For 57%

of women their deliveries had been exclusively at home. Women were predominantly farmers (37%) or traders (56%) (231).

Of all women in the county 30 years or older, 20,285 (50.3%) were included in the Lonnee-Hoffman (2012) study; of which 1,123 (5.5%) reported having undergone prolapse surgery. In the multivariable models, the odds of having prolapse surgery were shown to be significantly greater for women with BMI of 25 or greater, and for those who reported "marked" constipation (as compared to no or mild constipation). There was no relationship with smoking, asthma or occupation (228).

One hundred and ninety-one cases and an equal amount of matched controls were recruited in the Nygaard *et al*. (2014) study. The mean age of women was 50 years (SD 7). Cases tended to have a higher BMI than controls, and had significantly greater parity and more vaginal deliveries. Vaginal bulge was more prevalent in the cases than controls, but there was no difference in other pelvic floor symptoms. The authors found no evidence that physical activity (lifetime overall activity, leisure or strenuous physical activity) was associated with risk of prolapse in multivariable models. The exception was that strenuous physical activity in the teenage years showed a significant relationship with the odds of prolapse, indicating an increased risk of prolapse for those reporting 21 hours/week or more of strenuous physical activity when a teenager (229).

Elbiss (2015) found nature of occupation to be a significant predictor of prolapse symptoms (see below); women with non-physical jobs were more likely to report symptoms.

1.1.2.2 Association Between POP and Body Weight

Vergeldt *et al*. (2015) systematically identified 8 studies that examined the association of higher BMI and POP and presented the results in a narrative synthesis. The authors reported that 4/8 studies identified that higher BMI was a significant risk factor for POP; 3/8 found no relationship between high BMI and the development of primary POP and 1/8 study found that a "higher BMI slightly protective". The authors reported that the relationship between weight and POP was inconsistent; thus no conclusions can be reliably drawn (250). This well-conducted review was judged to be at low risk of bias.

Kudish and colleagues (2009) explored the relationship between prolapse progression (or regression) and weight change in 16,608 post-menopausal women (Table 26). This secondary analysis study was based on longitudinal data from the WHI E+P trial; a double-blinded RCT. Women aged between 50 and 79 years received annual pelvic examinations over a 5-year interval. The majority of women enrolled in the study gained weight, and the overall prolapse prevalence (stage I-III) increased from 40.9% at baseline to 43.8% by year 5. The risk of all types of prolapse increased in overweight and obese women compared to post-menopausal women with normal BMIs (Table 26). When the data was adjusted for women diagnosed with prolapse at baseline and baseline BMI, a 10% weight loss was associated with minimal change in overall POP (251). This study was judged to be at low risk of bias.

1.1.2.3 Association Between POP and Smoking

In the Estanol (2015) study, a total of 96 women were recruited: 32 with prolapse (16 smokers, 16 non-smokers) and 64 without prolapse (32 smokers, 32 non-smokers) (252). Smokers with prolapse had lower levels of vitamin C and higher levels of MMP-9, compared to non-smokers with prolapse, but this relationship was not statistically significant. However, comparing smokers without prolapse to non-smokers without prolapse, there were significant differences in both vitamin C and MMP-9, suggesting an impact of smoking on these collagen markers. Ignoring smoking status, vitamin C and MMP-9 levels in women with prolapse were similar to those without prolapse. The authors suggest that the damage to connective tissue that leads to prolapse may be different from the harm caused by cigarette smoking.

Lonnee-Hoffman *et al.* (2015) found no association between smoking and whether a woman reported having had prolapse surgery or not (228). Bathla *et al.* (2104) commented that 33% of the women having prolapse surgery were smokers (232).

1.1.2.4 Association Between POP and Bowel Function

Bezerra and colleagues reported that a total of 172 women with prolapse and/or urinary incontinence participated and initially none of them reported defecatory problems or anal incontinence, although 54.6% reported one or both on interview. Those with AI/defecatory problems were no more likely to report prolapse (sensation of a ball in the vagina) than those without these problems (68% versus 65%). Stage of prolapse was not associated with AI/defecatory problems either (253).

Of the 482 eligible women in the Elbiss (2015) study, 429 (89%) participated, of which 127 (29.6%) reported prolapse symptoms. Those women with and without prolapse symptoms did not differ in terms of age. Of the factors significantly associated with prolapse in the univariate analysis (BMI, education level, nature of occupation, history of chronic chest disease, constipation, diabetes, previous instrumental delivery, maximum birth weight, history of urinary incontinence and previous surgery for urinary incontinence) six were independent risk factors in the multivariable analysis: history of constipation, education level, chronic chest disease, nature of occupation, maximum birth weight and BMI. Women were more likely to have prolapse symptoms if they had chronic

chest disease or constipation, higher BMI or maximum birth weight, lower education level, and were a housewife or had a non-physical job (238).

Lonnee-Hoffman *et al* (2015) found that marked constipation (as compared to no or mild constipation) was significantly associated with having prolapse surgery (228).

1.1.2.5 Association Between POP and Nutrition

Navaneethan *et al* (2015) reported that of the 120 women who participated: 42.5% had PFD (54.9% prolapse alone, 27.4% SUI alone, 17.6% SUI and prolapse) and 57.5% had no PFD. Multivariable analysis showed that, after adjustment for age, having any PFD was associated with having lower vitamin D levels and being five years or more post-menopausal. However having prolapse was only associated with the latter, and there was no significant relationship with vitamin D (254).

Of 550 women potentially eligible to participate in the Parker-Autry (2012b) study, 394 were included (268 in the PFD group and 126 in the no PFD group). The prevalence of vitamin D insufficiency was 51% in the PFD group. Vitamin D insufficiency was independently associated only with IIQ-7 score. That is, there was no relationship with prolapse symptoms (255).

Summary

- There remain no trials of lifestyle modification interventions to prevent prolapse. Some new observational studies have added to our knowledge of potentially helpful ways to modify lifestyle risk factors.
- Two new good quality observational studies (228, 229) suggested occupation and physical activity are not risk factors for prolapse surgery or prolapse 1cm or more beyond the hymen on examination. A third study however found women who were housewives or in a non-physical occupation were more likely to report prolapse symptoms (238). The vast majority of studies reported in previous editions supported an association between current heavy occupational lifting and prolapse, overall therefore the evidence seems to be conflicting, and this may be due to different ways of defining prolapse **(Level of Evidence: 3; Grade of Recommendation: D Conflicting therefore no recommendation).**
- Recent evidence on the relationship between prolapse and bodyweight is conflicting. **(Level of Evidence: 3; Grade of Recommendation: D Conflicting therefore no recommendation).**
- Smoking was found not to be associated with prolapse in two studies: a matched case control study (Estanol) (high risk) and large cross-sectional survey with multivariable analysis (Lonnee-Hoffman) (low risk). No studies were found in earlier editions **(Level of Evidence: 3; No recommendation).**
- Evidence from previous editions regarding the association between constipation or straining at stool and prolapse was conflicting. Two new, low risk studies, which adjusted for covariates, concluded that constipation was associated with both prolapse symptoms and having prolapse surgery, contributing more evidence of an association **(Level of Evidence: 3; Grade of Recommendation: C New; Majority evidence of an association).**
- Two new, low risk studies on vitamin D supported previous findings (1 study, 5th Edition) of no association with prolapse **(Level of Evidence: 3; Grade of Recommendation: C Majority evidence of no association)**.

1.2. Treatment

Previously no studies that evaluated the effectiveness of lifestyle modification interventions in the treatment of women with POP had been identified. Subsequently we have identified one trial, which measured prolapse outcomes after weight loss programmes (243). Not all trial participants had prolapse however, which limits the usefulness of this evidence (see Table 26).

Quality of data

Myers and colleagues (2012) performed a secondary analysis of data from the PRIDE trial of an intensive weight loss programme versus an educational programme for urinary incontinence in overweight and obese women (243). Prolapse symptoms were measured at baseline and six months (post-intervention) using the prolapse items from the UDI. Any positive response to any questionnaire items indicated the presence of prolapse symptoms. A subgroup of women agreed to have urodynamics and POP-Q assessment before and after intervention. Women were classified as overweight, obese or severely obese according to their BMI. Women who had prolapse symptoms at baseline were analysed at 6 months for differences between the randomised groups. The risk of bias was judged as low in relation to selection, detection and attrition for the original PRIDE trial (6) in a recent Cochrane review (5).

Results

Myers *et al.*, (2012) reported that 338 women were randomised and 110 had urodynamics and POP-Q (243). Of the women randomised, 16% were overweight, 58% obese and 26% severely obese. At baseline 53% reported at least one prolapse symptom, but this did not differ across BMI groups. A significantly greater proportion of obese women reported feeling vaginal bulge compared to overweight women (10% severely obese vs 14% obese vs 0% overweight), but the mean number of prolapse symptoms did not differ across the BMI groups. The proportion

with prolapse beyond the hymen was 17% overall but did not differ across the BMI groups (24% overweight group, 17% obese group, 13% severely obese group). Post-intervention the intensive weight loss group had lost significantly more weight than the control group (mean 7.8kg vs 1.5kg). Over 70% reported cure or improvement in prolapse symptoms, although this was no different between the intensive weight loss group and the educational group. There was also no significant difference in prolapse beyond the hymen between weight loss intervention and educational groups. The findings would suggest a lack of relationship between weight loss and improvements in prolapse. However, the trial was designed for women with urinary incontinence rather than prolapse, and the post-intervention comparison was not randomised.

Summary

Currently, there is evidence from secondary analysis of one robust trial regarding the role of weight loss in the treatment of POP. The trial however was in overweight and obese women with UI, some of whom had prolapse. It would appear that weight loss in both groups led to an improvement in prolapse, however there was no relationship between degree of weight loss (intensive vs normal weight loss programme). Any weight loss may improve prolapse in overweight or obese women and UI. **(Level of Evidence: 2; Grade of Recommendation: D).**

2. PELVIC FLOOR MUSCLE TRAINING

The pelvic floor muscles play a critical role in giving structural support to the pelvic organs and pelvic openings. It is hypothesized that improving pelvic floor muscle function may improve this structural support for the pelvic organs.

A programme of supervised PFMT includes assessment of the woman's pelvic floor muscles and her ability to contract these muscles; education about the pelvic floor muscles and how they support the pelvic organs; instruction in how to correctly perform pelvic floor muscle exercises and "the Knack" (pelvic floor muscle bracing against increased intra-abdominal pressure, for example when coughing and sneezing) (256). An individualised exercise programme is prescribed for the woman to follow. Adjuncts to PFMT (such as biofeedback) or other physical therapies (such as neuromuscular EStim) may be used. These therapies aim to improve PFM strength, endurance, coordination and function. Other forms of physical therapy involving diaphragmatic aspiration are emerging.

2.1. Prevention

Quality of data

Previously there were no trials of PFMT for prevention of prolapse, only evidence from cross-sectional studies of a possible association between pelvic floor muscle function and risk of prolapse. Two RCTs have now been identified that evaluate the role of PFMT in prevention of prolapse (257, 258). A summary of the setting, design and study population of prevention trials is presented in Table 27. Blinding of patients is generally not possible in trials of PFMT so this is not taken into consideration in the risk of bias analysis.

Bo *et al* (2013) (258) carried out a trial in primiparous women after vaginal delivery of a singleton infant after 32 weeks gestation, comparing supervised PFMT with written advice to do PFMT (control), to prevent and treat prolapse. All women had received written recommendations to perform PFMT in the delivery ward. The PFMT group attended a weekly PFMT class for 4 months starting at 6-8 weeks postpartum, and performed home-based exercise. The control group had no further supervision or follow-up. Outcomes measured at 6 weeks and 6 months post-partum included POP-Q stage, bladder neck position (transperineal ultrasound) and symptom of vaginal bulge (ICIQ-VS). The trial was judged as low risk for selection bias, performance and detection bias, attrition bias and reporting bias. However, the trial was judged as unclear for other types of bias (Table 27).

The PREVPROL trial, undertaken by Hagen and colleagues, compared PFMT versus lifestyle advice leaflet as secondary prevention for women with pre-clinical signs of prolapse (257). Participants were women originally enrolled in a longitudinal follow-up of postnatal incontinence (at 3 months, 6 and 12 years) after giving birth in 1993/94. Those, who had not sought treatment for prolapse, but who showed early signs of prolapse (POP-Q stage I, II or III) were invited to take part. They were randomised to receive either a programme of PFMT (individualised physiotherapy appointments, maintenance via Pilates-based classes (progressive Pilates-based exercises, pelvic floor muscle training as given in the one-to-one intervention, core exercises from the "Pelvicore Technique with Kari Bo" DVD) and annual one-to-one check-ups) or a prolapse prevention lifestyle advice leaflet. Women were followed up at 1 and 2 years in terms of their prolapse symptoms (POP-SS), prolapse-related QoL, uptake of prolapse treatment, symptoms of urinary incontinence (ICIQ-UI SF), anorectal or sexual dysfunction (PISQ-12), perceived health benefit, and cost-effectiveness.

The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (Table 27).

Results

One hundred and seventy-five primiparous women were randomised in the Bo (2013) study, 87 to PFMT and 88 to control, mean age 30. At 6 months post-

partum there was no difference between groups in the prevalence of symptoms of bulging either inside or outside the vagina. There was no difference between groups in the prevalence of stage II prolapse at 6 months, or in any of the individual POP-Q measurements, or the bladder neck position (258).

In the PREVPROL trial 414 women were randomised, 207 to PFMT and 207 to control, mean age 46 years (257). There was a significantly lower POP-SS score at 2 years in the PFMT group compared to the control group, indicating fewer symptoms. Women in the control group were significantly more likely to have sought treatment for prolapse symptoms by 2 years. No significant difference was found between the groups in the percentage who experienced any urine leakage at 2 years, although there was a significant difference in favour of the intervention group in the ICIQ-UI short form score. Faecal urgency and leakage, and sexual function were not significantly different between the groups at 2 years. Women in the intervention group were more likely to say they felt a health-related benefit from the study compared to the control women.

Summary

Currently, there is evidence from two robust trials regarding the role of PFMT in the prevention of POP. The trials were in different populations of women however (postnatal women, 13% of whom had stage II prolapse, and middle-aged women with mild prolapse, 55% with stage II or greater, who had not sought treatment) and drew differing conclusions. It would appear that in younger post-natal women PFMT does not influence the development of prolapse by 6 months, whereas in older women, more than 12 years after giving birth, there was a significant benefit of PFMT in terms of fewer prolapse symptoms after 2 years and less uptake of treatment. PFMT can prevent symptoms of prolapse which develop in the longer term after childbirth but not immediately after giving birth.

Postnatal: Level of Evidence: 1; Grade of Recommendation: B New; majority evidence from RCT of no effect for postnatal.

12 years post-childbirth: Level of Evidence 1; Grade of Recommendation: B New; Majority evidence from RCT of effect in the long term after childbirth.

2.2. Treatment

Quality of data

Evidence from trials now exists relating to the role of PFMT in the treatment of prolapse. The role of PFMT as an adjunct to surgery or pessary has also been the subject of randomised studies. A Cochrane review specifically addressing this question was first published in 2004 (259), and updated in 2011 (220) and 2016 (in preparation) (221).

2.2.1 PFMT Alone

Thirteen trials now exist in this area, six of which were previously reported in previous consultations. Key characteristics of the seven new trials, and new published information about two earlier trials, are summarised in Table 28. Narrative descriptions of these trials are reported below.

Alves and colleagues carried out a trial in post-menopausal women in which they compared a general fitness programme (control) with a PFMT programme (intervention) (47). Both groups performed a fitness programme twice weekly for 6 weeks including global muscle stretching, endurance and functional exercises. In addition, the intervention group took part in a physiotherapist-supervised PFMT programme in groups of seven, 30 minutes twice weekly for 6 weeks. The control group women were taught about pelvic floor muscles and how to contract them correctly, but without any training. Outcomes were assessed after the intervention at 6 weeks. The trial was generally judged as low risk for performance and detection bias, attrition bias, reporting bias and other types of bias. However it was unclear if opaque envelopes were used in the allocation process, and an intention to treat analysis was not performed (Table 28).

Culligan and colleagues compared a standardised PFMT programme with a standardised Pilates programme in community women with POP-Q stage I prolapse to see if they provided similar improvements in PFM strength (260). The PFMT programme, made up of twice weekly 1-hour sessions for 12 weeks, included computerized biofeedback, vaginal manipulation, neuromuscular re-education, and manual therapy. Participants completing 20 or more of the 24 possible sessions were defined as “successful”. The control group attended a Pilates programme with the same pattern of sessions where they were taught full-body exercises focusing on the “core muscles”, and the pelvic floor in particular. Women were assessed at baseline and after the intervention at 12 weeks in terms of PFM strength and pelvic floor symptoms and impact (PFDI-20), Short Form Pelvic Floor Impact Questionnaire (PFIQ-7). The trial was judged as low risk for selection bias, attrition bias, reporting bias and other types of bias. However, performance and detection bias was judged as unclear risk of bias as it was unclear if outcome assessors were blinded (see Table 28).

Due *et al.* (2016) undertook a trial in women with symptomatic prolapse of stage II or greater, comparing a structured lifestyle advice programme plus PFMT (combined group) with lifestyle programme alone (lifestyle group) (261). The PFMT included both group PFMT (6 sessions over 12 weeks) and individual home training after an assessment and individual instruction. Women were assessed using the Patient Global Index of Improvement scale (PGI-I), POP-Q, PFDI-20, PFIQ-7 and PISQ-12 at baseline, immediately post-intervention (3 months) and at 6 months.

The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (261) (see Table 28).

Frawley *et al.* (2012) carried out a trial in four Australian centres involving women with symptomatic prolapse stage I to III, randomised to PFMT or a lifestyle advice leaflet (control) (262). This trial protocol was based on that of the UK POPPY trial (263) described below with some slight adjustments and additional measurements. Women were assessed at baseline, 6 and 12-month follow-up for PFM function (manometric and digitally-assessed strength and endurance (ICS scale)), prolapse symptoms (POP-SS) and severity/type (POP-Q). The trial was judged as low risk for selection bias, performance and detection bias, reporting bias and other types of bias. However, the trial was considered to have high risk of attrition bias. Communication with the author provided explanations about the dropout observed (Table 28).

Giraudo *et al*'s (2011) trial compared PFMT plus negative pressure abdominal work (intervention group) with PFMT plus abdominal hollowing exercise (control group) in women with untreated stage I or II prolapse (264). Both groups were taught correct contraction of the pelvic floor muscles and given tailored lifestyle advice on ways of reducing intra-abdominal pressure, as well as a standardised lifestyle advice sheet. There was no description of 1) the negative pressure abdominal work or 2) abdominal hollowing exercises but they are described elsewhere as 1) hypopressive exercises, which are thought to result in negative pressure in the thoracic cavity and involuntary contraction of the pelvic floor and abdominal wall, and 2) pulling the belly button in towards the spine. The intervention duration was 24 weeks, with individual supervision twice weekly for one hour each session during the first 3 months, followed by once a week for the last 3 months. Women were assessed at baseline and at 24 weeks for prolapse symptom severity (P-QOL), prolapse severity (POP-Q) and PFM strength (Oxford scale). The trial was judged as low risk for selection bias (randomisation only), performance and detection bias and reporting bias. The trial was judged as unclear risk of bias for selection bias (allocation concealment), attrition bias, and other types of bias (264) (Table 28).

Hagen and colleagues carried out a multicentre trial (POPPY trial) comparing an individualised PFMT programme (including lifestyle advice) with a lifestyle advice leaflet (control group) (263). Participants were outpatients attending with newly-diagnosed, symptomatic stage I, II, or III prolapse. The PFMT intervention which was delivered by a specialist women's health physiotherapist over 16 weeks in 5 sessions included teaching of anatomy and function of pelvic floor muscles, the correct exercise technique and 'the Knack', and a prescription of a home exercise programme. A standardised lifestyle advice leaflet and tailored lifestyle advice were given. The control group received the lifestyle advice leaflet by post. Outcomes measured at 6 and 12 months were prolapse symptoms (POP-SS), prolapse-related QoL, need for further prolapse treatment, bladder, bowel and sexual symptoms. POP-Q was measured at baseline and 6 months. The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (Table 28).

Kashyap and colleagues reported a single-centre trial in parous women with stage I to III prolapse, which compared taught pelvic floor muscle training plus a self-instruction manual (SIM) with the SIM alone as the control intervention (265). One person delivered the training to all intervention women. This included explanation of anatomy and function of pelvic floor muscles, PFMT training, plus exercise practice and checking for correct PFM contractions by vaginal examination. Pressure manometry was included for biofeedback and motivation. A home exercise programme was prescribed for 3 times daily. Women were instructed to perform the intervention for 24 weeks. After the initial training session, there were 6 follow up visits (at weeks 1, 3, 6, 12, 18 and 24). The content of the manual was not described and therefore what written instruction the control group received is unclear. Women were assessed at baseline and at 1, 3, 6, 12, 18 and 24 weeks using the POP-SS, a visual analogue scale and the PFIQ-7. The trial was judged as low risk for selection bias. However, the trial was judged as high risk for performance and detection bias, attrition bias, reporting bias and other types of bias (see Table 28).

Stupp/Resende carried out a three-arm trial comparing PFMT versus hypopressive exercises (diaphragmatic breathing) plus voluntary pelvic floor muscle contraction (PFMT+HE) versus lifestyle advice only (266, 267). Participating women were attending a urogynaecology service in Sao Paulo, Brazil, and had untreated stage II anterior or posterior prolapse. The PFMT intervention involved three physiotherapy appointments to learn how to perform PFMT correctly (weeks 0, 1, 2). Then a 12-week home exercise programme was prescribed consisting of three sets of exercises daily. The PFMT+HE group had three appointments (weeks 0, 1, 2) during which they had instruction in correctly performing hypopressive exercises and pelvic floor muscle contractions, and how to do these simultaneously. They practiced the exercises for 12 weeks. Both of these groups completed an exercise diary, had a telephone call from the physiotherapist every two weeks and a monthly appointment (weeks 6, 10, 14). The control group received one appointment, were given lifestyle advice and were instructed how to perform PFM contractions. However, it was unclear with whom the appointment was held, or whether the instruction was verbal or included a digital assessment. A standardised lifestyle advice sheet was given to all women containing global stretching exercises and advice on weight loss, constipation, coughing and avoidance of heavy lifting.

1550

Table 27 Summary of data on POP prevention

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Bø 2013 (1)	Parallel group RCT; 2 groups, PFMT vs control	175	Primiparous women, vaginal delivery, singleton infant, ≥ 32 weeks	All women: written advice in delivery ward to perform PFMT. 2 trained physiotherapists taught PFM contraction and assessed PFM function before randomisation by observation of the perineum and vaginal palpation. PFMT group: weekly PFMT classes delivered by trained physiotherapists for 4 months starting at 6-8 weeks postpartum. Performed home-based exercise, 3 sets of 8-12 close to maximum PFM contractions per day. Control group: no further supervision or follow-up during the intervention period.	Stage of POP and bladder neck position. Secondary outcomes: symptoms of POP (sensation of bulging) using International Consultation on Incontinence Vaginal Symptoms questionnaire	Assessed at 6 weeks (pre-test) and 6 months' (post-test) postpartum	Randomisation was computer generated and opaque sealed envelopes were used. Outcome assessors were blinded and the groups were comparable at baseline. Intention-to-treat analysis was employed and dropouts were clearly reported. The trial was judged as potentially having an unclear risk of bias as the authors noted that "*because of ethical reasons the control group was not discouraged from performing PFMT on their own, but they were asked to follow the prescription for the group they were randomised to.*"
Hagen 2014 (2)	Parallel group RCT; 2 groups, PFMT versus control (lifestyle advice leaflet)	407	Primi and multiparous women assessed for pelvic floor dysfunction 12 years after an index birth; women involved in the ProLong cohort study (3) who have POP-Q stage I, II or III); no previous treatment for prolapse (surgery, pessary, PFMT)	Intervention: 1:1 PFMT taught using digital palpation delivered in 5 physiotherapy appointments over 16 weeks, followed by Pilates-based classes, including PFMT. Classes were carried out in 6-week block (one class per week) and each woman was offered two 6-week blocks. Exercise DVD was provided for home use. Women offered a 1:1 physiotherapy annual review appointment at 1 and 2 years after randomisation. Control group: sent a lifestyle advice leaflet containing advice on weight loss, and avoidance of constipation, heavy lifting, coughing and high impact exercise.	POP-SS, Prolapse-related QoL, uptake of prolapse treatment, symptoms of urinary incontinence, anorectal or sexual dysfunction, women's perceived health benefit, and cost-effectiveness	Data collected at baseline, 1 and 2 years post randomisation	Randomisation was generated using a computer program located at the Trial Office on a password-protected PC. Outcome assessors were blinded and the groups were comparable at baseline. Intention-to-treat analysis was employed and dropouts were adequately reported. Questionnaire response rate: 81% year 1, 86% year 2 follow-up. Attendance at annual review appointments: 52% and 46% at year 1 and year 2 respectively, and uptake of classes in the UK was 33% and 17% at 1st and 2nd block respectively. By year 2, 77% in the intervention group reported they had done PFM exercises in the last 4 weeks

Abbreviations: PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; POP-SS: pelvic organ prolapse symptom score; QoL: quality of life; RCT: ran-domized controlled trial

Table 28 Summary of data on PFMT vs no active treatment for POP

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Alves 2015 (1)	Parallel group RCT, 2 groups, PFMT vs control	30	Women ≥5 years postmenopausal, with urogynecological complaints	Intervention: PFMT taught using digital palpation. Groups of 7 women; 12 sessions, twice weekly for 30 minutes, over six weeks. Include pelvic mobility exercises, stretching, strengthening and relaxation in supine, sitting, on Gym Ball, squatting and standing, along with PFM contractions, consisting of 4 sets of 10 fast contractions and 4 sets of 10 sustained contractions, 8 seconds hold followed 16 seconds relaxation All women: performed a Fitness Program based on global muscle stretching, endurance and functional exercises for the elderly	POP-Q, ICIQ-VS, ICIQ-UI SF, ICIQ-OAB, PFM assessment (digital palpation, sEMG), treatment satisfaction (VAS, 0-10)	Assessed at baseline and post intervention (6 weeks).	Generally low ROB. Randomisation by draw, with each participant blindly drawing a sealed envelope containing a pre-printed card; however it was unclear whether opaque envelopes were used. Outcome assessors were blinded. Sample size calculation was reported and the groups were comparable at baseline. ITT not employed but dropouts were adequately reported. High attrition rate for the intervention group; 30/42 women completed the trial.
Culligan 2010(2)	Parallel group RCT; 2 groups, standardised PFMT program vs standardised Pilates program	62	Non pregnant community women with POP-Q stage I, with or without complaint of pelvic floor dysfunction	Intervention: 1:1 PFMT, 24 1-hour sessions, twice weekly for 12 weeks. Included computerized biofeedback, vaginal manipulation, neuromuscular re-education, and manual therapy. Authors imply women taught contraction used digital palpation. Control: Pilates, 24 1-hour sessions, twice weekly for 12 weeks. Taught full-	PFDI-20; PFIQ-7, PFM strength (vaginal pressure)	Assessed at baseline and post-intervention at 12 weeks	Generally low ROB. Randomised using blocked random assignment, and allocation concealment used sequentially numbered opaque sealed envelopes. Unclear whether participants and outcome assessors were blinded. Groups were comparable at baseline. Although intention-to-treat analysis

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
				body exercises designed to emphasize the “core muscles” and pelvic floor.			was not employed, dropouts were adequately reported. Authors reported that seven of the eight participants who dropped out of the PFMT arm reported doing so because they found the treatments “unpleasant in some way”. All Pilates and PFMT sessions were free to the participants, who were also paid up to $75 for completion of the study protocol.
Due 2016 (3)	Parallel group RCT; 2 groups, Combined group (PFMT plus structured lifestyle advice program) and lifestyle group (structured lifestyle advice program alone)	109	Women ≥18 years with POP symptoms and a POP-Q ≥ stage II	Intervention: group PFMT and home training after a digital assessment and individual instruction. 6 group sessions delivered over 12 weeks. Include the Knack, home exercise 5 days a week (3 sets of up to 10, 10 second contractions). Plus lifestyle advice program as below. Control group: Lifestyle advice program, 6 1-hour group teaching sessions including information on POP-promoting factors, reducing pelvic floor pressure, bladder and bowel function, diet, body image and physical activity. No PFMT.	POP-Q; PFDI-20; PFIQ-7; PISQ-12; Patient Global Index of Improvement scale (PGI-I)	Assessed at baseline, immediately post-intervention (3 months) and 6 months	Low ROB for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias "Majority of the women in the lifestyle advice group (p≤0.001) had sought further treatment at six months follow-up, mainly as PFMT"
Frawley 2012 (4)	Parallel group RCT; 2 groups, PFMT vs control (lifestyle advice leaflet)	168	Women with symptomatic POP of stage I, II or III	This trial used the same protocol as the UK POPPY trial with some slight adjustments and additional measurements (see Hagen 2010 below)	POP-Q; POP-SS; PFM manometric strength and endurance; digitally assessed PFM strength/endurance (ICS scale)	Data collected at baseline and 6 and 12 month follow up	Generally low ROB. Randomisation was computer generated and participants were allocated to the trial using a remote randomisation service. Outcome assessors were blinded. Potentially high risk for attrition bias. Dropouts were accounted for

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
							but no explanations given for high attrition rates at 6 and 12 month follow up. Attrition was greater in the PFMT group at 6 months (14.3% vs 10.7%) but greater in the lifestyle group at 12 months (5.6% vs 21.3%).
Giraudo 2011 (5)	Parallel group RCT; 2 groups, PFMT plus negative pressure abdominal work vs PFMT plus abdominal hollowing exercise	44	Women with untreated stage I or II prolapse. No mention of whether women had symptoms.	Both interventions: PFMT delivered over 24 weeks, 1:1 supervised sessions twice-weekly for 1 hour for 3 months, once a week for last 3 months. Women taught to contract the PFMs correctly by vaginal palpation. Tailored lifestyle advice given on reducing intra-abdominal pressure plus standardised lifestyle advice sheet (advice on weight loss, constipation, avoidance of heavy lifting, coughing and high-impact exercise). Groups: individualised PFM contraction with either abdominal hollowing exercises or negative pressure abdominal work.	Prolapse symptom severity measured via P-QOL Questionnaire. Prolapse severity (POP-Q) and PFM strength (Oxford scale). ICIQ-UI SF also used but not reported.	Assessed at baseline and at 24 weeks	ROB was judged as low or unclear. Randomisation was computer generated, but allocation concealment was not described. The physician involved in the trial was blinded to study group allocation, but there was insufficient information about the blinding of participants. The groups were comparable at baseline and all pre-specified outcomes were reported. However although dropouts were accounted for, it was not clear when the women were excluded, and which group they had originally been allocated to.
Hagen 2014(6)	Parallel group RCT; 2 groups, individualised programme of PFMT vs prolapse lifestyle advice leaflet	447	Female outpatients with newly-diagnosed, symptomatic stage I, II, or III POP	Intervention: Anatomy/function of PFMs explained, taught to correctly contract PFMs (vaginal palpation, PERFECT) and pre-contracting against increases in abdominal pressure. 5 physiotherapy appointments delivered over 16 week period (weeks 0, 2, 6, 11 & 16). Home exercise prescribed - 3 sets of exercises per day: 10 maximum voluntary contractions held for up to 10s, with 4srest between; after 1 minute rest, up	POP-SS; POP-Q; women's perceived change in prolapse; interference due to prolapse; days of symptoms; uptake of prolapse treatment; ICIQ UI-SF; PISQ; SF-12	Assessed at 12 months, except POP-Q assessed at 6 months	Low ROB. Randomisation was computer generated, and university-based trial coordinator accessed the web-based application and then informed the woman, and the physiotherapist as necessary, of the allocated group. Outcome assessors and investigators (who were gynaecologists at trial sites), were masked to group allocation; the

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
				to 50 rapid contractions. Standardised lifestyle advice leaflet and tailored lifestyle advice given. Control group: received the same lifestyle advice leaflet by post.			statistician was masked until after data analysis. ITT analysis was employed and dropouts were adequately reported.

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Kashyap 2013 (7)	Parallel group RCT; 2 groups, PFMT and a self-instruction manual (SIM) vs SIM alone	140	Parous women attending gynaecology outpatient department, aged 20–70 years, who were willing to attend follow-up visits	Intervention: anatomy/function of PFMs explained. 1:1 PFMT training, plus exercise practice and checking for correct contractions of PFM by vaginal examination. Pressure manometry for biofeedback and motivation. Given SIM. After training session, 6 follow up visits (weeks 1, 3, 6, 12, 18 and 24). Home exercise programme of 3 times/daily set of exercises comprising 10 voluntary contractions, held for 10s each with 10s rest in between. Participants performed the intervention as described for 24 weeks. Control: SIM plus 3 follow-up visits (weeks 6, 18 and 24). Home exercise prescribed as above.	POP-SS; symptoms measured by visual analog scale (VAS), PFIQ-7, POP-Q	Assessed at baseline and at 1, 3, 6, 12, 18 and 24 weeks	Low risk for selection bias as the trialists had used a block randomisation method for randomisation, and a physician, who was not involved in the study, performed the patient allocation. Potential for high risk of bias, as "the study design did not include blinding". There was a crossover of 4 participants from group B to group A *after* randomisation. Details of attrition were not well reported: it was indicated that analysis was performed on all 140 participants however there was also reference to individuals "missing" and "lost to follow-up". Self-completed exercise diary but unclear how well adherence was actually delivered as planned.
Resende 2008/ Stupp 2011 (8, 9)	3-arm RCT; PFMT training vs hypopressive	58	Women with stage II POP and not undergoing surgery to correct it during	PFMT: Session 1 (week 0), anatomy/ function of PFMs explained, training on PFM contractions, observation on correct performance. Follow up sessions	POP-Q; symptom severity (Prolapse Quality of Life (P-QoL)); PFM	Baseline evaluation and immediately	Low or unclear ROB. Randomisation was computer generated, but allocation concealment was not described.

Author, year	Study design/ Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
	exercises plus PFMT vs lifestyle advice & instruction on PFM contraction (1 appointment)		the study. Not on hormonal treatment, not had previous PFMT or pelvic floor surgery. Recruited during routine consultation.	at weeks 1 (vaginal palpation), 2, 6, 10 and 14. 12 week home exercise programme of 3 sets of exercises daily: 1 set of 8-12 maximum contractions held 6-10s, double time rest between each contraction, then 3-5 fast contractions. Bi-weekly telephone calls. PFMT+HE: Hypopressive exercises plus PFMT (3 sessions). Monthly appointments, 12 week home exercise programme. Bi-weekly telephone calls. Control group: 1 appointment for lifestyle advice and instruction in PFM contraction. All: Standardized lifestyle advice sheet about weight loss, fluid intake, constipation and avoidance of heavy lifting.	function assessment (strength and endurance), electrical activity measured (sEMG)	after intervention (at 3 months)	The main investigator was blind to the study groups and not involved in delivering the intervention. Groups were comparable at baseline and dropouts were accounted for. Attrition was evident only in the control group where 16/21 (76%) were analysed. Single trial reported over multiple papers (confirmed by author). Reports do not agree about number of participants, age. Authors state: “The women who took part in the present study also participated in a randomized, controlled trial on PFMT to reduce POP, the results of which are not available yet. Therefore, in this study, we considered only the results regarding PFM function.”
Wiegersma 2014 (10)	Two parallel RCTs. POPPS 1 (described here) 2 groups; PFMT vs watchful waiting	287	Women aged at least 55 years with symptomatic mild POP identified via screening survey in 15 GP practices	Intervention: Explanation of the function of pelvis/pelvic floor/ pelvic floor dysfunctions, taught “the Knack”. Weekly visits to pelvic physiotherapist until able to correctly contract and relax PFMs (assessed by digital palpation), then 2-3 weeks intervals. Home exercise 3-5 times a week, 2 or 3 times a day. Advice on lifestyle (diet, body weight) and toilet habits. Control: no treatment or recommendations	Assessed 3 months from the start of treatment (or from randomisation for control group): PFDI-20, PFIQ-7, POP-Q, SF-12, PISQ-12, patients’ perceived change in symptoms (VAS) , PFM function (ICS method)	Data collected at baseline and at 3, 12, and 24 months after the start of treatment	Low ROB. Block randomisation; independent statistician generated the allocation sequence. Research physicians and pelvic physiotherapists were blinded to all answers on the participant completed questionnaires, and research physicians were blinded to the outcomes of the previous POP-Q measurements and previous evaluations of pelvic floor muscle function. ITT analysis employed; dropouts and missing data were accounted for.

Abbreviations: PFDI-20: pelvic floor distress inventory short form 20, PFIQ-7: pelvic floor impact questionnaire short form; PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; POP-Q; Pelvic Organ Prolapse Quantification system; PISQ-12: Pelvic organ prolapse/urinary incontinence sexual questionnaire’ POP-SS: pelvic organ prolapse symptom score; QoL: quality of life; RCT: randomized controlled trial; sEMG: surface electromyography

10. Wiegersma M, Panman CM, Kollen BJ, Vermeulen KM, Schram AJ, Messelink EJ, *et al*. Pelvic floor muscle training versus watchful waiting or pessary treatment for pelvic organ prolapse (POPPS): design and participant baseline characteristics of two parallel pragmatic randomized controlled trials in primary care. Maturitas. 2014;77(2):168-73.

Women were assessed at baseline and immediately after intervention (at 3 months) using POP-Q (blinded assessment); PFM strength and endurance (Oxford scale), electrical activity (sEMG) and symptom severity and impact (P-QoL). The trial was judged as low risk for selection bias (randomisation) and unclear risk for allocation concealment. The trial was also judged at low risk for performance and detection bias, attrition bias, reporting bias and other types of bias (266, 267) (Table 28).

Wiegersma and team conducted a trial in primary care (POPP1) of women aged ≥55 years with symptomatic mild prolapse (above the hymen) (268). Women in the trial were randomised to either PFMT or watchful waiting. Women in the PFMT group were given an explanation of pelvic floor anatomy and pelvic floor dysfunction, were taught "the Knack", and given lifestyle advice. They had weekly visits with the pelvic physiotherapist initially. The intervals between appointments were extended when they could correctly contract and relax their PFMs. Home exercise was recommended three to five times a week, twice or three times each day. Data were collected at baseline and at 3, 12, and 24 months after the start of treatment. The primary outcomes were change in bladder, bowel, and pelvic floor symptoms, as measured by the PFDI-20, assessed at three months. Secondary outcomes were condition specific and general quality of life, sexual functioning, and degree of prolapse, PFM function, and patients' perceived change in symptoms from the start of the study. The POPP1 trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (Table 28).

Results

In the Alves (2015) trial, 42 women were randomised, 21 in each group, however there was high attrition and only data from 18 and 12 women in the intervention and control group respectively were analysed. Two in the intervention group did not complete the treatment due to health or family problems, while 9 in the control group refused to complete the final physical exam: these women were excluded from the sample. There was a significant difference in favour of the intervention group in terms of decreased anterior prolapse, but no difference in posterior prolapse or the ICIQ-VS score. There was a significant difference between the groups in the ICIQ-OAB and ICIQ-UI SF scores after treatment, with improvement occurring only in the intervention group. There was a greater increase in PFM contractility (measured both by digital palpation and sEMG) in the PFMT intervention group compared to the general fitness control group at 6 weeks. Satisfaction with the treatment was reported to be greater in the intervention group (47).

Sixty-two women were randomised in the Culligan (2010) trial; 32 to PFMT and 30 to Pilates (control), of which 8 and 2 withdrew respectively (260). Seven of the 8 who dropped out of the PFMT arm did so because they found the treatment unpleasant, while the 2 in the Pilates arm withdrew for health reasons unrelated to the trial. All women could correctly contract their pelvic floor muscles (as assessed by perineometry at baseline) and most did not have pelvic floor symptoms at baseline. Both groups demonstrated improved PFDI-20 and PFIQ-7 scores and pelvic floor muscle strength, at 12 weeks, but these improvements were not significantly different between the groups. The authors concluded that it is feasible for a Pilates exercise program to strengthen the pelvic floor muscles of women with stage I prolapse.

In the Due (2016) trial, 109 women were randomised, 56 to the combined group and 53 to the lifestyle group (261). Of these 43% had POP stage III and 57% had POP stage II. Follow-up at 3 and 6 months was 82% and 78% complete respectively. Significantly more women in the combined group indicated improvement in the PGI-I at 3 and 6 months. There was no difference between groups in any PFDI-20 or PFIQ-7 scores at 3 months. Both groups improved significantly in the total PFDI-20 score and its subscores by 3 months, except the lifestyle group had no improvement in the POPDI sub-score. Significant improvement in PFIQ-7 could only be found in the lifestyle advice group. It was unclear if there were any differences between groups in PFDI/PFIQ at 6 months. The PISQ-12 and objective prolapse stage did not improve significantly. Significantly more women (68% vs 28%) in the lifestyle advice group had sought further treatment (mainly PFMT) at 6 months follow-up. The authors concluded that there was a small benefit of both lifestyle advices alone or combined with PFMT for women with stage II or III prolapse. There was a significant difference in the primary outcome (PGI-I) in favour of the combined group, but this was not really highlighted.

In the Frawley (2012) trial, 168 women were randomised to either the PFMT group (n=84) or the control group (n=84), with 12 and 9 lost to follow-up by 6 months and a further 4 and 16 by 12 months respectively, 19% and 30% in total (262). 82% of women in the PFMT group attended 4 or 5 of the 5 physiotherapist appointments. The POP-SS score was significantly lower, indicating fewer symptoms, in the PFMT group compared to the control group at both 6 and 12 months. There was no difference in POP-Q stage between groups at 6 or 12 months, although there was some evidence of a difference at 12 months between groups, in the posterior wall POP-Q measurements, Ap and Bp, in favour of the PFMT group. Digital muscle strength was significantly stronger in the PFMT group compared to the control group at 6 months but not at 12 months. There were no significant differences between groups in manometry outcomes, except total work performed was higher in the PFMT group at 6 months. The intervention was concluded to be beneficial immediately following the intervention, and after a further 6 months.

In a conference abstract, Giraudo and colleagues reported 47 women were randomised but 3 were excluded because they could not contract their pelvic

floor muscles, leaving 44, 23 intervention (PFMT + negative pressure abdominal work) and 21 control (PFMT + abdominal hollowing) (264). Improvement in prolapse symptoms and POP-Q values from baseline to 24 weeks was significantly greater in the intervention group compared with the control group. There was evidence of an improvement in PFM strength and endurance in both groups, but no significant difference between the groups. The authors concluded there may be benefit of adding negative pressure core exercises to PFMT for women with stage I and II prolapse.

Of the 447 women enrolled in the POPPY trial, 225 women were randomised to intervention and 222 to control (263). 84% and 66% of women completed questionnaires at 6 and 12 months respectively, with no differential drop-out. POP-Q re-assessments at 6 months were obtained for 75% (168) and 77% (171) of women respectively. 80% in the intervention group attended 4 or 5 of the 5 appointments. Women in the intervention group had a significantly greater reduction in prolapse symptoms at 6 and 12 months than those in the control group, although they were no more likely than control women to have a reduced severity of prolapse at 6 months. At 12 months, significantly more women in the control group than the intervention group had received further treatment. In particular significantly more women in the control group (27% vs 1%) had had a referral for PFMT. At 6 months, all aspects of daily life, and sexual, bladder, and bowel function (except for faecal incontinence), were significantly better in the intervention group compared to the control group. This was not sustained at 12 months. It was concluded that one-to-one PFMT is effective for improving symptoms in women with stage I to III prolapse in the medium term.

In the Kashyap trial, 140 women were randomised, 70 per group, although four women transferred from the control group to the training plus manual group and the group in which these women were analysed was unclear (265). Improvements were reported in POP-SS, VAS and PFIQ-7 scores in both groups from baseline to week 24. There were significant differences between groups in the change in POP-SS with the intervention group reporting greater symptom improvement. There was also significantly more improvement in the intervention group in terms of the VAS scores and the PFIQ-7 scores. Five women in the intervention group had an improved POP-Q stage compared to one woman in the control group. The authors concluded that one-to-one PFMT plus the SIM led to more symptom improvement than the SIM alone.

The Stuppe-Resende trial was reported over multiple publications (4 conference abstracts, 2 papers and a trial register entry) (confirmed by personal communication with an author), reporting on different comparisons amongst the three trial groups, and not all reports agreed on participant details (e.g. the number of participants, age) making it difficult to interpret the findings. 63 women were randomised in the trial: 21 to PFMT, 21 to PFMT plus hypopressive exercise, 21 to lifestyle group. Five women in the lifestyle group discontinued leaving 58 women at follow-up. The PFMT group women were more likely than the control group to have an improvement in their POP-Q stage of prolapse, both anterior and posterior. The domains and symptoms scores from the P-QoL were compared before and after in each group separately, but no between-group comparisons were made. However, the authors concluded erroneously that since the PFMT group scores improved significantly and the control groups did not, the PFMT group had benefitted more. Pelvic floor muscle assessment outcomes were compared between the three groups (266). Significant differences were found between the PFMT and PFMT+HE groups when compared to the control group, in favour of the PFMT groups, in terms of Oxford score, contraction endurance and muscle activity (SEMG). No significant difference was found between the PFMT and PFMT+HE groups in terms of Oxford score and muscle activity (SEMG), however PFMT group did significantly better than PFMT+HE in terms of contraction endurance.

Wiegersma trialists screened 4,465 women to identify those with mild prolapse (n=365) (268). Of these, 287 women were randomised, 145 to PFMT and 142 to watchful waiting, of which 250 (87%) completed the trial follow-up. Women in the intervention group improved their PFDI-20 score significantly more than those in the watchful waiting group, and were also more likely to report overall symptom improvement (57% vs 13%). There were no other significant differences between the trial groups including improvement in POP-Q stage. The authors concluded that the difference in PFDI-20 may not be clinically significant and that more studies are needed to examine the factors affecting success.

Summary

Results from an additional seven new trials are now available and more complete reports for two of the six earlier trials.

There have been different types of control groups used in the trials to date: minimal intervention control e.g. lifestyle leaflet or watchful waiting; other type of exercise as control e.g. Pilates or general fitness; lifestyle intervention as control; other form of delivery of PFMT as control e.g. self-instruction PFMT manual. One small trial compared PFMT of two different types (PFMT with negative pressure abdominal work and PFMT with abdominal hollowing).

Most evidence (8 trials) exists for PFMT versus a minimal intervention control, and it can now be concluded more confidently that PFMT significantly reduces pelvic floor symptoms in women with stage I to III prolapse. Evidence of effectiveness for PFMT relating to the specific symptom of a vaginal bulge or something coming down associated with prolapse was Level 1, but less consistent.

Six of these trials reported change in POP-Q stage, but a beneficial effect on the stage was reported in only 1 of these, and thus there was evidence of no effect of PFMT on prolapse stage.

In the other categories, four out of six trials providing data were small and very likely underpowered although they were otherwise at low risk of bias (Alves n=42, Culligan n=62, Giraudo n=47, Stupp n=63).

Of the remaining two, Due (n=109) found PFMT plus lifestyle advice to be superior to a lifestyle advice programme in terms of overall improvement on the Patient Global Index of Improvement Scale, but not prolapse symptoms or POP-Q severity, where both groups improved [46]. Kashyap (n=140) found a taught course of PFMT plus self-instruction manual was better than a self-instruction manual alone in improving prolapse symptoms [50]. The difference in findings might in part be due to different PFMT interventions: group PFMT delivered in the Due trial versus one-to-one PFMT in the Kashyap trial.

Based on previous studies and new evidence there is now evidence of benefit that PFMT is effective in reducing pelvic floor symptoms in women with prolapse **(Consistent Level of Evidence: 1, Grade of recommendation: A).** There is some evidence of benefit showing that PFMT is effective in alleviating specific prolapse symptoms (e.g. vaginal bulge) **(Majority Level of Evidence: 1, Grade of recommendation: C).** There is no evidence that PFMT is effective in reducing severity of prolapse based on POP-Q stage **(Consistent Level of Evidence: 1, Grade of recommendation: B).**

2.2.2 PFMT and Surgery

Two trials have been reported in previous editions of this chapter (269, 270). There have been an additional 4 trials published since the last edition (104, 271-274). Three trials compared surgery plus PFMT with surgery alone, and one trial compared surgery with PFMT (275). The latter did not report on prolapse outcomes and is therefore not discussed further. Salient features of each trial are described in Table 29.

Quality of data

Barber and colleagues carried out the OPTIMAL 2x2 factorial trial of PFMT as an adjunct to vault prolapse surgery (104). This trial compared two methods of suspending the vaginal vault in women undergoing surgery for prolapse. Additionally, participants were randomised either to adjunctive post-operative PFMT or routine care, to assess whether such adjunct therapy improves both anatomical and symptomatic outcomes two years after surgery.

The adjunct intervention consisted of one pre-operative visit and four post-operative visits with a behavioural interventionist for PFMT and education in behavioural strategies. Routine care was usual peri-operative teaching and post-operative instructions. The authors' primary outcomes were urinary symptoms at 6 months (PFDI-UDI), and prolapse symptoms (PFDI-POPDI) and anatomical failure (descent on the POP-Q or retreatment) at 24 months after surgery (Table 29).

The OPTIMAL trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (104) (Table 29).

McClurg and colleagues undertook a pilot trial of pre- and post-operative PFMT for women undergoing a primary prolapse repair (274). Women were randomised to either the intervention group receiving PFMT or the control group receiving usual care. Prior to surgery all women were seen by a physiotherapist to complete baseline outcome measures. Those in the intervention group were also seen once pre-operatively by another physiotherapist to be taught pelvic floor muscle exercises and the Knack. Women were advised to do three sets of exercise per day. After 6 weeks the intervention group women were seen for 5 visits over 16 weeks and an individualised home exercise programme was prescribed and advice given. Control group women received a lifestyle advice leaflet. Both groups completed outcome measures at 6 and 12 months post-surgery: POP-SS (primary), ICIQ-UI SF, ICIQ-BS, PISQ-12, SF-12, and PFM assessment (PERFECT and modified Oxford scale) (Table 29). The feasibility trial was generally judged as low risk for selection bias, attrition bias, reporting bias and other types of bias. However, there was potential for performance and detection bias (see Table 29) (274).

Pauls *et al.* (2011) (271, 272) undertook a trial in women undergoing vaginal reconstruction, comparing PFMT as an adjunct to surgery with standard care. Women were having planned surgical correction, including a native tissue vaginal repair with or without a vaginal hysterectomy or suburethral sling. PFMT consisted of one appointment 2 weeks before their scheduled surgery date, and five post-operatively, each with a specialist pelvic floor physiotherapist. The control group attended appointments with physician assessment alone at all the same post-operative intervals. There was a final follow-up assessment at 24 weeks (Table 29). The primary outcome was quality of life measured using the WHOQOL-Bref. Secondary outcomes included PFDI-20, PFIQ-7, POP-Q assessment, the Female Sexual Function Index (FSFI), PISQ-12, a modified Oxford scale for pelvic floor strength and contraction, short form General Health Survey (SF-12), and a 24-hour voiding diary (271, 272). The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and all other types of bias (Table 29).

Table 29 Summary of data on PFMT + surgery for POP

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up)
Barber 2014 (1)	2 x 2 factorial RCT: comparing to surgery types +/- PFMT	374	Women having surgical repair for apical or uterine POP of stage II or greater, who also have SUI	Women were randomised to both surgery type and PFMT. Surgery: 1) sacrospinous ligament fixation, or 2) uterosacral vaginal vault suspension Perioperative PFMT: 1) 1:1 PFMT (1 pre-operative + 4 post-operative visits for PFMT (2,4,6,8 and 12 weeks), examination at each visit, and exercise and education in behavioural strategies), or 2) usual care (usual peri-operative teaching and post-operative instructions)	Outcomes for PFMT: long-term improvement in anatomic outcomes (POP-Q) and prolapse symptoms (POPDI subscale of the PFDI); short term (6 months) improvement in urinary symptoms (UDI subscale of PFDI).	6, 12 and 24 months	Low ROB for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias
McClurg 2010 (2)	Parallel group RCT; 2 groups, treatment group (surgery and PFMT sessions) vs a control group (usual care)	57	Women attending the gynaecological clinic and for whom primary surgery was recommended due to their POP symptoms	Intervention: 1 pre-operative + 5 post-operative appointments within a period of 12 weeks. Pre-operatively, anatomy and function of PFMs, types of prolapse and the surgical procedure discussed with information about recovery/return to normal activities. Women taught by digital palpation to contract PFMs and 'the Knack'. Home exercise, 3 sets per day of 10 maximum contractions (up to 10s hold) with 4s rest between, 1-min rest followed by 10 fast contractions. Control: received the same lifestyle advice leaflet.	POP-SS; ICIQ-UI SF; ICIQ-BS; PISQ-12; SF-12; PFM assessment (PERFECT, modified Oxford scale).	All outcomes were measured at baseline, 6 and 12 months	Generally judged as low ROB. Randomisation generation and allocation concealment were judged as adequate. Outcome assessors reported as being blinded but researchers involved in the trial were not blinded and it is unclear what direct involvement they may have had with each participant. Groups were comparable at baseline, but there were more complaints of bowel dysfunction in the treatment group. Dropouts were clearly accounted for and all pre-specified outcomes were adequately reported.

1562

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up)
Pauls 2013 (3)	Parallel group RCT; 2 groups, PFMT vs standard care in women undergoing vaginal reconstruction	49	Women aged > 18 years having surgical correction to include a native tissue vaginal repair +/- a vaginal hysterectomy or suburethral sling	Intervention: physiotherapy appointment 2 weeks before surgery, and 2, 4, 6, 8, and 12 weeks postoperatively, in conjunction with a physician assessment. Sessions covered bladder and bowel function, pain management, breathing and relaxation, core exercises, scar tissue mobilization, increased strengthening and training over time. Control: attended appointments (biweekly until 12 weeks postoperatively) with physician assessment alone at intervals as above.	PFDI-20, PFIQ-7, POP-Q, Female Sexual Function Index (FSFI), PISQ-12, SF-12, WHO-QOL Bref, modified Oxford scale for PFM strength and contraction, 24-hour voiding diary	Assessments undertaken at baseline (some limited assessment at appointments occurred at 2, 4, 6, 8 weeks), and follow-up assessments at 12 and 24 weeks	Low ROB. Randomisation generation and allocation concealment were judged as adequate. Outcome assessors were blinded appropriately. Groups were comparable at baseline, dropouts were all accounted for and all pre-specified outcomes were reported. The trial is fully reported in two main papers.

Abbreviations: PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; POP: pelvic organ prolapse; POP-SS: pelvic organ prolapse symptom score; QoL: quality of life; RCT: randomized controlled trial; ROB: risk of bias; SUI: stress urinary incontinence; UI: urinary incontinence

Results

In the OPTIMAL trial, 408 women were randomised, 34 withdrew prior to surgery leaving 374 women randomised to PFMT (n=186) or usual care (n=188). There was no significant difference at 6 months or 24 months between the PFMT and usual care groups in the prolapse scores or POP-Q. The routine use of PFMT was concluded to be unnecessary (104).

McClurg (2010) randomised 57 women from three sites, 28 to PFMT and 29 to control, with the majority of women (n=27, 47%) coming from one site. By 6 months there was significant improvement in both groups on prolapse, bladder, bowel and general health measures, but no difference between groups. Analysing 12 month data from the highest recruiting site where longer follow-up was possible (there were significant recruitment and logistical issues at other sites which caused delays and limited the follow-up), there were significant differences between groups in POP-SS and SF-12: prolapse symptoms and general health were more improved in the PFMT groups (274).

In Pauls (2013) trial, a total of 57 women were randomised, 29 to physiotherapy and 28 to control, and 49 completed the study (24 and 25 respectively). Improvement over baseline was found in both groups in quality of life, PFDI and PFIQ measures, but there were no differences between groups. The PFMT group had better muscle strength after 12 weeks, but at 24 weeks this was no longer evident. (271, 272).

Summary

Although there were three new randomised studies reporting prolapse outcomes, only one trial (OPTIMAL) was both at low risk of bias and of adequate size (104). It found no evidence of an effect on prolapse symptoms or stage at 2 years of adding PFMT to surgery in women having vault prolapse repair **(Level of Evidence: 1)**. The other two small trials provided no evidence of an effect of PFMT.

Peri-operative PFMT does not improve prolapse symptoms in women undergoing surgery for vault prolapse **(Grade of Recommendation: B New).**

2.2.3 PFMT and Pessary

Three RCTs have been published since the 5th Edition when previously there had been none. Details of the categories and treatment components of the active interventions are provided in Table 30.

i) Pessary + PFMT vs pessary

Hagen and colleagues carried out a pilot trial in which women with stage I to IV prolapse of any type who had successfully been fitted with a pessary were randomised to have PFMT or not. PFMT was delivered by a specialist women's health physiotherapist in 5 appointments over 16 weeks (276) (Table 30). The pessary was removed at 6 months and outcomes (POP-SS, prolapse-related quality of life, prolapse severity (POP-Q), and perceived change in prolapse since pessary fitted) measured at 7 months. The authors aimed to randomise 50 women from 4 centres to inform the development of a larger trial. The PEPPY trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and all other types of bias (276, 277).

ii) PFMT vs PFMT + pessary

Cheung and colleagues carried out a trial in women with symptomatic stage I to III prolapse with no previous treatment for prolapse, who were randomised to either a vaginal ring pessary+ PFMT, or PFMT alone (278). Both groups were taught and encouraged to do PFMT standardized pelvic floor exercise training course which included a teaching session within 2 weeks after the first consultation and three individual training sessions at 4, 8, and 16 weeks. Women were advised to practice daily with at least two sets of 8–12 preset exercise repetitions per day, with 8– 10 exercises per session at least two times per week. Change in urinary symptoms was measured using the PFDI (including PFDI-UDI) before, 6 months and 12 months after the treatment. The PFIQ was also completed at 12 months. The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (Table 30).

iii) Colpexin sphere +PFMT vs PFMT

Manonai and colleagues (2012) studied the use of the Colpexin sphere in women with Stage I or II prolapse (279). The Colpexin sphere is an intra-vaginal device similar to a pessary except it requires the woman to actively contract her pelvic floor muscles to keep the device in place. Women were randomised to either PFMT alone (control) or PFMT along with a Colpexin sphere (study group). All women were instructed to perform three sets of exercises daily. Those in the Colpexin group exercised with the device *in situ*. The intervention duration was 16 weeks. Pelvic floor muscle strength was measured using the Colpexin pull test and digitally using the Brink scale, at baseline, 4, 8, 12 and 16 weeks after treatment. There were no specific prolapse outcomes reported. Participants were excluded if compliance with the daily pelvic floor exercise was less than 80%. The trial was judged as low risk for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias (Table 30).

Results

Of the 31 eligible women recruited to the PEPPY trial, 16 were randomised, eight to the pessary alone group and eight to the pessary plus PFMT group. The mean age of women was 63 years (SD 14); 25% had stage I prolapse, 50% stage II, and 25% stage III. Compliance with the intervention was good: 75% of intervention women attended 4 or 5 appointments. With such a small sample size statistical analysis was not carried out.

1564

Table 30 Summary of data on PFMT + pessary / other medical devices for POP

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Cheung 2016(1)	Parallel group RCT; 2 groups, Vaginal ring pessary + PFMT vs PFMT	276	Women had symptomatic prolapse (Stage I- Stage III), had received no previous treatment	Intervention: vaginal pessary, (ring pessary was used). Women also received regular PFMT. Home exercise performed at least 3 times a week and 2 times each day. Control: PFMT alone.	Total scores on PFDI and PFIQ. Change of urinary symptoms measured by PFDI-UDI and subscales (obstructive, irritative, stress).	Data collected at baseline and 6 months (PFDI-UDI only) and 12 months after treatment.	Low ROB for selection bias, performance and detection bias, attrition bias, reporting bias and other types of bias
Hagen 2010(2)	Feasibility pilot RCT; 2 groups, PFMT in conjunction with pessary management vs pessary management alone	16	Women with prolapse of any type, of stage I to IV, with a pessary newly successfully fitted (still in place after 2 weeks)	PFMT was delivered at 5 appointments over 16 weeks (as per Hagen 2010 in Table 28) with the pessary in place. Control: pessary management alone.	POP-SS, prolapse-related quality of life, prolapse severity (POP-Q), and perceived change in prolapse since pessary fitted.	Data collected at baseline (after pessary fitted but before randomization), 6 months post-randomization (with pessary *in situ*, then pessary removed), and 7 months post-randomization without pessary.	Low ROB for performance and detection bias, attrition bias, reporting bias and all other types of bias. Poor recruitment was a key issue within the trial – target was to randomise 50 women
Manonai 2012(3)	Parallel group RCT; 2 groups, Colpexin sphere with PFMT vs PFMT alone	91	Women aged 20 years+, prolapse stage I or II	All participants: taught about home-based practice with booklet of PFM. Visual inspection of contraction. Home exercise involved tightening the PFMs, holding for 10s, relaxing 10s and doing 10 repetitions 3 times a day for a period of 16 weeks. Colpexin+PFMT: exercised as above with the Colpexin sphere *in situ.*	ICIQ-VS (Thai version), POP-Q, PFM strength (Colpexin pull test, digital test using Brink scale)	POP-Q and ICIQ-VS at baseline and 16 weeks. PFM data collected at baseline, 4, 8, 12 and 16-week after starting treatment.	Low ROB. Random sequence generation was computer generated and information for decoding randomisation was kept secure and opaque sealed envelopes were used during the allocation process. Although ITT analysis was not employed, all dropouts were clearly accounted for. The groups were comparable at baseline and the authors reported a sample size calculation.

Abbreviations: PFM: pelvic floor muscles; PFMT: pelvic floor muscle training; POP-SS: pelvic organ prolapse symptom score; RCT: randomized controlled trial

2. Hagen S. Pessary Plus Physiotherapy for Pelvic Organ Prolapse (PEPPY). http://ClinicalTrialsgov/show/NCT011368892010.
3. Manonai J, Harnsomboon T, Sarit-apirak S, Wattanayingcharoenchai R, Chittacharoen A, Suthutvoravut S. Effect of Colpexin Sphere on pelvic floor muscle strength and quality of life in women with pelvic organ prolapse stage I/II: a randomized controlled trial. Int Urogynecol J. 2012;23(3):307-12.

However, from observing the mean scores it was apparent that symptoms in both groups were worse a month after the pessary had been removed (month 7) compared to baseline (when the pessary had been in place for 2 weeks), and there was no indication of a symptom or objective benefit for those women who had received PFMT on any of the outcomes. In both groups 2 out of 7 women said their prolapse was the same or worse at 6 months after the pessary had been inserted. Recruitment was problematic in the trial, and it was concluded that this would need to be addressed before moving to a larger trial (276, 277).

Of the initial 311 women recruited to the Cheung trial, 276 were randomised, 137 to PFMT treatment and 139 to vaginal pessary plus PFMT. Authors reported in one abstract an intention-to-treat analysis of the difference between the groups in PFDI-UDI and its subscores, and on the prevalence of women with SUI, UUI and voiding difficulties (278). Prolapse outcomes were not reported. Although there was significant improvement on all outcomes at 12 months, there was no significant difference between the groups. In a second abstract the authors reported a non-randomised comparison of those women who continued successfully with their pessary until 12 months (n=78) and those who continued successfully with pelvic floor exercises only (n=118) (278). At 12 months the pessary group had significantly better scores that the PFMT group on all the PFDI and PFIQ scores and subscores. This would seem to suggest that generally pessary and pelvic floor exercises are equally effective at improving urinary symptoms in women with prolapse, however in the select subgroup of women who adhere to treatment, the pessary provides extra benefit in reducing pelvic floor symptoms (278).

A total of 91 women were randomised in the Manonai (2012) trial, 45 in the study group and 46 in the control group. Eighty-five women (93%, equal in both groups) completed the 16-week assessment with 80% compliance to daily exercise. There was no significant difference in improvement in pelvic floor muscle strength between the groups at 16 weeks; either measured using the pull test or the digital assessment (279).

Summary

Three new trials were found, one comparing pessary alone versus pessary plus PFMT and two comparing pessary plus PFMT versus PFMT alone. The first was a pilot trial with recruitment difficulties and a very small sample, which did not contribute to the evidence (276). The other two trials were larger and concluded no difference between pessary plus PFMT and PFMT alone in terms of muscle strength at 4 months (279) or prolapse symptoms at 12 months (non-randomised comparison) (278). Combined pessary and PFMT and PFMT alone can be equally effective **(Level of Evidence: 1)**

PFMT + pessary may be as effective as PFMT alone in reducing symptoms. **(Grade of Recommendation: B New; however; some caution since the two trials considered two very different devices).**

3. PESSARIES

A pessary is defined as a device that is inserted into the vagina to provide structural support to one or more of descending vaginal compartments, i.e., the uterus, anterior vaginal wall (and bladder), posterior vaginal wall (and rectum) and/or vaginal apex (with or without small intestine after a prior hysterectomy (280). They offer a non-surgical option for the treatment of urinary incontinence and pelvic organ prolapse (POP). This section, discusses evidences for use of pessary to prevent or treat POP; evidence for use of pessaries to prevent or treat UI will be covered in chapter 20.

A range of vaginal pessaries (Figure 8) exist which can be broadly divided into two types: support and space-filling pessaries. Support pessaries lie along the vaginal axis, with the posterior component sitting in the posterior fornix and the anterior component coming to rest just under the symphysis pubis, thus providing a supportive shelf for the descending pelvic organs. As there is no evidence to support the use of a specific type of pessary, choice is based on clinical experience and trial and error. It is generally accepted that the ring pessary should be tried first because of ease of insertion and removal, and if this fails, other pessaries can be used (281).

A recent review of data obtained from public use files from the Centres for Medicare and Medicaid Services in the United States over a 10-year period from 1999 to 2009 showed that the rates of pessary insertion were consistent at 11-13% over the period (282). In the United Kingdom, a postal survey demonstrated that 87% of consultants use vaginal pessaries for management of POP (283). The likely candidates for vaginal pessaries are those with co-morbid medical conditions, those who still wish to bear children, as interim relief prior to surgery and for those who prefer

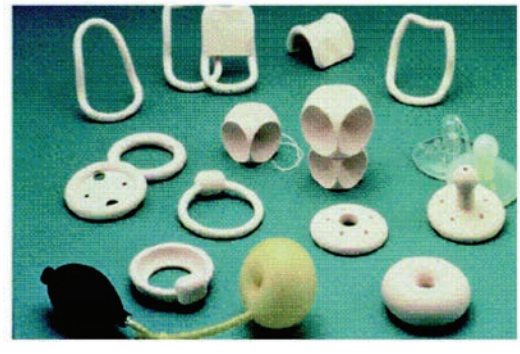

Figure 8 Pessaries

non-surgical treatment (284). Other indications include vaginal laxity, neonatal prolapse mainly seen in association with neural tube defects such as spina bifida and prolapse during pregnancy (285).

Factors that predict the type of treatment chosen for POP have been evaluated in various studies. Younger women (286) and those with a higher incidence of stress incontinence (286) are more likely to refuse pessary use. Age greater than 65 years at the time of pessary insertion and more severe prolapse (Stage III-IV) were more predictive for pessary discontinuation at one year (287-289). Ko *et al.* (2011) found that substantially older women or post menopausal women opted for a pessary rather than surgery, and more sexually active women expressed a significantly greater preference for surgery. In addition to opting for surgery over pessary use, younger sexually active women are more likely to change from conservative to surgical treatment over a one-year period (290).

3.1. Prevention of POP with Pessaries

Previously no trials had examined pessaries as an intervention in the prevention of POP. In this update, no further trials were identified.

3.2. Treatment of POP with Pessaries

3.2.1 Pessary Alone

Three new studies were included. Study details are presented in table 31. Ding *et al.* (291) evaluated 81 women with stage 3 and 4 prolapse who were successfully fitted with a ring pessary with support after 3 months. Subjective evaluation was carried out using non-validated questions and prolapse was objectively assessed using POP-Q.

To evaluate if the cube pessary can be used as a first line treatment, Nemeth *et al.* (292) prospectively evaluated 78% of women who had a cube pessary inserted after one year. Subjective outcome was established by using a non-validated questionnaire as a validated questionnaire was not available in Hungarian. As one of the aims of the study was to evaluate if it was well tolerated, the authors rated the process of pessary insertion and general wellbeing on a numeric rating scale and also on a patient global improvement scale.

Brazell *et al* (293) reported findings from a secondary analysis of a study that sought to evaluate if pessary use was associated with improvement in bulge symptoms and improvement in body image (294). They focused on bowel symptoms using the Colorectal Anal Distress Inventory, a subscale of PFDI-20 and Colorectal Anal Impact Questionnaire, a subscale of PFIQ-7. The study had a high attrition rate as only 43 women of the initial 104 had complete data at 12 months.

Results

The study by Ding *et al.* (295) found improvement in prolapse and bladder symptoms 3 months after use of a ring pessary with support in women with stage 3 and 4 prolapse. Of the 74% who were initially successfully fitted with the pessary, 10% failed to retain the pessary at 3 months. Their findings contradict the manufacturer's recommendations regarding use of this type of pessary in early prolapse. Of interest, 82.7% women who were of the median age of 70 years were able to manage the pessary themselves indicating that with proper counselling and encouragement hospital care can be minimised.

The cube pessary seemed to be a viable option for sexually active women to self-manage their pessary as Nemeth *et al.* (292), were able to demonstrate a significant improvement in general wellbeing in the 78% women who were still using the pessary at 12 months, 85% rated pessary care use as easy or very easy.

Brazell *et al.* (293) demonstrated a significant improvement in both bowel related symptoms and quality of life. Patients who completed the 12-month follow-up were significantly older and more likely to have stage 3 and 4 prolapse compared to stage 2.

3.2.2 Pessary Versus no Treatment

No new studies were identified.

3.2.3 Pessary and PFMT

- Pessary versus PFMT

One new study was identified. A RCT comparing PFMT to pessary treatment in 160 women (PFMT n=79, pessary n=81) aged ≥55 years with advanced POP. A pessary was fitted successfully in 47/81 (58 %)women (296). Only those women in whom a pessary was fitted successfully, were compared. Risks of bias were high as both participant and evaluator were not blinded and an ITT analysis was not performed.

In women aged ≥55 years with an advanced symptomatic POP, PFMT resulted in a significant but not clinically relevant improvement of pelvic floor symptoms after 3 months (PFDI-20). There was no difference between PFMT and pessary treatment. PFMT was more effective in improving anterior wall POP than pessary treatment on POP-Q (Table 31).

- Pessary plus PFMT versus PFMT

Refer to section III.2.3.2

- Pessary plus PFMT versus Pessary

Refer to section III.2.3.2

3.2.4 Pessary Versus Surgery

One new study was identified (297), making a total of three studies comparing pessary versus surgery (Table 32). All were prospective, observational cohort case controlled. The new study by Lone *et al.* (297) evaluated 133 women who opted for surgery and 154 who opted for surgery one year after pessary treatment using the ICIQ-VS and ICIQ-UI (297). Women

who had surgery were older with no difference in characteristics like body mass index, parity, ethnicity, history of hysterectomy and prolapse surgery. 69% women who used pessary and 67% women who had surgery completed the questionnaire at one year. The non-randomised design of the study with approximately 30% attrition rate suggested a high risk of bias.

Three studies (285, 297, 298) compared patient related outcomes after pessary use and surgery. Abdool demonstrated a significant improvement in prolapse, urinary, bowel and sexual function in both treatment arms but no difference between the two groups. Using the ICIQ-VS and ICIQ-UI, Lone *et al.* found a statistically significant vaginal, sex, QOL and urinary symptoms score improvement in both groups but no statistically significant difference was noted between the surgery and pessary groups. However, Barber (2006) found that subjects in the surgery group had significantly greater improvement in each of the scales of the PFDI and the prolapse and urinary scales of the PFIQ than did the pessary group.

3.2.5 Comparison of One Pessary to Another

No new trial was identified for this update, making a total of one trial included in this section comparing pessary to another device. Cundiff (299) conducted the largest multi-centre crossover trial, comparing a ring with support and a Gellhorn pessary for the treatment of symptomatic stage II or greater symptomatic prolapse in 134 women. There were no significant differences between groups in baseline characteristics. Participants were fitted with one of the pessaries for three months, and with the second for a further three months. During each three-month period, data was collected at one, six and twelve weeks from women who had a successful fit. Outcomes were measured at enrolment, three and 12 months, and included objective assessment using POP-Q and subjective assessment using PFDI, PFIQ, and a sexual function questionnaire. Allocation was by computer-generated random numbers using permuted blocks of variable size. Opaque, sealed envelopes were used to store the random allocation. Participants and clinicians were not blind to the allocation, but data was coded such that the analysis was conducted blind. Those women who were successfully fitted were asked to wear the pessary for three months, but if they discontinued prior to three months' data collection was accelerated. Attrition rates in the study were high with only 85 of the 134 women completing the study leading to high risk of bias. However, the trial was not underpowered due to the cross over design.

Cundiff *et al.* (299) found a statistically and clinically significant improvement in the majority of the PFDI scales and many of the PDIQ scales with both pessaries but no difference between the ring or Gellhorn pessary. Approximately 60% of women offered a pessary continued treatment in the long term irrespective of the type of device.

Success rates

There is no agreement as to what constitutes a successful fitting of a pessary. Some consider success if a pessary was perceived comfortable by a patient when retained during Valsalva and voiding at the initial visit, while others consider it success if a patient continues to use the pessary until the following visit to the doctor. Thus quoted rates of successful fitting vary widely with differing follow-up times. (Table 33). Reasons for failure range from expulsion due to complications such as vaginal discharge, erosion, *de novo* SUI, pain, voiding difficulty and constipation (Table 33). The risk factors for failure also vary, making it difficult to draw conclusions.

Complications

Minor complications after pessary insertion range from vaginal discharge, erosion, *de novo* SUI, bleeding, pain and constipation (Table 33). A recent study by Collins (300) has shown that women who have a pessary are more likely to be bothered by discharge (30.0% vs 2.1%, $p < .001$) and this develops early and may be due to an inflammatory process in the vagina (300). Using the cube pessary appears to be complication free, probably because it has to be removed on a regular basis.

Rarely major complications may occur. Neglected pessaries present with more serious complications namely fistula formation and peritonitis. Erosion into the bowel or bladder and dense adhesions to other pelvic structures have been reported. Unusual complications of cervical entrapment, small bowel incarceration, and hydronephrosis have also been reported (301).

Conclusion

As in the most recent Cochrane review (222) and 1 recent RCT, there is no good quality evidence from randomised controlled trials on which to base the management of POP using pessaries.

Prospective case controlled cohort studies suggest that pessaries are a viable option for women who complain of symptomatic prolapse. **(Level of Evidence: 3).**

There appears to be no advantage of pessary use over PFMT, from one high risk of bias RCT **(Level of Evidence: 3).**

One single randomised study, with a high attrition rate of 40% found no significant difference between ring pessaries with support and the Gellhorn pessary in PFDI and PFQI scores **(Level of Evidence: 2).**

Table 31 Summary of data on PFMT vs pessary for POP

Author/ year	Study design	Comparison group	Participants	Type of pessary	Subjective assessment	Objective assessment	Length of follow-up	Improvement in symptoms
Panman CM, 2014	RCT	PFMT (n=79): No standard protocol – individual adaptation in line with normal practice (included being able to use electrical stimulation) vs PESSARY (n 81): Fitting – opted for 2 week try of pessary with refit at 2 weeks if necessary and max of 3 refits.Fitted by 'trained research physician'	160 women aged ≥ 55 years with self identified POP symptoms (on screening) POP at or beyond hymen (POPQ)	First ring, then ring with support and then Shaatz or Gellhorn	Primary outcome: PFDI-20	Secondary: change in POP-Q stage	3 months	No sign diff. in PFDI POP-Q Anterior compartment: 26.5% >=1 stage change in PFMT v 7.1% pessary p=0.013 * No ITT, only 47 of 81 (58%) with successful fitting included in analysis

4. RECOMMENDATIONS

There is growing attention being paid to the effectiveness of conservative interventions for POP. There are encouraging signs of more rigorous research in the area.

4.1. Recommendations for Practice

4.1.1 Lifestyle Modification

1. Constipation is associated with development of prolapse **(Grade of Recommendation: C New).**
2. Smoking cessation, while generally recommended, cannot be recommended specifically for the avoidance of prolapse development **(Grade of Recommendation: D).**
3. Vitamin D deficiency is not associated with development of prolapse **(Grade of Recommendation: C New).**

4.1.2 Pelvic Floor Muscle Training (PFMT)

1. PFMT does not influence the development of prolapse post-natally **(Grade of Recommendation: B New**).
2. PFMT intervention delivered 12 years+ after childbirth can reduce symptoms of prolapse which develop in the longer term (**Grade of Recommendation: B New**).
3. There is evidence of benefit that PFMT is effective in reducing pelvic floor symptoms **(Grade of recommendation: A New**)
4. There is some evidence of benefit showing that PFMT is effective in alleviating specific prolapse symptoms (e.g. vaginal bulge) **(Grade of recommendation: C New)**
5. There is no evidence that PFMT is effective in reducing severity of prolapse based on POP-Q stage **(Grade of recommendation: B New)**.
6. Peri-operative PFMT does not improve prolapse symptoms in women undergoing surgery for vault prolapse (**Grade of Recommendation: B New**).
7. Combined pessary and PFMT and PFMT alone can be equally effective in reducing symptoms and increasing muscle strength and should be considered for treatment (**Grade of Recommendation: B New**).

4.1.3 Pessaries

1. In a choice between the Gellhorn pessary and a ring with support, offer either to improve prolapse symptoms and reduce their impact **(Grade of Recommendation: B).**

4.2. Future Research Directions

4.2.1 Lifestyle Interventions

1. Trials of interventions for constipation are needed to assess their effectiveness in preventing/treating prolapse.
2. Studies to fully investigate the association between occupation/heavy lifting, and bodyweight and prolapse are needed as current evidence is conflicting. These studies should ensure that:

i. Occupation, physical activity and diet are assessed rigorously, using instruments with sound psychometric properties.

ii. Potential confounding variables are considered. Attempts are made to overcome recall bias inherent in assessing lifetime occupational history, and healthy worker bias, which is a problem when attempting to compare prolapse in women currently employed in heavy labour type jobs versus others.

iii. Outcome measures used are valid and reliable, and are consistent across studies; prolapse symptoms should be the primary outcome within studies, followed by prolapse anatomical severity.

4.2.2 Pelvic Floor Muscle Training (PFMT)

1. Further studies are needed to confirm the role of physical therapies in the prevention of POP.
2. Further trials are needed to add to the evidence regarding:

i) The effectiveness of PFMT for different stages and types of prolapse.

ii) The role of PFMT as an adjunct to surgery for anterior and posterior prolapse.

3. More trials needed to improve the evidence relating to the following comparisons:

i) Low versus high intensity supervision of PFMT (taught PFMT vs self-instruction manual already trialled)

ii) Individual versus group PFMT (group PFMT vs group lifestyle already trialled)

iii) PFMT versus surgery (anterior/posterior repair vs PFMT already trialled)

iv) PFMT versus pessary. (PFMT vs PFMT plus pessary already trialled)

The assessment and measurement of POP and the assessment of prolapse symptoms need to be made in a standardised fashion using a validated outcome measure (such as the POP-Q examination). A single validated symptom tool was not apparent in new studies, but the PFDI, PFIQ and POP-SS tools were most commonly used and may provide a useful basis for comparisons across trials in future.

4.2.3 Pessarie for Prolapse

Although the use of pessaries has been common clinical practice and has been used for many centuries robust evidence of their use is lacking. There is a pressing need for well-designed randomised studies using validated measures for subjective and objective assessment. Areas that need focus are:

- Pessary versus no treatment
- Pessary versus PFMT
- Pessary versus surgery
- Risk benefit of the use of local oestrogen in conjunction with a pessary
- Progression or regression of prolapse using in women using pessaries
- Optimal management protocols for pessary usage e.g. indications, interval between pessary changes, complications and their treatment and which pessary is indicated for a specific type of prolapse.

IV. URINARY INCONTINENCE IN MEN

As in earlier consultations, UI in men remains underreported and under-studied in comparison to studies of women. Pooled prevalence of UI in community based men ranges from 4.81-32.17%. (302). UI and other LUTS in men increase with age, with variation in prevalence rates reflecting different study populations, definitions of incontinence and methods (303). Despite the prevalence of UI and LUTS in older men, the only aspect which continues to receive systematic consideration with respect to conservative management is post-prostatectomy urinary incontinence after radical prostatectomy (RP). The primary conservative approach for prevention and treatment of UI after RP, or transurethral resection (TURP), remains PFMT, with or without some form of biofeedback (BF). PFMT, in combination with anal EStim, BF or transcutaneous electrical nerve stimulation (TENS), MStim, and novel therapies such as dyadic planning and concentration have been utilised for UI in men.

The PFMT, EStim, MStim and PTNS interventions, and other combinations of PFMT with general exercise and other approaches, in the current review were kept in the same organizational format as the previous consultation to reflect evolving evidence and emerging directions of research. All new studies of EStim and MStim in men undergoing or post prostatectomy combined these modalities with PFMT and thus were included under the PFMT section. Penile vibratory stimulation (PVS) was added as a novel technology category. The study on PVS involved men incontinent after RP, but did not include PFMT, so was kept in a separate section, as were studies of EStim and MStim for non-prostatectomy related incontinence or other LUTS. Studies on PTNS are presented in section V.1.

A literature search of relevant systematic reviews and reports of RCTs and quasi-RCTs was updated. No other types of study designs were considered. One systematic review, an update of the Cochrane systematic review on conservative management of post-prostatectomy incontinence, was identified (304). For this review, 14 new published trials (305-318) and eight abstracts (319-326) were identified. Table 34 provides summary information on the 22 trials added in this review. One study previously included only as an abstract (327) is now included as a full publication (328). This study is included in the table as in the full publication with additional information that was not previously included in the abstract. The published peer reviewed journal publication (329) of a previously included report of two parallel trials (RP and TURP arms) was added to the references which previously included an abstract and health technology report (330, 331). One study previously excluded as it was a study in progress (332) was included this time as a peer reviewed publication of a completed trial (307). Nine ongoing trials were identified from trial registries, but not included in this review.

1. LIFESTYLE

Lifestyle recommendations such as smoking cessation, healthy eating, appropriate body weight, avoiding excessive caffeine or alcohol are all part of a primary care approach and are intended to be preventative in the onset of obesity, cardiovascular disease, diabetes. Up until the last ICI edition, no trial had addressed the topic of lifestyle interventions alone in men with UI. In this edition, a few new trials have been added.

1.1. Weight Loss by Obese or Overweight Men

One new trial was identified on weight loss in overweight/obese men (7, 333) and has been added in this update. This was the partner study to Phelan, Kanaya *et al.* (2012) conducted to determine the effect of an intensive weight loss programme over 4 years previously outlined in the look AHEAD trial - on a subset of male participants (n=1910). Men were randomised to an intensive weight loss programme or diabetes support and education group. Self-report of incontinence, nocturia and daytime voiding frequency were recorded at baseline and 1 year. The odds of prevalent UI at one year were reduced by 38% in the intensive lifestyle modification intervention group compared to the support and education group, with UI decreasing from 11% to 9% in men. As reported for women there was uncertainty over the risk of selection bias for a number of key parameters including: random sequence generation and allocation concealment. Performance bias was unclear as the blinding of participants and staff was not undertaken. Both

studies did ensure the blinding of outcome assessment but neither provided complete outcome data and both provided only selective reporting indicating possible reporting bias (Table 2).

1.2. Smoking

One new trial was found however data was not presented separately for women and men. (Refer to section II.1.2.4 for more details)

1.3. Dietary Modification in Men

In a separate sample (from the study by Davis, Vaughan *et al.* 2013 presented in Lifestyle intervention in women's section II.1.2.5) 3960 men over 20 were included (16).

The authors found that the highest level of caffeine intake was associated with having moderate to severe UI (1.72, 95% 1.18-2.49 and 2.08, 95% 1.15-3.77) respectively. All parameters in terms of risk of bias reporting were unclear or high risk. The blinding of participants and personnel and blinding of outcome assessment were at high risk of bias and the likelihood of incomplete outcome data and selective reporting was also high.

A sample of 683 men aged 40-75 who completed a food frequency questionnaire and the Consultation on Incontinence short Form (ICI-SF) as part of the Hirayama study (18). The data showed a slight increase in the risk of UI at the highest level of caffeine consumption (similar to the US data), but this was not significant after adjusting for confounding factors with OR: 95% CI, 1.36 (0.65-2.88) in the male participants. The risk of bias reporting was largely unclear in this study with blinding of participants and personnel and blinding of outcome assessment, incomplete outcome data and selective reporting all of high risk. Results of sex stratified analysis of the data from the sample of Japanese men and women did not show an association between caffeine and UI, the authors suggest the need for further larger samples to explore any association further (Table 5).

Summary

Evidence from 1 RCT supports lifestyle modification interventions promoting weight loss as a tool to reduce urinary incontinence in men who are overweight or obese. **(Level of Evidence: 2**; 1 new RCT**)**.

Evidence from a small new RCT indicates that urinary frequency may be improved by smoking abstinence, **(Level of Evidence: 3).**

Caffeine consumption is likely to play a role in exacerbating UI in men. New epidemiological evidence from a large cross sectional study supports this conclusion **(Level of Evidence: 3).**

Recommendations

Weight loss: Where weight loss through lifestyle changes should be recommended to obese and overweight men with UI, particularly those with type 2 diabetes. **(Grade of Recommendation: B New)**

Smoking abstinence should be recommended for men with UI. **(Grade of Recommendation: C New)**

A reduction in caffeine intake is recommended for those with incontinence symptoms; evidence suggest the equivalent of 2 cups of coffee a day (250mg) is associated with urinary incontinence in both men and women. **(Grade of Recommendation: C)**

Larger RCTs to assess effect of lifestyle modification interventions are important.

Table 34 Summary of data on conservative management in male urinary incontinence

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Pelvic Floor Muscle Training (PFMT)							
Ahmed *et al*. 2012 (1)	3 group comparison PFME vs PFMT plus EStim vs PFMT plus EStim plus biofeedback	N= 90 men randomized, N=80 completed trial Group 1 n= 26 Group 2 n=26 Group 3 n= 28 Randomization by computer generated random number list in sealed envelopes. Surgeons blinded to randomization. Blinding of outcomes assessor not indicated.	Men undergoing RP for clinically localized prostate cancer	Treatments started one week after catheter removal, twice weekly for 12 weeks Group 1 PFME (control) Group 2 PFMT plus EStim starting one week after catheter removal, twice weekly for 12 weeks Group 3 PFMT plus EStim plus biofeedback starting one week after catheter removal, twice weekly for 12 weeks EStim – electrodes on skin over sacrum Biofeedback - surface electrodes on abdomin and perineum	Primary outcome 24 hour pad test, secondary was quality of life assessed with IIQ-7. Mean leakage significantly lower in Group 3 (EStim plus biofeedback) at 6 through 24 weeks ($p < 0.05$) Significant differences in continence at weeks 12 and 24 with Group 3 having more continent patients, followed by Group 2. Concluded early EStim and biofeedback decrease duration and degree of postprostatectomy UI	Continence assessed at baseline, 6, 12 and 24 weeks	Dropouts: none reported Sample size analysis reported (n=80) Dropouts Group 1= 4 (2 radiotherapy, 2 postoperative complications Group 2 = 2 (both radiotherapy) Group 3 = 4 (2 radiotherapy, 2 declined followup) No intention to treat analysis.
Baroni *et al*. 2013(2) Abstract only	Intervention (individual PFMT and group treatment) vs control (individual PFMT)	N= 40 men Divided into two groups (randomization not described). Intervention: n = 16 patients mean age 61.8 years Control n = 24 mean age 67.5 Assessor blind to allocation until assignment.	Men with SUI or mixed UI after RP (time after surgery not reported)	Intervention: 5 individual training sessions with a physical therapist followed by small groups sessions (total 15 sessions at the rehabilitation centre), home exercises. Control: individual training sessions with physical therapist.	Outcomes included adherence to training program (exercise at home), self report of change in continence using VAS scale and number of pads, quality of life ICIQ-SF, cost effectiveness (therapist time). Non significant difference in home practice (intervention 69% vs 58% controls). No difference between groups	Initial briefing by therapist, final evaluation one month after rehabilitation.	Dropouts: none reported. No sample size analysis reported.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
					on VAS or pads used per week. Authors conclude group treatment allows cost effective improvement.		
Burkert *et al.* 2011(3)	Intervention (dyadic PFME planning) vs one of three controls	N = 112 prostatectomy patients and their partner (dyads). 2x2 mixed design. Couples randomized in blocks of four to one of four groups Intervention n= 28, Controls n= 29, 29 and 26 Research assistants blinded to allocation Mean age of patients 62.8 years, partners 59.3 years.	Men undergoing laprascopic RP who had a partner willing to participate	All patients received standard care including written information on PFME 1 day post surgery (PFME 3x day for 10 minutes), physical therapist introduced PFME on day 3 or 4. Discharge day all participated in single 30 minute planning session intervention with completion of planning sheet for health behaviours (in dyad or individually). Intervention: dyad PFME planning Control: (dyadic nutrition planning, Control: individual PFME planning, Control: individual nutrition planning	Main outcome: self reported dyadic planning and PFME. Self reported dyadic PFME planning increased with both the dyadic and individual PFME planning session. No effect on PFME was found. Continence was not an outcome.	Questionnaires at 2 days, 2 weeks, 1, 3 and 6 months post-surgery.	Dropouts Intervention n=5 Control: dyadic nutrition planning n=2 Control individual PFME planning n=7 Control: individual nutrition planning n= 4 Sample size analysis required 112 couples (dyads). Intention-to-treat analysis completed.
Collado, Serra 2013 (4) Abstract only	Intervention PFMT plus BF pre-op vs Control PFME after RP	N= 193 patients recruited Randomization and blinding detail not provided. N= 179 included in final analysis	Men with localized prostate cancer scheduled for RP	Intervention: starting 3 weeks before surgery included weekly assisted BF sessions (surface electrodes) with periodic, rapid, intense and maximal	Primary outcome: Degree of continence improvement compared to week 1 during followup (continence not defined)	No detailed description. Pad tests reported for week 1, week 6, month 3, month 6 and 1 year.	Dropouts –detail only for intervention group n=5 (2 perineal pain, 2 post RP complication, 1 left treatment. No sample size calculation provided.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
		Intervention = 87 Control = 92		strength contractions and transversus abdominis activation plus daily PFMT performed at home with written instruction (no detail on whether it was continued post-operatively) Control: oral instruction on PFME post surgery, structured program of BF, transversus abdominis activation and PFMT 3 months post surgery	Secondary outcomes 24 hour pad test and ICIQ-UI SF score Significant difference in continence improvement reported for week 6, month 3, month 6 and 1 year favouring intervention group. Difference in 24 hour pad test significant only at 3rd month, favouring intervention group.		No intention–to-treat analysis.
Dijkstra-Eshuis *et al.* 2015 (5)	Intervention PFMT plus biofeedback pre-op vs Contol PFME post-op	N=122 patients recruited, N= 121 randomized. Pre-operatively. Mean age 63.7 years. Randomization by computer generated random numbers (block randomization, variable block size). Therapists and participants blinded to randomization until first visit. Intervention n= 65 Control n= 56	Men undergoing laparascopic RP (one surgeon), prostate cancer state T1 or T2.	All participants assessed pre-op by physical therapist Intervention: once weekly 30 minute session of PFMT with biofeedback pre-op x 4 weeks provided by physical therapist with twice daily practice at home. Told to restart immediately after catheter removal. Written instructions for 2 sets of 30 contractions. Control: standard care of written PFME instructions on catheter removal (7-10 days post surgery)	Primary outcome: urinary continence defined as no leakage on 24 hour pad test and self report by KHQ, IPSS and PeLFI (pelvic floor inventories) 20.8% of patients continent at 6 weeks, 43.6% at 3 months, 61.5% at 6 months, 72.3 % at 9 months, 77.2% at one year. No difference in SUI or QoL between intervention and control at any time points. Authors suggested that post-prostatectomy UI likely due to intrinsic sphincter deficiency that cannot be treated with exercise.	Questionaires, 24 hour diary and pad test at 6 weeks, 3, 6, 9 and 12 months post-operatively. PeLFT and examination of the pelvic floor pre-operatively and 1 year post-operatively.	Dropouts Intervention: language barrier (1), lost to followup (4), discontinued intervention (4) Control: Lost to followup (4), discontinued intervention (6) Sample size analysis was 124 patients in each group (n=248), interim analysis planned at 122 patients. Trial halted as interim analysis showed no benefit.

Geraerts *et al.* 2013 (6)	Intervention PFMT plus biofeedback pre-op vs Control PFMT post-op	N= 180 men Computer generated randomization using permuted blocks for strata (age <65/≥65, surgical approach open/robot assisted laproscopic Intervention n= 91 Control n=89	Men undergoing open or robot assisted laproscopic RP (3 surgeons)	Intervention: 30 minute session of therapist guided PFMT with biofeedback weekly starting 3 weeks prior to surgery plus home program of 60 contractions per day. Restarted PFME day 4 post-op with catheter *in situ* Control: PFMT after catheter removal Both groups: Post-op weekly session to discuss bladder diary and have guided session with digital or EMG biofeedback plus home program. PFMT continued until continent	Primary outcome: incidence of contience and time to continence. Continence defined as 3 consecutive days of 0gm urine loss on 24 hour pad test. Other measures were: 1 hour pad test, VAS, IPSS, KHQ (QoL). No difference between groups on duration of UI, pad test, VAS or IPSS. Median time continence was 30 (control) and 31 (intervention) days. Intervention group scored better on impact of incontinence at 3 and 6 months	Pre-operative baseline and 1, 3, 6 and 12 months post-operatively	Dropouts: Intervention n=6 died (1), stroke (1), transport problems (3), refused further participation (1) Control n= 4 transport probems (2), refused further participation (2) Sample size analysis required 166 for power.
Ghanem *et al.* 2013 (7) Abstract only	Intervention PFME pre-op vs Control PFME post-op	N=100 men randomized. Randomization technique not described. Intervention N=50 Control N=50	Men with localized prostate cancer undergoing radical prostatectomy	Intervention: PFME protocol for 2 weeks prior to surgery (detail not provided) with post-operative PFME program. Control: postoperative PFME program only	Continence defined as using 0-1 pads. Also completed the ICIQ SF male. More intervention patients continent at 14 weeks than controls ($p< 0.05$). 70% of patients in both groups continent at 18 weeks, 85 % by 54 weeks.	Timepoints for measurement not clear, last dated reported at 54 weeks post-op.	Dropouts: not described Sample size analysis not described.
Hou *et al* 2013 (8)	Intervention post-op PFME vs control	N= 66 randomized. Randomization technique not described.	Men undergoing TURP for benign prostatic hyperplasia.	Intervention: PFME after removal of catheter day 2 post-op. Instructed to contract PFM for 5 seconds, relax for 10 seconds.	Outcome: early recovery of bladder function post TURP using the IPSS and SF-36. Q-max (maximum urinary flow), voided	Baseline and 1, 4 and 12 weeks post-op	Dropouts n= 5 (group assignment not identified) delay in catheter removal prior to discharge (2), lost to followup (3).

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
		N= 61 completed study (intervention n= 32; control n= 29)		Surface EMG to confirm PFM contraction. Home program 5 minutes practice 3 x per day. Weekly telephone reminders. Control: not described	volume and PVR (post void residual volume). At 12 weeks, intervention group had significantly less severe LUTS compared to control (p<0.001), Qmax (p=0.026) and QoL physical (p=0.029) and mental health domains (p= 0.005). No significant differences in voided volume or PVR.		Sample size analysis not provided. No intention-to-treat analysis.
Kakihara *et al*. 2007 (9)	Intervention (PFMT with EStim) vs PFME only	N=20 men from a single urology clinic, mean age 64.3 years Randomly divided into two groups (detail on randomization technique not provided) Intervention group n=10, control n=10 N=18 in final analysis for pad test and visual analogue data : intervention n=8, control n=10	Men with urinary incontinence post RP (minimum of 6 months post-op, had undergone urodynamic testing)	Intervention: Physical therapy taught functional PFMT with EStim. PFME started with 2s contractions increasing daily by 1suntil 10s reached. Patients were instructed to do 90 contractions/day at home (divided equally into 3 times per day). Also had EStim with endo-anal electrode weekly. UUI – 8 Hz increasing to 10 Hz after 3 months, for SUI 35Hz increasing to 50 Hz after 3 months. Control: Physical therapy taught functional PFMT only	UI measured with 1 hour pad test (incontinence < 2 gm), visual analogue scales for incontinence patient perception of the problem, and pad use Intervention group: 4 patients UUI, 6 had SUI, mean time post surgery 12.3 months. Control group: 5 had UUI, 5 SUI, meantime post surgery 16.8 months Significant decrease in urine loss on pad test and self report baseline to 12 months in both groups. No difference between groups	Measures at baseline, visit 2, and 3, 6 and 12 months.	Dropouts Intervention n=2 discharged at 3rd and 6th months, reason not provided. Control n=3 discharged at 3rd, 6th and 12th as regained continence Length of time EStim continued for the intervention group unclear. No sample size or intention-to-treat analysis reported.
Kongtragul *et al.* 2014 (10)	Intervention (PFME with concentration	N= 138 men recruited from a single hospital	Men 17-80 years of age with prostate	Intervention: Starting 3 weeks post-operatively, PFME with	Primary outcome was urinary incontinence	Measurements at baseline (3 weeks post surgery) and	Dropouts Intervention n=1 (refused treatment)

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
	therapy) vs control (PFME only)	N= 135 cases in final analysis (n= 68 intervention, n= 67 control) Randomization technique not given. Sample stratified for time of catheter removal (prior to or after discharge) and type of surgery (no further detail provided).	cancer who had no incontinence prior to radical prostatectomy surgery	concentration therapy (concentrating on the exercise and eliminating other issues or use of the *rehabilitation health spa rock* - not clearly described). PFME was practiced 240 times daily by holding and relaxing muscle tension around the anus. Control: PFME only	(incontinence ≥ 2 gm urine on 1 hour pad test) 65/68 in intervention group compared to 48/67 controls achieved continence (p< 0.001 More men in intervention group 66/68 practiced regularly than in control group 34/67 (p<0.001)	weekly for up to 3 months	Control n=2 (refused treatment) Needed 69 cases in each group for power. No intentiontotreat analysis.
Laurienzo *et al*. 2013 (11)	3 groups Pre-op PFMT plus EStim vs pre-op PFMT vs control	N= 58 men recruited. Randomization by computer generated list. All intervention provided by a single therapist N= 49 completed study (n= 17 PFME plus EStim, n= 17 PFME, n= 15 control)	Men with prostate cancer stage T2 waiting RP	Intervention Group 1: 10 pre-op physiotherapy sessions of EStim using rectal probe. Tonic fibers – 20HZ, 700 microseconds, work time 6s, rest 6s. Phasic fibers – 65 HZ, 150 microseconds, work time 6s, rest 18s. Five exercises for PFM contraction. Group 2: 10 pre-op physiotherapy sessions with only the PFME. Control Pre-op information on prostate anatomy only No post-op PFM rehabilitation for any group	Primary outcome: continence assessed by 1 hour pad test (> 2 gm incontinence). Secondary outcomes: ICIQ-SF, SF-36 No significant differences between groups on pad test at any time points. No differences in QoL (SF-36)	Measurements at 1, 3 and 6 months post surgery.	Dropouts N=9 (detail on group not provided). Desistance (sic)(2), adjuvant radiotherapy (1), urethral stenosis (1), urinary fistula (1), surgical risk (1), inadequate followup (1) No sample size analysis described. No intention-to-treat.
Laurienzo *et al* 2015 (12)	3 groups	N=123 men incontinent after RP	Men with more than 3 gram loss	Assisted PFMT described as two	Outcomes Incontinence and quality of life using the	Patients evaluated pre-	Dropouts not discussed.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Abstract only	PFMT plus EStim vs PFMT vs control	Randomization by computor, sealed envelopes. Group 1 n=40 control, no treatment Group 2 n=41 assisted PFMT Group 3 n=42 EStim with assisted PFME No details on blinding.	of urine on a 1 hour pad test one month after RP	series of ten exercises taught by verbal command EStim protocol was 20 minute sessions twice weekly over 7 weeks. Frequency 35 HZ	ICQ-SF, erectile dysfunction by IIEF-5, IPSS, 1 hour pad test, evaluation of pelvic floor with perineometer. No differences between groups in quality of life, erectile dysfunction or PFM strength at any time point post-surgery. Pad test data not provided.	operatively and then at 1, 3, and 6 months post RP	Sample size analysis not provided.
Martini *et al* 2011 (13) Abstract only	Intervention pre-op PFMT vs control	N= 70 men recruited N= 49 with pelvic floor impairment identified on exam randomized to intervention or control. Intervention n=24 Control n=25 Randomization details not provided.	Men undergoing laparoscopic RP for localised prostate cancer T1-T3	Intervention: 5 sessions of physical therapist guided PFMT 2-3 weeks before surgery, PFME continued post-op Control: usual care – written instruction on PFME provided post-operatively	Outcome: focus on PFI as a potential factor in post RP UI. Continence defined by not wearing a pad. Other: 24 hour pad test, pad use, 7 day bladder diary, QoL. Patients with PFI used more pads and had more SUI episodes. PFI independent predictor of UI at 3 and 6 months. For those with PFI, UI on getting up and squating was significantly lower in intervention group at 1 month (p=0.006) but not other time points.	Measurement pre-op baseline, and 1, 3 and 6 months post-op.	Dropouts: not identified. Sample size analysis not provided.
Morihoro *et al* 2011 (14) Abstract only	Intervention post-operative PFME with EStim vs control PFME	N= 34 men Randomized post-operatively to 2 groups. Randomization technique not described. Intervention n=20 Control = 14	Men who had undergone laparoscopic RP	Intervention: PFME and EStim 2x daily for 15 minutes for one month after catheter removal, starting on day 5 after surgery. Control: PFME alone	Outcome UI, defined as not needing a pad to keep clothing dry. Recovery of urinary continence significantly favored intervention group at 12 months (p = 0.007). Multivariate analysis showed EStim associated	Measurement at 1, 3, 6, and 12 months.	Dropouts: not described. No sample size analysis based on multivariate or other analysis provided.

					with continence recovery at 6 and 12 months.		
Ng 2014 (15) Abstract only	Intervention pre-op PFMT vs control	N=66 men Randomization technique not given.	Men undergoing radical prostatectomy	Intervention: PFMT started 3 weeks pre-operatively from advanced practice nurse. Control: Standard care (no detail provided).	Primary outcome: urine loss on 24 hour pad test. Secondary outcomes: incontinence impact and potency satisfaction. Earlier return to continence in intervention group at 3 months compared to controls (p= 0.002). Intervention group also had higher score on potency at 3 months (p = 0.005).	Measures at 1,2, 3 and 6 months	Dropouts: no information provided.
Ocampo-Trujillo *et al*. 2014 (16)	Intervention (pre-op PFMT with biofeedback) vs control (standard pre-op teaching only)	N=16 men, mean age 58 years Randomized to 2 groups Intervention n=8, control n=8 Randomization –single blind, centralized. Researchers blind to group assignment prior to enrollment.	Men > 40 years waiting RP for prostate cancer (T<3 N0M0 PSA<20)	Intervention: Intensive PFMT 3 times daily for 4 weeks prior to surgery. Biofeedback audible and visual signals, anal pressure probe. Control: standard pre-operative diet and general health teaching	24 hour pad test for continence, histological analysis of muscle tissue from external sphincter of urethra. Health related quality of life assessed with UCLA-PCI and SF 12. Continence defined as 3 consecutive days of no urine loss on 24 hour pad test, results not reported. 6/8 intervention vs 4/8 of controls did not need pads at 8 weeks. Self report of symptoms favoured improvement in intervention group (no p values provided except for erectile dysfunction). Intervention patients had higher values in cross sectional area of external	Measurements (pad test, health related quality of life) at week 0 prior to surgery and week 8 post-op. Histology samples taken at the end of the intervention and on day of surgery.	Dropouts: none No histiology samples taken prior to start of intervention.

	control no intervention	hormone or hormone and radiotherapy randomized to 2 groups. n= 36 intervention n= 33 control Mean age 71 in both groups. N=66 completed	prostate cancer (time period not identified). Details of randomization approach not provided.	education, PFMT, exercises to radiate muscle strength. Duration 24 weeks, 16 weeks of supervised work, 8 of autonomous exercise. PFMT performed with music, focus on biofeedback (sense of awareness). Slow twitch (≤1s) and fast twitch (5s) contractions. Control group: watchful waiting by telephone contact	Sandvik scale and VAS-UI and FACT-P (urinary related QoL). Also included data on obesity, muscle resistance, constipation andactivity. 33.33% of intervention group had stress UI compared to 36.36% controls. The rest had urgency UI or mixed UI. Significant improvement on VAS-UI scale regarding intensity UI symptoms favouring intervention group. QoL improvement greater in those with greater improvement in UI. Pad test dated/number achieving continence not reported.	Calculated sample size achieved.	Control: None No intention-to-treat.
Tienforti *et al*. 2012 (20)	Intervention (pre-operative and post-operative PFMT with biofeedback) vs control group (post-op PFME only)	N= 34 men screened and recruited pre-op, computer generated randomization schedule. N= 32 men in the final analysis (n= 16 in intervention, age 60-74; n= 16 in control age 52-74). No significant differences between intervention and control groups in age, disease stage, intra or post-operative features.	Men undergoing standard open retropubic RP for localized prostate cancer at one centre.	Intervention: Pre-operative biofeedback (anal probe, reference electrode on anterior superior iliac spine) with teaching on PFM the day prior to surgery. After catheter removal, oral and written PFME with structured exercise program (3 daily 10 minutes sets 5 second contractions followed by 5 seconds relaxation) lying/sitting/ standing, recorded in diary. Monthly	Recovery of continence (self report on ICIQ-UI) primary outcome. Significant difference in achievement of continence favoring intervention group at 1, 3 and 6 month followups. 10/16 intervention vs 1/16 control patients continent at 6 months. Patients in intervention group reported higher QoL (IPSS QoL), difference not significant Concluded pre-operative biofeedback with PFME and monthly assisted	Measurements at baseline, 1, 3 and 6 months.	Dropouts Intervention: n=1 (intolerence to rectal probe insertion) Control: n=1 (intraoperative surgical complications) No intention-to-treat.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
				supervised biofeedback and motivation sessions Control: oral and written instructions on home PFME post-op after catheter removal, no diary, monthly followup Pre-op session provided by a dedicated caregiver.	sessions improves recovery to continence.		
Zopf *et al.* 2015 (21)	Intervention (combined exercise with PFME vs control (no intervention)	N = 85 men who had undergone prostatectomy for prostate cancer. n= 56 in intervention group n= 29 in control group N= 70 (50 intervention, 20 control) completed followup	Men recruited 6-12 weeks after prostatectomy +/- radiation. Multicentre, partially randomized controlled trial. Patients who consented to randomization were to be randomized, patients who refused randomization were to receive intervention of their choice. As all patients indicated a group preference, trial was not randomized.	Intervention: 15 month supervised multimodal exercise program (aerobic, resistance and PFME) with one of 4 community sports groups. Exercise 60 minutes per week Details of PFME not provided. Control: No intervention	Multiple secondary outcomes including urinary incontinence as measured by 20 minute pad test. Primary endpoint was physical fitness. Significant improvement in UI for intervention group between baseline and post testing (p= 0.005). No significant difference between intervention and control. Significant improvement of self reported urinary symptoms (EORTC-QLQ PR 25) in favour of intervention group.	Measures for UI at 3 time points, detail not provided. Authors identify poor compliance with pad testing was a limitation. Calculated sample size not achieved, limited power to detect differences between groups.	Dropouts Intervention: n=6, reasons not related to intervention Control: dropouts not described. Intention-to-treat analysis performed.
Penile Vibratory Stimulation (PVS)							

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
Fode 2015 (22)	Intervention PVS vs control delayed PVS	N= 39 randomized by computer generated list 1 :1 ratio N= 31 in analysis (Group 1 early intervention n= 19; Group 2 delayed intervention n=20	Men with UI > 1 year post RP. All patients had previously received PFMT with RP.	12 week study. Intervention: PVS for first 6 weeks of study. Stimulation of ventral surface of glans once daily; 10 seconds of stimulation followed by 10 second pause repeated 10 times. Control: delayed intervention – no intervention in first 6 weeks, PVS in second 6 weeks	Primary outcome: difference in leakage measured by 24 hour pad test and 72 hour voiding diary. Subjective assessment by ICIQ-SF, IPSS and satisfaction questionnaire. Early intervention group: 12/15 had reduction in leakage on pad test baseline to 6 weeks (p = 0.021); maintained in 8/12 at 12 weeks (p= 0.04) Delayed intervention group: reduction (not significant) with treatment weeks 6-12. No significant difference between groups at 6 weeks. Pooled analysis: Significant overall median decline in urine loss on 24 hour pad test (p= 0.07) Authors suggest sufficient evidence to move to larger trial.	Measures at baseline prior to inclusion and 6 and 12 weeks.	Drop outs: Group 1 early intervention n=4 lung infection (1), pain on stimulation (2), non compliance (1) Group 2 delayed intervention n= 5 untreated diabetes (1), urinary tract infection (2), change in drinking habit (1) discontinued after 6 weeks non compliance (kept in analysis) (1) Sample size calculation was n=50, enrollment stopped early as sample size deemed adequate for purpose (pilot)
Scheduled Voiding Regimes							
Burgio 2011 (23)	Combined behavioural treatment (PFME, urge suppression, delayed voiding) vs drug therapy	N=143 men from 2 sites. Randomized using sealed envelopes after stratification for voiding frequency Behaviour treatment n=73 Drug therapy n=70	Men with continued OAB symptoms after treatment with an alpha blocker for prostatic obstruction.	Intervention: 8 weeks (4 clinic visits) combined behavioural treatment composed of elements of bladder training (PFME, urge suppression techniques and delayed voiding). Verbal instruction by	Primary outcome: post treatment 24 hour voiding frequency on 7 day bladder diary. Other OAB symptoms (nocturia, urgency, incontinence) also collected on bladder diary. Secondary outcomes: global	Baseline assessment and measure, post treatment measures.	Intention-to-treat analysis undertaken. Dropouts reported: n=9 in behavioural therapy group, n= 10 in drug therapy group.

Author, year	Comparator	N	Study population	Modality details or parameters	Outcomes/results	Follow up	Notes (side effects, loss of follow up…)
				nurse practitioners, and PFME guided practice using verbal feedback based on anal palpation. Daily practice of 45 exercises (3 sessions of 15 exercises). Also used fluid management. Control: drug therapy with oxybutynin 5-30mg.	perception of improvement and patient satisfaction. Results Frequency: both groups had statistically significant improvement from baseline to after treatment. Equivalence analysis showed post treatment voiding frequency equivalent between behaviour and drug therapy groups ($p< 0.001$) Behaviour therapy group had greater reduction of nocturia episodes, but urgency scores were lower in the drug therapy group. No difference in reduction in incontinence episodes.		

BF – biofeedback; RP – radical prostatectomy; TURP – transuretheral prostatectomy; PFME – pelvic floor muscle exercises; PFMT – Pelvic floor muscle training; PVS – Penile vibratory stimulation; ICIQ-SF – International Consultation on Incontinence Questionnaire Short Form; IPSS – International Prostate Symptom Score

2. PELVIC FLOOR MUSCLE TRAINING (PFMT)

Almost all studies of PFMT in men focused on UI associated with prostate surgery. In the 5thICI, improvement in the quality of trials included was found when compared to earlier reports, although heterogeneity and varying outcome measures continued to affect the ability to compare trial findings. Studies in the first part of this section remain grouped into three types: pre-operative interventions, mixed pre- and post-operatives' studies of all men undergoing prostatectomy and studies of post-operative interventions for men with established incontinence. A total of 20 new RCTs of PFMT alone or combined with other conservative interventions focused on prostate surgery were added to the 38 studies from the previous ICI reports. Nineteen of the new trials involved men pre or post RP (N= 1597 randomized), one trial involved men post TURP (N= 66 randomized). Recommendations are at the end of the section.

2.1. Pre-Operative RP PFMT

Trials in this section compared pre-operative interventions. Three new trials of pre-operative PFMT intervention (313, 314, 320) were identified and added to the two previously included trials. Ocampo-Trujillo (314) compared pre-operative PFMT with BF (n=8) to standard pre-operative teaching (n=8). Laurienzo (313) randomized to three groups, reporting group numbers for only the 49 of 58 men that completed the study: pre-operative PFME plus EStim (n= 17), pre-operative PFME (n=17) and control which received only pre-operative information on prostate anatomy (n=15). Collado-Serra (320) also reported group numbers for those completing (179 or 193) and compared an intervention group receiving pre-operative PFMT plus BF (n=87) to a control group (n=92) receiving only oral PFME instruction post-surgery followed by PFMT plus BF 3 months later.

Quality of data

Ocampo-Trujillo (2013) used a centrally randomised, single blind approach, with researchers blind to the group assignment prior to enrolment. No information on sample size analysis or post hoc power analysis was provided. This was a very small study that was likely underpowered. There were no dropouts from the study. Laurienzo (2013) described randomization using a computer-generated list. Detail of blinding was not provided and a single therapist provided all interventions. There was no report of sample size calculation, post hoc power analysis or intention-to-treat analysis. Nine dropouts were reported, but the group from which they withdrew was not given. Collado Serra (2013) study was available only as an abstract and did not report how participants were randomized or if there was any blinding. There was no information on sample size, and no intention-to-treat analysis reported. Only dropouts from the intervention group (n=5) were described.

Results

Ocampo-Trujillo and colleagues (2013) did not report the results of the 24-hour pad test data but did report that 6/8 (75%) of the intervention group compared to 4/8 (50%) of the control did not require pads at 8 weeks. The authors also report a statistically significant difference in objective measures of muscle tissue from the external sphincter of the urethra favouring the intervention group. As no histology samples were taken prior to the intervention, the claim that the difference is due to the intervention cannot be supported. Subjective report of symptoms reportedly favoured improvement in the intervention group. Laurienzo (2013) reported no differences between intervention and control groups at any time point (1, 3 and 6 months post-surgery) on objective measure of incontinence (one-hour pad test). There were no differences between the two interventions and one control group on subjective report of quality of life. Collado Serra (2013) reported improvement in continence at week 6, month 3, month 6 and 1-year favouring intervention group, but did not clearly define its primary outcome. Significant difference on objective 24-hour pad test was only at 3 months favouring the intervention group.

2.2. Pre-Operative and/or Post-Operative RP PFMT, Post RP Continence Status Not Established Prior to Intervention

Trials in this section addressed the effect of PFMT initiated pre-operatively and/or post-operatively but before post-op continence/incontinence was established. In these studies, men were recruited pre-operatively or immediately post-operatively and the investigators compared a treatment group that received the intervention pre-operatively and/or post-operatively RP to a group receiving an intervention only post-operatively. Nine new studies (305-307, 309, 315, 321, 323, 324, 326) were added to the 10 previously included trials, for a total of 19 trials in the category, over three subsections.

2.2.1 Pre-Operative PFMT Instruction with Post-Operative Home PFMT Versus Control

Four new trials (307, 321, 323, 326) were added to three previously included studies. In the previous consultation, studies varied in support of an earlier return to continence with PFME plus or minus biofeedback. Dijkstra-Eshuis (2015) compared an intervention group that received preo-perative PFMT plus BF with home practice and post-operative home PFME (n=65) to a control group that received written post-operative PFME instruction (n=56). Ghanem (2013), available only in abstract, compared an intervention group with a PFME programme two weeks pre-operatively and continued post-operatively (n=50) to a control group that received only a postoperative PFME programme (n=50). Detail of the PFME programme was not provided. Ng (2014), also only available in abstract, compared an intervention (of PFMT

starting 3 weeks pre-operatively to a control group that received standard care. A total of 66 men participated, but numbers randomized to each group and details of the standard care were not provided. Martini (2011), again in abstract only, described an intervention group (n=24) that received five physiotherapy guided PFMT sessions 2-3 weeks pre-operatively, with continued PFME post-operatively. The control group (n=25) received post-operative written instruction on PFME.

Quality of data

Dijkstra-Eshuis and colleagues (2015) reported adequate random allocation concealment. Participants and therapists were blinded to randomisation until first visit. They also reported results of follow up were send to clinic of the single surgeon performing the RP, but blinding of outcome assessment is not made explicit. Sample size analysis was provided, intention-to-treat was not addressed. Dropouts in both intervention (n=9/65, 13.6% and control groups (n=10/56, 18%) were described. Three studies (321, 323, 326) were available only as abstracts with randomisation, blinding, sample size calculation and dropouts not described.

Results

In all new studies, the primary outcome was continence measured by either the pad test or number of pads used, secondary outcomes were self-report of symptoms and/or quality of life on standardised questionnaires. Dijkstra-Eshuis *et al.* (2015) found no differences between intervention and control at any time points on the primary objective outcome (24-hour pad test) or on secondary self-reported symptom and quality of life measures but the trial was stopped prior to full recruitment after a planned interim analysis showed no demonstrated benefit, with the authors concluding that post RP UI is likely due to intrinsic sphincter injury and not treatable with exercise. Two other studies (321, 326) reported an earlier postoperative return to continence (at 14 weeks and 3 months respectively) favouring the intervention group, but the effect was not demonstrated later time points. Similarly, Martini (2011), who included only men with demonstrated pelvic floor impairment prior to surgery, reported significantly less UI on getting up and squatting (no quantification provided) in the intervention group at 1 month but not at later time points.

2.2.2 Pre-Operative PFMT Instruction Followed by supervised Post-Operative PFMT Versus Post-Operative PFMT

Two new trials (309, 315) were added to the previous four studies in this subsection, making a total of six studies included. Tienforti (2012) randomized 34 men undergoing RP, but reported only on group assignment for those completing the study. The intervention (n=16) was pre-operative and post-operative PFMT with BF, started the day before surgery and continuing monthly, with daily home practice, during follow-up. The control group (n=16) received oral and written instructions post-operatively with no monthly follow-up. Geraerts (2013) compared the intervention (n=91) of PFME plus BF and a home program starting 3 weeks prior to surgery with PFME starting 4 days post-operatively to a control group (n=89) that started PFMT post-operatively. Both groups received weekly post-operative treatment that included BF and bladder diary review, with PFMT continuing until continence achieved.

Quality of data

Tienforti (2012) used a computer-generated randomisation schedule. Information on blinding to group assignment and outcome assessment was not provided. In this small study, no sample size calculation or intention-to-treat was reported. Dropouts in each group, one in each intervention and control (6% from each group) were described. Geraerts (2013) used computer generated randomisation using stratification for age and surgical approach, blinding to group assignment and outcome assessment was not provided. In this large trial, sample size calculation recruited an adequate sample to power the study. Intention-to-treat analysis was not discussed. There were n=6/91 (7%) dropouts in the intervention group, and n=4/89 (5%) in the control, reasons were provided.

Results

The newer studies continue to report variable results. Tienforti (2012) found a significant difference in achieving continence at one, three and six months favouring the intervention group, but this was by self-report of symptoms, with no objective measure of continence included as an outcome. In the Geraerts (2013) study, which was larger and of good quality, there were no differences between the groups with regards to objective duration of UI measured by 24-hour pad test or self-reported symptoms at any time point. The intervention group scored better on impact of incontinence at 3 and 6 months, but not at 12 months follow up.

2.2.3 Post-Operative PFMT Immediately Before or After Catheter Removal (No Pre-Operative Instruction)

Three new trials (305, 306, 324) were found comparing post-operative PFMT immediately before or after catheter removal, bringing the total to six. In the previous consultation, there was considerable heterogeneity in intervention and findings. Ahmed (2012), compared three groups, reporting on group assignment only for those completing the trial. Group 1, the control group (n=26), received PFME post-operatively. Group 2 (intervention, n=26) started PFME plus EStim after catheter removal for 12 weeks, and Group 3 (intervention, n=28) started PFME plus EStim and BF after catheter removal for 12 weeks. Morihoro (2011) was available only in abstract form, and compared an intervention group (n=20) that received PFMT with EStim for one month after catheter removal to a control group (n=14) assigned to PFME

alone. Burkert (2011), using a 2x2 mixed design, randomized patients and their partners to one intervention group (n=28) that received dyadic PFME planning or to 3 control groups (n= 29, 29 and 26) that received dyadic nutrition planning, individual PFME planning or individual nutrition planning.

Quality of data

Morohiro (2011) available only as an abstract, did not describe randomisation, blinding, sample size calculation or dropouts. Ahmed (2012) randomised using computer generated random numbers in sealed envelopes. Surgeons were blinded to randomisation but blinding of the outcomes assessor was not clear. Sample size was met, and dropouts from each group described: control n= 4/26+4 (13%), intervention Group 2 n= 2/26+2 (7%) and intervention Group 3 n=4/28+4 (12.5%). No intention-to-treat analysis was undertaken. In the Burkert (2011) study, research assistants were blinded to allocation. Sample size calculation and intention-to-treat were not discussed. Dropouts for the intervention group n=5/28 (18%) and three control groups (n= 2/29 (7%), 7/29 (24%), 4/26 (15%) were presented but no reasons for withdrawal were provided.

Results

Ahmed (2012) reported more men continent at 12 and 24 weeks post RP in the two intervention groups (PFMT plus EStim and PFMT plus EStim and BF) compared to PFMT alone using the objective 24-hour pad test as primary outcome. Mean leakage was significantly lower in intervention Group 3 at 6 through 24 weeks. Morihoro (2012) found recovery of urinary continence favoured the intervention group (PFMT with EStim) at 12 months. Incontinence was measured by subject report of requiring a pad to keep clothing dry. Burkurt reported only adherence to PFMT with no continence data provided. There were no differences between the groups.

Summary

A total of 9 new trials are now included which apply a variety of pre- or immediately post-operative or post-catheter removal PFMT based interventions (or a combination of both, plus or minus BF and EStim). As in earlier consultations, differences between intervention and control groups were modest and short term, and often reflect self-reported but not objective data such as the pad test. Few differences were sustained up to 12 months post-surgery. Many of the studies reviewed were small, varied in design and quality, and had different outcome measures. The two larger studies that were of better quality (307, 309) found no difference between intervention and control groups. The authors of one of larger study (307) suggested post RP UI is likely often due to a mechanism such as intrinsic sphincter deficiency that is not amenable to exercise based treatment. It is possible that this is true for some men with persistent UI post RP, and they may require surgical rather than conservative intervention. Studies that include evaluation of the extent of sphincter function using imaging techniques would be helpful in understanding the subpopulations where conservative treatments are most helpful. There is modest evidence but inconsistent evidence that therapist delivered PFMT with or without BF or EStim before or after surgery may support an earlier return of continence after RP in some men up to 3-6 months post-surgery, however this difference is not significant at 12 months post-surgery **(Level of Evidence: 2).**

Variation in outcomes measurement remains problematic. As concluded in the previous consultation, it is possible that the emphasis on quantitative outcomes (i.e. pad test) is not meaningful to participants as men appear to find therapy helpful and value the direction provided by a therapist. Studies comparing the effectiveness of pre- versus post-operative PFMT, and the number of sessions required, are needed so that practitioners may advise men about pre-operative preparation and budget conscious health services can make informed decisions on programme funding. In designing such studies, the natural history of UI after radical prostatectomy must be considered because the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols. As well, attempts to identify which men might benefit more, such as in the study by Martini (2011) who focused the intervention on those with identified pelvic floor impairment, need to be undertaken.

Recommendations

Some pre-operative instruction or immediate post-operative instruction in PFMT for men undergoing RP may be helpful in earlier recovery of continence **(Grade of Recommendation: B Clarified).**

Use of BF to assist PFMT should remain a therapist/patient decision based on economics and preference. **(Grade of Recommendation B).**

2.3. Post-Operative RP PFMT for Incontinent Men

Trials in this section addressed the effect of PFMT post-operatively after incontinence was established. In these studies, incontinent men were recruited at variable lengths of time after surgery.

2.3.1 PFMT with Digital Rectal Feedback (DRE) After Radical Prostatectomy

No new trials were identified to add to the previous five trials in which PFMT was taught using digital rectal feedback (DRE) to men incontinent after RP.

Summary

There are no new trials to clarify whether PFMT taught by DRE offers any benefit over and above verbal or written instruction, **(Level of Evidence: 2).**

Recommendations

The recommendation is unchanged **(Grade of Recommendation: B).**

2.3.2 PFMT with BF After Radical Prostatectomy

No new trials were found under this category to add to the six previously included trials.

Recommendations

The use of BF in clinic, over and above home PFMT, should remain a therapist/individual decision based on economics and preference. **(Grade of Recommendation: B).**

2.3.3 PFMT Plus or minus BF with EStim or MStim after Radical Prostatectomy

Three new trials (311, 322, 325) were added to the eight previously included in this section. As in the earlier consultation, a problem of heterogeneity of study samples in this category was noted. Kakihara (2007) compared an intervention of physiotherapy lead PFMT with EStim (n=10) to PFMT alone (n=10) in men a minimum 6 months post-surgery (mean 12.3 months for intervention group, 16.8 months for control). Pedriali (2014) recruited incontinent men one-month post RP and assigned them to post-operative pilates (n=26) versus PFMT plus EStim (n=28), but reported group assignment in only the 54/69 (78%) of men completing the study Laurienzo (2015), available only in abstract, also included men incontinent one-month post RP, randomising to three groups: Group 1 control (no treatment) (n=40), Group 2 PFMT (n=41) and Group 3 PFMT plus EStim (n=42).

Quality of data

Kakihara (2007) did not provide information on randomisation or blinding. No sample size calculation was given. Dropout numbers for each group were given, but the reasons for dropping out of the intervention group were not provided. Three participants were discharged from the control group at 3, 6 and 12 months as continence was achieved and were included in the final analysis. Pedriali (2014), available only as an abstract, did not provide details of randomisation, blinding, sample size calculation or dropouts. Laurienzo (2015) was only available in abstract, but did describe randomisation approach, but not blinding, sample size calculation or dropouts.

Results

In the Kakihara (2007) trial, there was improvement in urine loss on 1-hour pad test in both groups between baseline and 12 months, but no difference in men receiving PFMT with EStim compared to those who received only PFMT. Men had undergone urodynamic testing, and both those with UUI and SUI were included. Pedriali (2014) reported 58% of the Pilates group and 50% of the EStim plus PFME achieved continence, as measured by use of no pads. The difference was not statistically significant and the authors concluded that Pilates, which includes pelvic floor strengthening, is as efficacious as EStim plus PFME. Laurienzo (2015) reported no differences between controls and two intervention groups (PFMT, PFMT with EStim) at any time points, objective pad test results not provided, subjective reports of quality of life and symptoms only.

Summary

Data suggest no further benefit of EStim when added to PFMT over PFMT alone for men with incontinence post RP **(Level of Evidence: 2).**

Recommendations

There does not appear to be any benefit of adding EStim to a PFMT programme for men with persistent post-prostatectomy incontinence. **(Grade of Recommendation: B)**.

2.3.4 PFMT Compared to or Plus Other Interventions After Radical Prostatectomy

Four new trials (312, 316, 318, 319) were identified that combined PFMT post-operatively with other novel interventions in men with post prostatectomy incontinence, adding to the two previously included studies. The previous consultation found variation in intervention and time since surgery. Zopf (2015) recruited men 6-12 weeks post RP, and assigned them to either an intervention of a multimodel exercise programme with PFME (n=50) or a control group that received no intervention (n=20). Serda (2014), using a two group design, randomised men post RP to a combined exercise and PFME intervention group (n=36) or control with no intervention (n=33). Time after surgery was not reported. Kongtragul (2014) randomised 138 incontinent men recruited in hospital after RP. Group assignment was reported only for those completing the study; 68 men were in the intervention group with PFME and concentration therapy (no detail provided) starting 3 weeks post-surgery. The control group (n=67) received only PFME. Baroni (2013) was available only in abstract. Men with SUI or mixed UI after RP (time after surgery not reported) were assigned to an intervention of individual PFMT and group treatment (n= 16). Controls (n=24) received only individual PFMT.

Quality of data

The Zopf (2015) study had intended to randomise those who consented, but as all participants refused randomisation and gave a group preference, blinding of outcome measurement was not described. The authors indicated intention–to-treat analysis was undertaken but the study did not achieve the calculated

sample size and was thus underpowered. Dropouts from the intervention group only (n=6/50 12%) were described, but reasons were not provided. Serda (2014) randomised participants but did describe how this was done. Blinding to outcome assessment was not reported. Calculated sample size was achieved, number of dropouts (intervention group (n=3/36 8%; control 0/33) and reason for withdrawal was provided. Baroni (2013) was available only in abstract and had no detail on randomisation but reported the assessor was blinded until assignment. Sample size calculation and dropouts were not described. Kongtragul (2014) did not describe the approach to randomisation or blinding, but dropouts (intervention n=1/68+1, 1%; control n=2/67+2, 3%) were described. The study did not achieve the number in each group required for power to detect a difference between groups.

Results

Zopf (2015) reported a significant improvement in UI, as measured by the 20-minute pad test, from baseline to post testing, but no significant difference between intervention (exercise plus PFMT) and controls (no intervention). However, a significant difference between the groups on reported urinary symptoms was found. Serda (2014) reported a significant improvement in favour of the intervention group (combined exercise and PFME) on self-report of the intensity of urinary symptoms, but did not report the results of the 20-minute pad test. Baroni (2013) reported no significant difference between intervention and control on the VAS, number of pads used or home practice. In the study of concentration exercises plus PFME (Kongtragul 2014), significant differences were found between intervention and control groups on achieving continence measured by the 1-hour pad test.

Summary

Interventions were varied: general exercise plus PFME (316, 318) PFME with concentration therapy (not defined by author) (312) and individual PFMT compared to individual and group therapy (319). There was also heterogeneity of samples in terms of time since surgery. There is some early evidence that novel interventions, such as general exercise programmes, use of support groups and concentration exercises added to PFME after RP for incontinent men may be beneficial, but this is very limited. Some of the trials are small and of low quality. Larger studies of high quality are needed to determine the benefits of these adjuncts to PFME.

2.4. Pre-Operative TURP PFMT

No new trials were identified. Little research has been dedicated to UI after TURP as the incidence of UI after TURP is reported to be very low.

2.5. Pre-Operative and/or Post-Operative TURP PFMT

No new trials were identified.

Summary

In the absence of sufficient data from rigorous and well-reported trials it is not known if PFMT reduces UI following TURP. More systematic investigation of the natural history of UI after TURP is probably needed, to establish the potential cost/benefit of intervention, before further trials are initiated.

2.6. Post-Operative TURP PFMT for Incontinent Men

One new study (310) was added. The previous consultation reported limited evidence in this area. The larger well designed study previously included showed no benefit in terms of objective measures of incontinence. Hou (2013) reported group assignment only for those completing the study. The intervention group (n=32) was given instruction in PFME two days after surgery when the catheter was removed, and instructed to practice daily at home, with weekly telephone reminders. The control group (n=29) activity was not described.

Quality of data

Approach to randomisation, blinding, sample size calculation and dropouts in the smaller, newly included trial (Hou 2013) were not described.

Results

Hou (2013) found a statistically significant difference in self-report of symptom severity favouring the intervention group at 12 weeks. No objective measure of incontinence, such as the pad test, was reported.

Summary

There continues to be limited evidence on the benefit of PFME post TURP. The new smaller trial suggests a potential benefit on perception of symptom severity of UI, but no objective data were reported.

2.7. Factors Affecting Outcome

Based on the current evidence, it appears that time from surgery to implementation of exercises does affect outcome and that by three months after surgery less improvement is noted. Future trials should consider analysis to evaluate the effect of sphincter insufficiency, pelvic floor dysfunction, urethral length, length of time from prostatectomy, co-morbid conditions, prior pelvic surgery, medications, other risk factors (including smoking and alcohol use) on treatment outcome.

2.8. PFMT for Other LUTS

2.8.1 PFMT for Post-Micturition Dribble (PMD)

No new trials were identified to add to the two previously included trials.

Recommendations

Offer men with PMD instruction to do a strong PFM contraction immediately after voiding, or urethral massage to empty the urethra **(Grade of Recommendation: C).**

3. ELECTRICAL STIMULATION (ESTIM)

An extensive overview of EStim in men is reported in the 5th consultation(2). Rectal or surface electrodes are most common; surface electrodes are positioned over the perineal region. EStim can also be applied via the posterior tibialis nerve (PTN). Trials of EStim in men post-prostatectomy combined this treatment with PFME, and are included in the sections on post-prostatectomy treatment above.

3.1. Prevention of UI

No new trials were identified**.** There remain no studies on the effect of EStim for prevention of non-post prostatectomy UUI or SUI in men.

3.2. Treatment of UI

No new trials were added to the nine previously included RCTs, four of which included PFME plus EStim post prostatectomy. New trials that combined EStim with PFME were reported in the PFMT section above as the separate effects of EStim alone cannot be assessed.

3.2.1 Is EStim Better than No Treatment, Placebo or Control Treatments?

No new trials were identified to add to the two previously included trials. Both previously included trials did not separate male and female results. In the continued absence of sufficient data from rigorous and well-reported trials it is not known if EStim, as a standalone treatment for male UUI or SUI, is better than no treatment, placebo or control treatments.

3.2.2 Is One Approach to EStim Better Than Another?

No new trial was identified. No studies comparing EStim protocols were included in previous consultations.

3.2.3 Is EStim Better Than Other Treatments?

No new trials were identified. Three studies, two comparing EStim to Mstim and one EStim to medication, had been included in previous consultations. Details of these were provided in the 5th consultation (Moore 2013): insufficient data exist to establish if EStim is better than either intervention. Both studies combined male and female data.

3.2.4 Does the Addition of EStim to Other Treatments Add Benefit?

All of the studies combining EStim with other treatments included the PFMT plus EStim combination, and are reviewed under the Pelvic Floor Muscle Training section.

3.3. Other LUTS

No new studies were identified. No previous studies of EStim alone for other LUTS were included in previous consultations.

3.4. Factors Affecting Outcome

The previous consultation identified age, type of incontinence (SUI post prostatectomy versus OAB and UUI) and other factors (types of electrodes, frequency and duration of treatment) as potentially affecting outcomes. No trials have investigated these factors in males.

4. MAGNETIC STIMULATION (MSTIM)

Although MStim has been used to treat UI after RP and to inhibit DO, no new studies were identified.

4.1. Prevention of UI

No trials investigating the primary or secondary prevention effects of MStim for men with UI were found.

4.2. Treatment of UI

No new trials to add to the three trials (two published, one abstract without data) identified and described in the 5th consultation were found. Only the two published trials were included in the previous consultation.

4.2.1 Is MStim Better Than No Treatment, Placebo or Control Treatment?

No studies were found addressing this question.

4.2.2 Is One Approach to MStim Better Than Another?

No studies were found addressing this question.

4.2.3 Is MStim Better Than Other Treatments?

No new studies were identified.

4.3. Other LUTS

No studies were found.

4.4. Factors Affecting Outcome

The relationship between age (or any other factor, such as treatment parameters, treatment adherence, or diagnosis) and the outcome of MStim has yet to be determined.

5. PENILE VIBRATORY STIMULATION (PVS)

This is a novel conservative treatment, based on the stimulation of the pudendal nerve via penile vibratory stimulation (PVS) to treat SUI in men post prostatectomy.

PVS has been shown to increase external sphincter pressure in men with spinal cord injury (334, 335), and vibratory stimulation applied to the perineum in healthy women also increased external urethral pressure (336).

5.1. Prevention of UI

No trials of prevention were identified**.**

5.2. Treatment of UI

One new trial was identified (308). Fode (2015) randomised 39 men with UI over one-year post RP to two groups. Group 1 (n= 19) was the early intervention group who received PVS using a commercially available hand held personal vibrator for 6 weeks. Stimulation was performed on the ventral surface of the penis once daily with 10 seconds of stimulation followed by a ten second pause, repeated 10 times. Group 2 was the delayed treatment control group, who had no intervention the first 6 weeks, but performed PVS in the second 6 weeks.

Quality of data

Computer generated randomisation technique was described, but blinding of outcome measurement was not (308). A sample size calculation was provided, but the authors report stopping recruitment early as the study was a pilot and the sample achieved was thought to be adequate. Drop outs in both early (n=4/19, 21%) and delayed (n=5/20, 25%) intervention groups were described, with one of five dropouts in the delayed intervention group kept in the analysis, although others were not. The participant kept in had a pattern of non-compliance over the study, and discontinued after 6 weeks.

Results

Primary outcome was difference in leakage measured by 24 pad test. Participants also completed voiding diary. Results showed a significant improvement in the early intervention group from baseline to 6 weeks, but not in the delayed intervention group. Pooled analysis results from both early and delayed intervention groups showed significant overall median decline in urine loss on 24-hour pad test (p= 0.07).

Conclusion

This was a small pilot study of a novel intervention. Further well designed studies are needed to understand the place for PVS in treatment of male UI. No recommendation can be made.

5.3. Other LUTS

No trials were identified.

6. SCHEDULED VOIDING REGIMENS

Scheduled voiding regimens include bladder training, timed voiding, habit training and prompted voiding. They are frequently combined to achieve maximum benefits. Although there is evidence to suggest that scheduled voiding regimens, especially bladder training and timed voiding, are commonly used in the treatment of men with UI and other LUTS, there has been substantially less research that addresses their use in men compared to the literature on their use in women, leaving insufficient evidence to comment on effectiveness.

6.1. Prevention of UI

No trials investigating the preventive effects of scheduled voiding regimens for men with UI were found.

6.2. Treatment of UI

6.2.1 Bladder Training

One new trial of a mixed behavioural treatment approach composed of elements of bladder training compared to drug therapy in men with OAB was identified (317) and added to the five previously included trials of bladder training that have included men. Burgio (2011) compared a combined behavioural treatment (PFME, urgency suppression, delayed voiding) to drug therapy (n=73) with drug therapy (individually titrated extended release oxybutynin) for OAB (n = 70. This category previously included studies that have included BT plus caffeine reduction, BT plus placebo or anticholinergic drug therapy

Quality of data

Burgio and colleagues (2011) used sealed envelopes to randomise, blinding of person(s) gathering data on outcomes was not described. Sample size analysis was not given, but intention-to-treat analysis was undertaken. Dropouts from each group (combined behavioural therapy n=9/73, 12%; drug therapy n=10/70, 14%) were reported, reasons were not provided.

Results

Primary outcome was 24-hour voiding frequency recorded on a seven-day bladder diary. Secondary outcomes were other OAB symptoms, perception of improvement and satisfaction.

Results showed that treatment with behavioural strategies (bladder training) compared to pharmacological

treatment was equivalent. There was no significant difference between incontinence episodes between the behaviour and drug therapy groups.

6.2.2 Timed Voiding

No new trials were identified.

6.3. Other LUTS

One new study was identified for treatment of other LUTS in men. The newly included study, described above (317) also measured OAB symptoms, with the primary outcome being frequency of voiding.

Quality of data

Refer to C.VI.2a above.

Results

Primary outcome was 24-hour voiding frequency recorded on a seven-day bladder diary. Secondary outcomes were other (non UUI) OAB symptoms including nocturia and urinary urgency; perception of improvement and satisfaction. Treatment with behavioural strategies (bladder training) compared to pharmacological treatment was equivalent. The behaviour therapy group had greater reduction in nocturia episodes, but urgency scores were lower in the drug therapy group.

Summary

In men, behavioural treatment may be just as effective for some LUTS, including UI, as pharmacological therapy. Further studies of high quality are needed before a recommendation for practice can be supported.

6.4. Factors Affecting Outcome

Age: No new trials were found addressing age as a factor affecting outcome.

Other: No studies were identified on other factors affecting outcome of BT or prompted voiding in men.

7. COMPLEMENTARY AND ALTERNATIVE MEDICINES

Therapies include acupuncture, relaxation, meditation, imagery, hypnosis, naturopathic and herbal remedies. In previous consultations, only trials of acupuncture therapy were found in men with UI. Studies were small, objective measured of UI were missing and long-term follow-up was lacking, leaving only limited evidence on the effectiveness of acupuncture for men with UI.

7.1. Prevention of UI

No new trials were identified on the preventative role of complementary therapies in men.

7.2. Treatment UI

No new trials were identified.

7.2.1 What Is the Most Effective Acupuncture Protocol?

No new trials were identified.

7.2.2 Acupuncture Versus No Treatment, Sham Acupuncture or Any Other Treatment

No new trials were identified.

7.3. Other LUTS

No new trials were identified.

7.4. Factors Affecting Outcome

No new trials were identified.

8. SUMMARY

Despite the prevalence of UI and LUTS in older men, research continues to focus mainly on men following radical prostatectomy. Overall, the effect of conservative treatment (lifestyle interventions, physical therapies, schedule voiding regimes, complementary therapies) for men has received much less research attention compared to women.

8.1. Recommendations for Practice

There is generally insufficient **Level 1 or 2 evidence** on which to base recommendations for practice, and most recommendations are, in effect hypotheses, that need further testing in research.

Lifestyle interventions

Weight loss through lifestyle changes should be recommended to obese and overweight men with UI, particularly those with type 2 diabetes. **(Grade of Recommendation: Grade B New)**

Smoking abstinence should be recommended for men with UI **(Grade of Recommendation: C New)**

A reduction in caffeine intake is recommended for those with incontinence symptoms. **(Grade of Recommendation: C New)**

Pelvic floor muscle training (PFMT)

- Some pre-operative or immediate post-operative instruction in PFMT for men undergoing radical prostatectomy may be helpful in earlier recovery of continence. **(Grade of Recommendation: B Clarified).**
- In men with persistent post-prostatectomy incontinence, PFMT taught by digital rectal examination (DRE) may be undertaken but it is unclear whether this offers any benefit over and above verbal or written instruction in PFMT **(Grade of Recommendation: B Clarified).**
- Use of BF in clinic, over and above home PFMT should remain a therapist/patient decision based

on economics and preference **(Grade of Recommendation: B).**

- There does not appear to be any benefit of adding EStim to a PFMT programme for men with persistent post-prostatectomy incontinence **(Grade of Recommendation: B).**
- Use of a strong pelvic floor muscle contraction immediately after voiding, or urethral massage to empty the urethra, should be offered for symptoms of post-micturition dribble **(Grade of Recommendation: C).**

Electrical Stimulation (EStim)

For men with persistent post-prostatectomy incontinence there does not appear to be any benefit of adding EStim to a PFMT programme **(Grade of Recommendation: B).**

8.2. Future Research Directions

Despite recognition that there is much scope for research on the effects of conservative therapies for UI and LUTS in men in the 6th consultation, this remains largely unexplored. Research that is urgently needed, in the opinion of committee members, is highlighted with the use of italics. The committee continues to support the recommendations that apply to all future studies in men, namely:

- All future intervention studies must be designed to allow standardised and comprehensive reporting of results based on the ICS and CONSORT recommendations.
- The natural history of UI after radical prostatectomy must be considered in study design as the spontaneous recovery rate means that sample sizes must be large to detect any differences between protocols.
- More research is needed to find out what are the most important outcomes for men with UI, so such measures can be incorporated as the primary outcome measures in further trials.
- Data is needed to establish to the cost, and cost effectiveness, of conservative therapies in men with UI.
- Surgical approaches with laparoscopy or robotics offer promising improvements in visualisation for nerve-sparing procedures; further research should address continence and erectile function after these newer surgical procedures.

8.2.1 Lifestyle Interventions

- The effects of interventions such as weight, caffeine reduction, constipation and physical activity are priorities for future research.

8.2.2 Pelvic Floor Muscle Training (PFMT)

- Further studies to test the hypothesis that preoperative proprioceptive training plus PFMT is more effective than PFMT alone to prevent UI in men undergoing radical prostatectomy.
- A comparison of pre-operative versus post-operative PFMT verbal and written feedback to reduce prevalence and severity of UI following radical prostatectomy is needed.
- Methods of PFMT instruction and supervision require further investigation. Two areas of research interest are:
  - Whether PFMT taught by DRE offers any benefit over and above verbal or written instruction.
  - The effect of group exercise as peer support may be helpful to a healthy recovery.
- Future studies should focus on identification of men more likely to benefit from conservative interventions, such as those with pelvic floor dysfunction, and screening those with potential intrinsic sphincter deficiency post-surgery. This might be established using imaging. Men with extensive sphincter deficiency should be referred for urological intervention. Studies of conservative measures including PFMT should include those with milder damage in order to determine efficacy in this group.
- More systematic investigation of the natural history of UI after TURP is needed, to establish the potential cost/benefit of intervention, before further trials are initiated.
- The relationship between age, or any other factor (urethral length, PFM function), and the outcome of PFMT for UI in men, and predictors of success needs to be investigated.

8.2.3 Electrical Stimulation (EStim) and Magnetic Stimulation (MStim)

- It is not known if pre- or post-operative EStim or MStim has a role in reducing UI after radical prostatectomy.
- RCTs in larger samples, with long-term follow up, are needed to investigate all aspects of the effectiveness of EStim and MStim as a treatment for UI in men, including:
  - Either type of stimulation versus no treatment, sham stimulation or other control conditions.
  - Comparisons of both EStim and MStim protocols.
  - EStim versus MStim.
  - Either type of stimulation versus medication.
  - Whether the addition of either type of stimulation to other treatments adds benefit, in particular, the addition of stimulation to PFMT.

- The effect of age, and other factors, on outcome of stimulation. Older men may have more co-morbid conditions than young men and a more pragmatic ap-proach to inclusion in EStim studies is needed.

8.2.4 Scheduled Voiding Regimens

- RCTs of voiding regimens and combinations of conservative treatments in men with OAB and UUI are needed. Further comparison of these conservative approaches to drug therapy would be helpful for clinicians in recommending treatment to patients.

V. URINARY INCONTINENCE IN MEN AND WOMEN

1. POSTERIOR TIBIAL NERVE STIMULATION (PTNS)

Posterior tibial nerve stimulation (PTNS) is a form of peripheral neuromodulation targeted towards symptom relief of OAB and UUI (141). Evidence for the use of PTNS for the prevention and treatment of UI in men or in adults (study with men and women with results combined) is presented below.

Questions addressed are:

- Can PTNS prevent UI?
- Is PTNS better than no treatment, placebo or control treatments for UI?
- Is PTNS better than other treatments for UI?
- Does the addition of PTNS to other treatments add any benefit?
- What is the best programme of PTNS for UI in adults?
- What is the effect of PTNS on LUTS other than UI?
- What factors might affect the outcome of PTNS?

A literature search for reports of relevant systematic reviews and reports of RCTs and quasi-RCTs was performed (see section I). Trial data reported in conference abstracts as well as full text papers were included. Since this is a new section for the Conservative Management chapter no date restrictions were applied.

Eligibility criteria:

1. Reports of RCTs or quasi-randomised trials of PTNS, percutaneous or transcutaneous.
2. Adult men and women with UI and/or OAB (with or without urgency incontinence) presentation of data for men only or combined for men and women. Trials including women only are presented in section II.5.

Evidence overview

A total of 7 RCTs of posterior tibial nerve stimulation (PTNS) in adults were identified (337-343) and one Cochrane systematic review of anticholinergic drugs versus non-drug active therapies for non-neurogenic overactive bladder syndrome in adults (141), in which PTNS trials with adults of both sexes and men only were included. Only one randomised trial of PTNS in men has been reported (344), which addressed post–stroke neurogenic bladder dysfunction and therefore did not meet the inclusion criteria for the conservative management chapter. No trials of non-neurogenic bladder dysfunction have been reported for men only.

The trial data is summarised in tables 35 to 38.

Three randomised trials compared PTNS with a sham intervention (337-339).

Four trials were comparative:

- Two compared different anticholinergics (340, 341)
- Two compared different stimulation protocols (342, 343)

Percutaneous PTNS was used in 5 randomised trials (337, 339-342)

Transcutaneous PTNS was used in 2 (338, 343).

No direct comparisons of percutaneous and transcutaneous PTNS for treatment of UI have been undertaken in the adult population or in men only.

On the basis of the included studies, percutaneous PTNS seems to involve a standard protocol with regard to stimulation parameters of frequency and session-duration using the Urgent PC^{TM} stimulator. However, the number of individual sessions, overall duration of programme and timing of delivery protocols may vary. There is also variation between percutaneous and transcutaneous stimulation parameters and one transcutaneous device study (343) did not report stimulation parameters, preventing comparison with other results. This variability reflects the limited understanding of the mechanisms of PTNS, which cannot be assumed to be identical for both percutaneous and transcutaneous routes. Further investigation is required for both percutaneous and transcutaneous PTNS to determine the most effective type of stimulation and treatment protocols.

1.1. Prevention of UI

There have been no studies on the effect of PTNS for prevention of UUI/OAB in adults or in men only.

1.2. Treatment of UI

1.2.1 Is PTNS Better Than No Treatment, Placebo or Control Treatments for UI?

Three randomised controlled trials address this question in adult men and women. One RCT (337) is adequately powered whereas Vohra (339) and Booth (338) are both pilot RCTs.

Quality of evidence

Computerised randomisation was used in all three studies with adequate allocation concealment reported in two (337, 338) and unclear in one (339). Subjects and outcome assessors were blinded throughout in two studies (337, 338), with blinding unclear in one(339). Two studies reported intention-to-treat analysis (337, 338); the type of analysis was not reported in one (339). There was no apparent inequality in loss to follow-up across the groups: in one trial (345) seven subjects were lost to follow-up in the PTNS and 5 in the sham group thus 94% and 95% respectively were analysed. Two of the 30 subjects (6.6%), both from the sham group, discontinued in one trial (338) and one subject (4.5%) from the control group discontinued in the other trial (339). Mild or moderate treatment related adverse events were reported by 6 PTNS subjects in one trial (337). They included ankle bruising (1 of 110, 0.9%) discomfort at needle site (2 of 110, 1.8%) bleeding at the needle site (3 of 110, 2.7%) and tingling in the leg (1 of 110, 0.9%). No subjects in the transcutaneous PTNS trial (338) reported adverse events and presence of adverse events was unclear in one study(339). Two trials were reported as pilots with no sample size calculation (338, 339) and one was adequately powered (337) however the payment of subjects for time and expense was a potential limitation and the efficacy achieved may not be equivalently reflected in translating to real world practice. Long term follow-up to 3 years post-initial treatment was reported by Peters (345). Overall risk of bias was low in two trials (337, 338) and high in one (339).

Results

No study reported cure rates for UI, however all three trials reported improvements. In the SUmiT trial(337) 37.9% PTNS subjects reported moderate or markedly improved urgency incontinence compared to 22.1% sham subjects (p=0.02). Voiding diary analysis showed PTNS to be statistically superior to sham in reducing urge incontinence episodes (p=0.002) from a median of 3.0 episodes accompanied by moderate to severe urgency per day at baseline, to a median of 0.3 episodes at 13 weeks (p<0.0001). In the two pilot trials Booth (338) reported improved ICIQ-UI SF in 10 of 15 (67%) transcutaneous PTNS group and 6 of 13 (46%) sham group (p=0.132, NS); Vohra reported significantly reduced UI in 7 of 11 PTNS subjects but no estimates of effect size were provided; data was not differentiated for men and women. In one large trial (337) PTNS subjects reported statistically significant improvements in overall bladder symptoms with 54.5% reporting moderate or markedly improved Global Response Assessment (GRA) from baseline compared to 20.9% of sham subjects (p<0.001). A significant difference between the groups in favour of PTNS was found for the OAB-q quality of life scores (p=0.006) and the SF-36 general health survey quality of life scores significantly improved between baseline and 13 weeks for the PTNS group in the physical (p=0.002) and mental (p=0.049) domain scales. One pilot trial (339) reported significant improvements in quality of life (QoL questionnaires not specified and SF-36) but provided no data or figures to support this.

A prospective study to assess long-term outcomes and determine frequency of top-up stimulation sessions required was reported (345). Fifty responders to the original trial underwent a fixed 14-week tapered stimulation protocol, followed by a personal treatment plan aimed at maintaining improvements. Twenty-nine of 50 (58%) completed the outcomes. 77% of these maintained moderate or marked improvement in OAB symptoms at three years with a median 1.1 treatments each month.

Summary

The results of two trials, one rigorous, well-reported trial and one low quality pilot trial, showed that percutaneous PTNS is a safe and more effective intervention than a sham treatment for improving urgency incontinence in adults with OAB/UUI.

There is evidence that, with regular treatment, effects are sustained for up to 3 years. **(Level of Evidence: 1).**

One small high quality pilot trial indicates that transcutaneous PTNS is safe and may be more effective than sham stimulation for reducing UI and urinary symptoms in older adults in institutional care. Further studies are needed to determine the effectiveness of transcutaneous PTNS. **(Level of Evidence: 2)**.

Recommendation

Percutaneous PTNS can be offered to men and women (adults) with UUI/OAB who do not achieve satisfactory results from first line lifestyle and behavioural intervention and pharmacological therapy. **(Grade of Recommendation: B New).**

In this population, Transcutaneous PTNS may be a useful option to test in the adult with UUI/OAB earlier in the algorithm, following lifestyle and behavioural interventions and before more invasive therapies are considered.

1.2.2 Is PTNS Better Than Other Treatments for UI?

One RCT compared PTNS with another treatment for UI. The other treatment was extended release tolterodine 4mg daily (341). There are no trials comparing transcutaneous PTNS with other treatments.

Quality of evidence

1:1 randomisation to percutaneous PTNS or tolterodine was implemented using a random block design stratified by investigational site however the success of allocation concealment was unclear. Blinding of subjects, clinicians or assessors was not possible given the different nature of the interventions. An intention to treat analysis was not undertaken. Seven subjects (14%) withdrew from the drug group and 9 (18%) from the percutaneous PTNS group; none due to adverse effects. Adverse effects were mild or moderate in both groups with 14.3% (7 subjects) from the tolterodine arm reporting moderate adverse effects and 16.3% (8 subjects) from the percutaneous PTNS group. Percutaneous PTNS related adverse events included leg cramps, intermittent foot/toe pain, generalised swelling, headache, haematuria, inability to tolerate stimulation, worsening incontinence and vasovagal response to needle placement. A sample size calculation was provided and the study was adequately powered for a non-inferiority margin of 20% in number of voids per 24 hours. Long-term follow-up of percutaneous PTNS subjects for nine months after initial treatment completion was reported (346). The overall risk of bias was high.

Results

Data was reported for the whole group with no differentiation by sex. The global response assessment (GRA) demonstrated that subjective assessment of bladder symptom change compared to baseline was statistically significant with 79.5% (35) of the percutaneous PTNS group reporting cure (1) or improvement (34) and 54.8% (23) of the tolterodine group reporting cure (2) or improvement (21) (p=0.01). Both groups had improved significantly. Symptoms of UUI reported in the voiding diaries improved significantly in both groups however there was no significant difference between the groups for these measures. Quality of life scores showed statistically significant improvements for both treatment groups (P<0.001) but between group differences were not statistically significant. The percutaneous PTNS group reported statistically significantly less dry mouth than the tolterodine group (p=0.01) and a non-significant lower rate of constipation.

Follow-up to determine duration of effect up to 12 months from baseline was offered to percutaneous PTNS responders (those who reported a successful response to GRA after 12 weeks) (346). Thirty-three of the 35 responders chose to continue. The GRA showed sustained improvements in 96% at 12 months with a mean of 21 days between treatment sessions.

Summary

Evidence from a single RCT indicates that percutaneous PTNS may be as effective as tolterodine for urgency UI with an improved side effect profile; however, design limitations suggest caution and further studies are recommended to establish the effects of percutaneous PTNS and transcutaneous PTNS in comparison to other pharmacological treatments **(Level of Evidence: 2).**

As there were no trials comparing transcutaneous PTNS with another active treatment trials are also needed to determine the effects of transcutaneous PTNS compared to common anticholinergic drugs used to treat UUI/OAB in adults.

Recommendation

Percutaneous PTNS can be offered as an alternative to tolterodine for OAB/UUI in adult men and women. **(Grade of Recommendation: B New).**

1.2.3 Does the Addition of PTNS to Other UI Treatment Add Any Benefit?

One RCT was identified (340) that compared percutaneous PTNS with percutaneous PTNS and oxybutynin for treatment of patients with overactive bladder (with or without incontinence) and urodynamically diagnosed detrusor overactivity (DO).

Quality of evidence

Randomisation following urodynamic studies into percutaneous PTNS group or percutaneous PTNS plus 5mg daily oxybutynin hydrochloride was reported but no description of method of randomisation. Adequacy of allocation concealment and blinding of subjects, clinicians or assessors was not reported nor was type of analysis, which was unclear. It appears that no subject dropped out and reported adverse events were mild: percutaneous PTNS plus drug group - seven reported dry mouth, one blurred vision; percutaneous PTNS group – one reported a small haematoma, one local tenderness. There was no sample size calculation, no long-term follow-up and overall risk of bias was high.

Results

Four of five subjects receiving percutaneous PTNS only and all five subjects receiving percutaneous PTNS and oxybutynin, with urgency UI reported cure on voiding diary. The numbers were too small for statistical analysis. Overall treatment response was defined as patient-reported improvement in OAB symptoms of frequency, urgency and urge incontinence by > 35% and occurred in 61.6% percutaneous PTNS group and 83.2% percutaneous PTNS plus oxybutynin group. The between group difference was not statistically significant.

Summary

The evidence is limited to a single low quality trial **(Level of Evidence: 2)** which indicates there may be additional effects if oxybutynin is added to a programme of percutaneous PTNS. Further trials are needed to establish whether the addition of an anticholinergic drug enhances the effectiveness of percutaneous PTNS in adults with UUI/OAB and which drugs provide the greatest effect.

As there were no trials comparing transcutaneous PTNS added to another active treatment with the active treatment alone studies are also needed to determine the effects of adding transcutaneous PTNS to first line lifestyle and behavioural treatments for OAB and UUI including bladder training and percutaneous PFMT, with these first line lifestyle and behavioural treatments alone.

Recommendation

Oxybutynin may be considered in addition to percutaneous PTNS in adults with DO. **(Grade of Recommendation: B New).**

This hypothesis needs to be investigated further with high quality trials

1.2.4 What is the Best PTNS Protocol for UI in Adults?

Two RCTs compared different stimulation protocols (342, 343). Details are provided in table 38.

Quality of the evidence

Randomisation methods were not described for either study. Allocation concealment could not be determined from the reports and blinding of subjects or clinicians was not possible with this design. Neither study reported the type of analysis undertaken. Primary outcomes were reported at the end of the (342) treatment protocol. No long-term follow up was reported. Withdrawals were high (29.2 %) in the Seth (343) pilot trial, with 8 of the 14 withdrawals being device related, although no significant adverse events occurred. There were no withdrawals in the Finazzi-Agro trial and no adverse events reported.

Results

In the Finazzi-Agro (342) trial 4 of 11 (36%) subjects with UI in the weekly percutaneous PTNS group and 5 of 11 (45%) subjects with UI in the 3 X weekly percutaneous PTNS group reported complete cure after treatment. Overall success of >50% reduction in micturition episodes/24 hours or (if incontinent) UI episodes/24 hours was confirmed for 11 of 17 (63%) subjects in the weekly percutaneous PTNS group and 12 of 18 (67%) subjects in the 3 times weekly percutaneous PTNS group. Subjective improvement was reported after 6-8 sessions, regardless of frequency of delivery. In the Seth (343) trial 18 of 34 (54%) subjects who completed the 12week protocol were responders, who rated their improvement as moderate to significant on the General Response Assessment (GRA). Statistically significant improvements in ICIQ-OAB (p=0.001) and ICIQ LUTSqol (p=0.000) were reported for both daily and weekly stimulation groups. There were no statistically significant differences in ICIQ or bladder diary parameters between those with idiopathic and OAB of neurogenic origin.

Summary

Two small trials indicate that no additional benefit is conferred by a more than once weekly stimulation protocol for percutaneous or transcutaneous PTNS. However, it is possible that symptom improvement may be more rapid with a more frequent delivery protocol **(Level of Evidence: 2**).

Further rigorous and well-reported trials are needed to establish the most effective timing and duration of PTNS protocols.

Recommendation

Percutaneous or transcutaneous PTNS should be delivered at least once weekly and the protocol determined by patient preference. **(Grade of Recommendation: B New).**

1.3. What is the Effect of PTNS on LUTS Other Than UI?

No trials were identified that analysed the effect of PTNS in adults or men with other LUTS alone i.e. frequency of voiding, urgency, nocturia and integrated reporting of UI and other LUTS was a feature of all studies. For percutaneous PTNS compared with sham percutaneous PTNS, in one large well reported trial, the percutaneous PTNS group reported statistically significant improvements in voiding diary symptoms of frequency, night-time voids and voids with moderate to severe urgency, compared to the sham group (337). A small pilot trial reported reduced day and night time frequency and urgency after 12 weekly 30 minute percutaneous PTNS sessions by 63% of percutaneous PTNS subjects, although no EStimates of effect size were provided. The elimination of detrusor overactivity on repeat urodynamic testing was also shown (339).

For transcutaneous PTNS compared with sham transcutaneous PTNS one trial in care home residents (338) reported statistically significantly improved total American Urological Association Symptom Index AUASI urinary symptom scores for 87% of the transcutaneous PTNS group compared to 31% sham group ($p<0.001$).

When comparing percutaneous PTNS with another treatment one trial (341) reported significant reduction in bladder diary reports of void frequency, nocturia, moderate to severe urgency episodes in both groups and no between group differences.

One trial comparing two percutaneous PTNS protocols (342) reported a statistically significant reduction in frequency ($p=0.01$) for both once and three times weekly treatment regimes.

1.4. Factors Affecting Outcomes

None of the included percutaneous PTNS trials addressed the effect of age or any other factor on prediction of outcome of PTNS. Effectiveness of transcutaneous PTNS in older adults resident in care homes was the focus of one study where the mean age was 84.2 years (338). The adherence to the transcutaneous PTNS was 100% for all participants, with no adverse effects reported and a response to therapy similar to that found with younger groups. A prospective study (347) of prognostic factors for successful percutaneous PTNS showed that gender, age, weight, body mass index, indication for percutaneous PTNS, duration of symptoms, number and type of previous treatments, number of UI episodes/24 hours, voiding frequency/24 hours and total IQoL scores were all unrelated to the success or not of percutaneous PTNS in men and women with OAB, non-obstructive urinary retention or chronic pelvic pain. A low Mental Component Summary Score on the SF-36 was a negative predictive factor for success of percutaneous PTNS, both subjectively and objectively. Additionally patients with detrusor overactivity had poorer outcomes than those without, as did those with low bladder capacity at baseline (143). This means that there is no reason to exclude older adults, those with a long symptom history, weight difficulties, severe symptoms or failure of previous treatments and they should be offered PTNS where indicated, except where recognised contraindications to PTNS, such as a cardiac pacemaker are present. Only in those patients with poor mental health and/or DO and/or low capacity bladders at baseline should the possibility of limited success be considered.

New factors are emerging which may influence understanding of potential effects for different diagnostic groups. In one pilot study (343) urinary neurotrophin levels (nerve growth factor and brain derived neurotrophic factor) were measured. Results indicated that for idiopathic OAB higher levels of nerve growth factor at baseline may predict poor response to transcutaneous PTNS. Level of brain derived neurotrophic factor significantly reduced over the treatment course in those who responded to transcutaneous PTNS, which suggests a potential biomarker for response in idiopathic OAB but the reduction was not seen in responders with neurological disease. Further investigation is required to fully understand the influence of these patient factors.

Summary

The evidence on which to base recommendations for best practice in the use of PTNS to treat OAB/UUI in men and women is sparse, for both percutaneous and transcutaneous PTNS. However it is sufficiently robust to support the use of percutaneous PTNS when less intensive and invasive behavioral treatment options have failed **(Level of Evidence: 1)** and there is the suggestion that percutaneous PTNS may be as effective as some drug therapy, making it a viable alternative **(Level of Evidence: 2).**

Only two small trials investigated transcutaneous PTNS but the promising results indicate that further well-designed and reported trials would allow decisions to be made about the place of transcutaneous PTNS in the treatment algorithms for OAB/UUI in men and women.

Health economic information is required to establish the cost effectiveness of the different forms of PTNS, particularly in comparison to pharmacotherapy.

Recommendations for practice:

In adults with OAB/UUI percutaneous PTNS is better for improving UUI than no treatment or sham and should be offered to adults with UUI/OAB who do not achieve satisfactory results from first-line lifestyle and behavioral interventions or drug therapy. **(Grade of Recommendation: B New)**

At least weekly PTNS sessions should be offered during an active treatment program with regular top-ups provided to sustain benefits for up to three years. **(Grade of Recommendation: B New)**

Transcutaneous PTNS is a safe treatment option and may be offered to frail older adults with UI or urinary symptoms however definitive evidence of effectiveness is needed. **(Grade of Recommendation: C New)**

Percutaneous PTNS can be offered as an alternative to tolterodine for OAB/UUI in adult men and women. **(Grade of Recommendation: B New).**

Oxybutynin may be considered in addition to percutaneous PTNS in adults with DO. **(Grade of Recommendation: B New).**

Future research directions:

Currently available evidence compares percutaneous PTNS with older antimuscarinics. Future rigorous trials should compare percutaneous PTNS with other commonly used antimuscarinics and beta 3 adrenergic agonists for efficacy and adverse effect profiles, in men and women with OAB/UUI.

The effectiveness of adding drug therapy to percutaneous PTNS should be investigated in high quality trials with adults with OAB/UUI.

Definitive evidence of the effectiveness of transcutaneous PTNS to treat OAB/UUI in adults is needed and its place in the treatment algorithm defined.

Research comparing transcutaneous PTNS with all types of drug therapy is required.

Direct comparison of percutaneous PTNS and transcutaneous PTNS to treat OAB/UUI in adults should be investigated.

Further rigorous and well-reported trials are needed to establish the most effective dose of percutaneous PTNS and transcutaneous PTNS, including the timing and duration of PTNS protocols.

I. INTRODUCTION

Surgery for male incontinence is an important aspect of treatment with the changing demographics of society and the continuing large numbers of men undergoing surgery and other treatments for prostate cancer.

Basic evaluation of the patient is similar to other areas of incontinence and includes primarily a clinical approach with history, pad testing, frequency-volume chart or bladder diary, and physical examination. Since most of the surgeries apply to patients with incontinence after other operations or trauma, other investigations such as radiographic imaging of the lower urinary tract, cystoscopy, and urodynamic studies may provide important information for the treating clinician.

Although prostatectomy for benign disease has become less frequent in many countries, the complication of incontinence is a rare but unfortunate occurrence that merits treatment. After a period of conservative therapy has been tried, surgical treatment is indicated following similar strategies applied in post-prostate cancer treatment incontinence i.e. slings and artificial urinary sphincter (AUS).

Despite the changes in prostate-specific antigen (PSA) testing following the recent US Preventive Services Task Force Statement (USPSTF),[1,2] radical prostatectomy (RP) for prostate cancer is performed far more frequently now than 15 to 20 years ago, with nearly two-thirds of surgical cases performed via the robotic-assisted laparoscopic approach in the United States.[3]

The diffusion of minimally invasive radical prostatectomy (MIRP) in the United States may have led to adverse patient outcomes due to rapid surgeon adoption and collective inexperience.[4] According to an analysis of the Surveillance, Epidemiology and End RESULTS-Medicare dataset, which identified men who had open RP and MIRP for prostate cancer from 2003-2009, MIRP was associated with a higher risk of voiding dysfunction (HR 1.31, 95% CI 1.20-1.43) and ED (HR 1.43, 95% CI 1.31-1.56), but a lower risk of bladder outlet obstruction (HR 0.86, 95% CI 0.75-0.97). Approximately 5-25% of patients will experience incontinence that fails to improve with conservative management, and a substantial minority will ultimately undergo surgical treatment.[5] The AUS has provided a satisfactory result in most cases, regardless of the degree of urinary incontinence, with a positive impact on quality of life. Sling procedures have emerged as an efficacious treatment in many men with mild to moderate stress urinary incontinence, however, they have not proven predictably successful in men with higher degrees of incontinence. Injectable agents have not shown durable long-term results. Volume adjustable balloons have been limited in their utility due to a high complication rate. Newer techniques involving adjustable urethral slings have demonstrated efficacy similar to that of non-adjustable slings, with the potential advantage of postoperative alterations in sling tensioning (tightening) but a higher complication rate.

Stratification of treatment based on the degree of stress incontinence is now feasible. Men with milder degrees of incontinence and normal bladder function are candidates for either artificial urinary sphincter placement or sling surgery, each with similar success rates. Sling surgery appears to have a lower risk of surgical complications in this population and patient preference may be for a sling vs a mechanical device in this group of patients.[6] On the other hand, with more severe incontinence, AUS surgery has a more predictable success profile than does sling surgery.

Incontinence following radiation therapy, cryosurgery, high-intensity focused ultrasound, other pelvic operations and trauma is a particularly challenging problem because of tissue damage inside and outside the lower urinary tract. In such instances, periurethral bulking, sling procedures, and inflatable periurethral balloons have generally proven inefficacious and worsening of incontinence may happen after such surgery. The AUS is the most successful surgical procedure in this setting, but is associated with a higher rate of complications compared to implantation following surgery in the absence of adjuvant cancer therapy. With tissue damage beyond the urinary

TABLE 1. Classification of Surgically Correctable Problems

Sphincter Related	*Postoperative*
	Post-prostatectomy for prostate cancer
	Post-prostatectomy for benign disease
	TURP and radiation for prostate cancer
	Post-cystectomy and neobladder for bladder cancer
	Post-traumatic
	After prostato-membanous urethral reconstruction
	Pelvic floor trauma
	Unresolved pediatric urologic incontinence
	Exstrophy and epispadias
Bladder Related	*Refractory urgency incontinence*
	Small fibrotic bladder
Fistulae	*Prostatorectal (urethrorectal)*
	Urethrocutaneous

sphincter, other surgical approaches may be necessary. Patients with unresolved problems from childhood and with associated incontinence from detrusor overactivity may benefit from a variety of complex reconstructive surgical procedures. Patients with primarily overactive bladder symptoms who have failed conservative management may benefit from neurostimulation or botulinum toxin injection. Other complicated problems encountered include urethrocutaneous fistulae, and fistulae between the prostate, bladder neck, or urethra and rectum. Surgical reconstruction, in experienced hands, often in a staged manner, is usually successful.

With decades of worldwide use of the AUS in the surgical management of male incontinence, its complications and their management are well known. Durability of the device is an important aspect that impacts on outcome and cost of treatment. A growing body of literature regarding male sling surgery, its indications, factors affecting outcome, and complications and their management, has changed the landscape of incontinence surgery over the past 10 years.

Although the literature is replete with well-done cohort studies, there is a continuing need for prospective randomized clinical trials, especially needed for adequate comparisons among surgical techniques.

1. MATERIALS AND METHODS

The committee was charged with the responsibility of assessing and reviewing the outcomes of surgical therapy that have been published since the Fifth Consultation[7] for non-neurogenic male incontinence. Articles from peer-reviewed journals, abstracts from scientific meetings, and literature searches by hand and electronically formed the basis of this review. The outcomes were analyzed, discussed among the members of the committee and included in the chapter.

The incontinence problems were classified according to their etiology, ie, either primarily sphincter or bladder related, and are listed in Table 1. Treatment of fistulae is covered separately.

Specific recommendations are made on the basis of published results and determined by the levels of evidence. Consensus of the committee determined the recommendations, which are found at the end of the chapter. Recommendations for future research are also included.

II. EVALUATION PRIOR TO SURGICAL THERAPY

Recommendations for evaluation prior to surgery have not changed substantially from the last edition in 2013.[7] A basic history and physical is the cornerstone of this evaluation. The history should focus on the precipitating events (surgery, trauma, etc) that led to the incontinence, the evolution over time of the leakage symptoms (has there been improvement, etc), what precipitates the leakage (straining, cough, exercise, etc – suggestive of stress urinary incontinence (SUI) or the sudden sense of the urge to void particularly in the absence of any physical activity – suggestive of urgency urinary incontinence) as well as other potential comorbidities. A general sense of

the degree of bother of these symptoms, sexual function and pad use is important as well. The physical examination should note any gross urine leakage per meatus with patient straining or coughing as well as general characteristics of the lower abdomen, perineal area and penis and scrotum. Assessment of upper extremity function is important to assess manual dexterity for manipulation of an implanted device. A brief neuro-urological examination (perineal sensation, anal tone, voluntary contraction and relaxation of the anal sphincter, bulbocavernosus reflex[8]) should be performed. A urinalysis to rule out infection or signs of inflammation or hematuria should be obtained.

A frequency-volume chart,[9] or bladder diary (indicating daytime and nighttime frequency of micturition, incontinence episodes, voided volumes, 24-hour urinary output, etc.) is also helpful. According to Wyman et al,[10] the 7-day diary can be considered as the gold standard for voiding diaries. Schick et al[11] demonstrated that a 4 day frequency-volume chart gives a reliable snapshot of the patient's situation. However, in obvious situations (eg post-prostatectomy incontinence where the patient coughs and leaks during exam such a diary may not be necessary. A pad test quantifies the severity of incontinence and may be the most objective measure of the incontinence. Severity of incontinence (quantified by pad weight) affects surgery outcomes. In men with greater than 200 g/d urine loss, the transobturator sling has been associated with lower success rates.[12] The 24-hour pad test and micturition diary are reliable instruments for assessing the degree of urinary loss and number of incontinent episodes, respectively. Increasing test duration to 48 and 72 hours increases reliability but is associated with decreased patient compliance.[13] Overall, the 24-hour home test is the most accurate pad test for quantification and diagnosis of urinary incontinence because it is the most reproducible.[14] The 1-hour pad test may be used because it is easily done and standardized, however there is no strict parallel with the 24-hour pad test and it may underestimate the weakness of the sphincter in the later part of the day. A pad test may be helpful in quantifying leak in AUS failures.

Postvoid residual urine measurement is a good estimation of voiding efficiency.[15,16] These basic investigations are recommended in incontinent males prior to surgical therapy.

Blood testing (BUN, creatinine, glucose) is recommended only if compromised renal function is suspected or if polyuria (in the absence of diuretics) is documented by the frequency-volume chart.[17]

Further evaluation should be adapted to the particular patient. Cysto-urethroscopy will verify the integrity of the urethral wall (anterior aspect of the distal sphincteric mechanism in post-TURP incontinence,[18] erosion by the cuff of the artificial sphincter, and the status of the bladder (trabeculation, stone, diverticula, etc). It will allow observation of the urethral sphincter and voluntary contraction on the part of the patient. The presence or absence of urethral, prostatic, or bladder neck stenosis is also necessary to ascertain prior to incontinence surgery, especially in patients who have undergone treatment for prostate cancer.

Imaging techniques include plain film of the abdomen (KUB or Kidneys, Ureters, Bladder), in cases of incontinence following artificial sphincter implantation when during the original procedure the hydraulic system was filled with contrast medium. A KUB immediately following sphincter implantation serves as a reference point for subsequent comparisons.[19] Figure 1 illustrates the case of a young spina bifida patient in

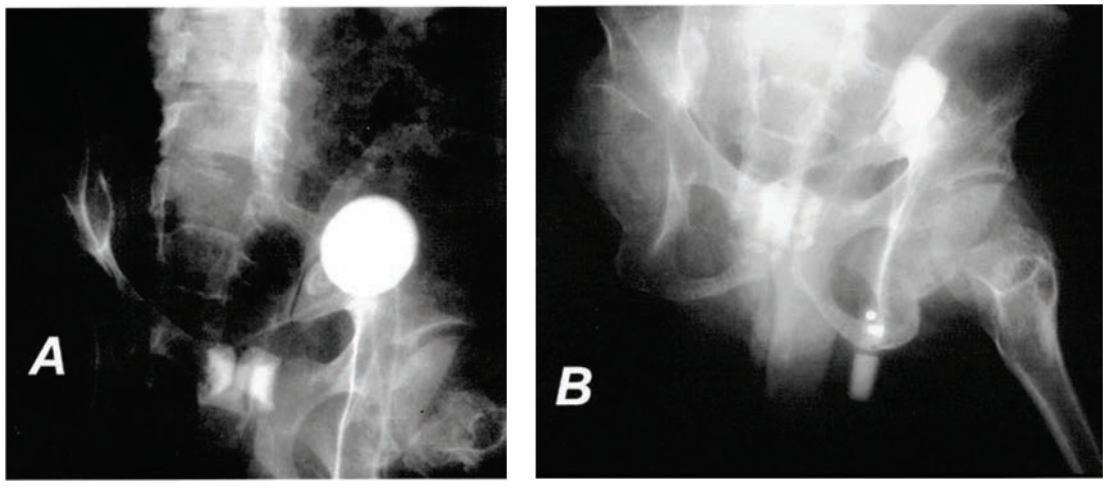

Figure 1. Young spina bifida patient who had a bladder neck artificial sphincter implanted. After more than 10 years, he become incontinent. Early abdominal plain film, A, shows a full reservoir. After leakage started abdominal plain film, B, demonstrates loss of fluid from the reservoir.

whom an artificial sphincter has been implanted with the cuff around the bladder neck. After more than 10 years, he became suddenly incontinent. Comparing the second KUB to the original one clearly demonstrated fluid loss from the system. Contrast studies include cystography which may demonstrate an open bladder neck when bladder denervation is suspected[20] (e.g., following abdominoperineal resection of the rectum). CT or MRI may be useful as well particularly in cases where there is concern that components of the AUS have shifted or herniated (Figure 2A and B).

Cystourethrography may be used to demonstrate a fistula, stricture or urethral diverticulum eg, following healing of the urethral wall erosion caused by the cuff of the artificial urinary sphincter. Ultrasound is widely used not only to evaluate the upper urinary tract, but also to evaluate postvoid residual urine. The sensitivity of 66.7% and specificity of 96.5% when post-void residual is 100 ml or more is adequate for routine clinical use.[21] It has been shown to be cost-effective when compared to catheterization.[22] Other modalities, for example transurethral ultrasound[23] and magnetic resonance imaging of the external sphincter are still under development.

1. URODYNAMIC TESTING

Urodynamic studies (UDS) have traditionally been performed in men under consideration for invasive treatment in order to assess Valsalva Leak Point Pressure (VLPP), detrusor overactivity and bladder compliance. However, there are now several studies, which call into question the use of routine UDS in men with pure SUI. These studies will be commented on at the end of this section.

When performing UDS there are specific issues that must be considered. Sphincter weakness can be documented by the Valsalva[24] or cough[25] abdominal leak point pressure. However, in patients with incontinence secondary to RP who develop bladder neck stenosis, the urethral catheter can create obstruction giving false values for VLPP. Catheter size seems to have a significant influence even with a small size 7-F urethral catheter,[26] and the correlation is extremely high between the test-retest leak point pressure when the same size of catheter is used.[27,28] In male patients, abdominal leak point pressure may be evaluated via a rectal catheter because a urethral catheter is much more likely to invalidate VLPP measurements than it does in female.[29] It has become evident that bladder volume influences VLPP, ie, it decreases with bladder filling.[30,31,32] However, this observation is not consistent.[33] Unfortunately, there is no agreed standardization of the technique currently which somewhat limits its usefulness.[34] Measurement of leak point volume may also provide information on the functional capacity of the bladder.[35]

Retrograde leak point pressure has been used to study incontinence following placement of an artificial sphincter.[36,37] It correlates with the lowest abdominal leak point pressure.[38] The intraoperative use of this technique has been proposed and this allows early recognition of intraoperative urethral injury and mechanical malfunction.[39] Intraoperative retrograde perfusion sphincterometry may be helpful to determine the appropriate tension on male slings.[40] Similarly, others have utilized repeated intraoperative abdominal leak point pressure (ALPP) measurements to adjust the tension for male slings.[41] Electrophysiologic studies, mainly sphincter electromyography, may be useful to document denervation of the pelvic

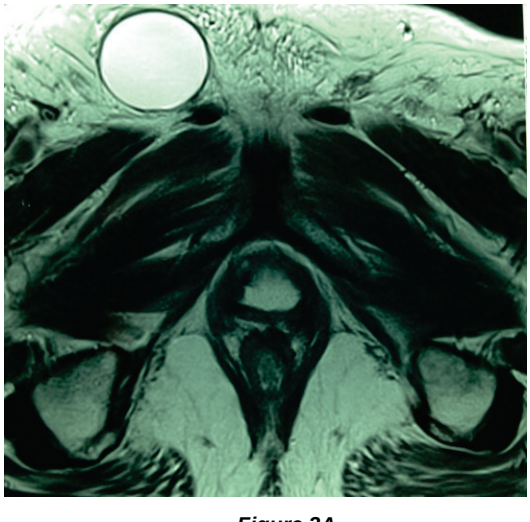

Figure 2A

floor when nerve injury or neuropathology is suspected.[42]

Detrusor function is best evaluated by multichannel urodynamics. Its main purpose is to detect **detrusor overactivity and/or decreased compliance during bladder filling.** It can be coupled with fluoroscopic imaging - video-urodynamics. It has also been proposed by some that fluoroscopy be replaced by transrectal ultrasound.[43,44] Ultrasound measurement of bladder wall thickness was proposed as a better predictor of bladder outlet obstruction than uroflowmetry[45] but is still controversial.[46] In some cases with severe SUI and "early" leakage the urethra/bladder neck can be occluded to get a better idea of detrusor characteristics.

Non-invasive pressure-flow urodynamic evaluation based on Doppler ultrasound seems to have potential for diagnosing bladder outlet obstruction.[47] However invasive pressure-flow studies are still the gold standard in the incontinent male to rule out bladder outlet obstruction accompanied by detrusor overactivity[48] which in turn can cause incontinence.

In most recently published studies, urodynamic testing has been done prior to surgery.[49,50,51,52,53] Cystoscopy is frequently done as well.[52,54,55,56,57,58] However, as noted above, there are some reports that question the value of urodynamics studies in predicting outcomes after surgery. Thiel et al[59] found no evidence that patients with detrusor overactivity, low first sensation filling, decreased compliance or low bladder capacity had worse outcomes after artificial sphincter placement in 86 men. Trigo Rocha et al[60] also found that preoperative urodynamic findings such as detrusor overactivity, impaired detrusor contraction, low valsalva leak pressure, bladder outlet obstruction, and mildly reduced compliance did not lead to a bad outcome after artificial sphincter implantation. Ballert et al[61] studied the association between patients with or without detrusor overactivity, and postoperative outcome after male sling surgery, and found no difference in the number of pads used postoperatively. Finally, Lai et al[62] reviewed 129 patients with post-prostatectomy incontinence, all of whom had multichannel videourodynamics, and noted that the presence of adverse preoperative urodynamic features (such as detrusor overactivity, early sensation of desire to void, reduced cystometric capacity of <200cc, low abdominal LPP <30 cm H_2O, low peak flow <10 cm H_2O and poor bladder contractility) did not negatively affect the continence results after AUS implantation. However, it should be noted that after discussion with a panel of experts (ICI meeting, Tokyo, September 2016) it is evident that there is a difference of practice between North American and other urologists - the non-North Americans are much more likely to obtain urodynamics preoperatively in all cases.

The proposed evaluation of the incontinent male is summarized in Table 2.

TABLE 2 Evaluation Prior to Surgical Therapy

- *History*
- *Physical examination*
- *Urinalysis*
- *Urine culture*
- *Post-void residual (by ultrasound)*
- *Voiding diary (2-7 days)*
    - *Polyuria without diuretics: BUN, Creatinine, Glucose*
- *Pad-test*

        - *To characterize the incontinence and to detect detrusor overactivity, decreased compliance and/or outflow obstruction*

III. INCONTINENCE AFTER RADICAL PROSTATECTOMY FOR PROSTATE CANCER

1. INCIDENCE AND PREVALENCE

Urinary incontinence occurring after RP is a substantial problem. Despite improvements in continence preservation[63] during the 1990s and 2000s primarily due to a better understanding of the pathophysiology and improvements in surgical technique, continence rates have generally plateaued over the past decade. As RP has continued to increase in popularity as a treatment for prostate cancer, especially with the advent of robotic-assisted surgery, the *prevalence* of post prostatectomy incontinence (PPI) has increased in developed countries, which has led to an overall increase in the number of patients affected.

Data from large multicenter studies and prostate cancer databases suggest that following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of post prostatectomy incontinence (PPI) depends on the definition of urinary incontinence and the length of follow-up.[64,65,66] In addition to numerous definitions of incontinence, the tools used to evaluate incontinence vary from self-administered validated and non-validated questionnaires, to interviews from a data manager, to response to the surgeon's inquiry, to insurance database inquiries regarding secondary surgical procedures. It should be noted that SUI also affects men who have not had surgery for prostate cancer, occurring at a baseline prevalence of 1.3%-4.8%.[67,68] In addition, men with prostate cancer who choose radiation therapy, androgen ablation, or even watchful waiting also develop urinary incontinence, recently reported at rates of up to 12%, 11%, and 3%, respectively.[69,70] In addition to urinary incontinence, bothersome lower urinary tract symptoms may affect patients following any treatment (or even watchful waiting) for prostate cancer.

Typically, reports of large cohorts use definitions that include "total control/perfect continence/dry", "occasional leakage but no pad", and "less than one pad". Because 1/3 to 1/2 of men who do not wear pads will have occasional leakage of urine,[64,71] it is important to distinguish among those men who leak enough to require pad use vs those who do not, as it has been demonstrated that health related quality of life (QOL) is strongly correlated with the level of incontinence. Wearing one pad, even if this pad is considered "a security pad", more significantly affects the quality of life than wearing no pad at all.[72,73] In addition, not all men who leak will elect to have further treatment. Most large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery.[74,75,76,77] Several large cohort studies are listed in Table 3.[66,71,73,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96]

Another bothersome type of incontinence occurring during orgasm in men post-prostatectomy has been termed 'climacturia' and may significantly affect the quality of men with post-prostatectomy potency.[97]

Finally, some men may experience post-micturition dribbling. This can usually be managed with urethral milking or pelvic floor muscle contraction.

TABLE 3. Continence Rates After Radical Prostatectomy According to Definition of Continence

Authors	N	Mean age (yrs)	Continence Follow-Up at 12 Months			Type of Surgery
			Total control without any pad or leakage (%)	No pad use but loses a few drops of urine (%)	Use none or 1 pad per day (%)	
Anstasidis et al[90]	70 230	65 64			67 72	RRP LRP
Augustin et al[87]	368	63.3			87.5	RRP
Boris et al[94]	50 50	64 64			96 96	RRP RALP
Deliveliotis et al[82]	149	66.5		92.6		RPP
Di Pierro et al[95]	75 75	64 63	80 89			RRP RALP
Harris et al[83]	508	65.8		96		RPP
Hofmann et al[85]	83			74.7	88	RRP±Rx
Jacobsen et al[89]	172 67	64 61	87 83		88 50	RRP LRP

Authors	N	Mean age (yrs)	Continence Follow-Up at 12 Months			Type of Surgery
			Total control without any pad or leakage (%)	No pad use but loses a few drops of urine (%)	Use none or 1 pad per day (%)	
Kielb et al[78]	90	59.6	76		99	RRP
Krambeck et al[92]	588 294	61 61		94 92		RRP RALP
Lepor and Kac[i80]	92	58.7	44.6		94.6	RRP
Liss et al[73]	420	61	54	67	82	RALP
Madalinska et al[81]	107	62.6	33	65		RRP
Maffezzini et al[84]	300	65.5		88.8		RRP
Olsson et al[66]	115	65.2	56.8	78.4	100	LRP
Rassweiler et al[88]	219 219	65 64			89.9 90.3	RRP LRP
Reynolds et al[96]	1005	60	28	68	90	RALP
Rocco et al[93]	240 120	63 63			88 87	RRP RALP
Ruiz-Deya et al[86]	200	63			93	RPP
Sacco et al[91]	985	65	83	92	93	RRP
Sebesta et al[79]	675	< 65	43.7	69.2	82.2	RRP
Wallerstedt et al[71]	1163	63	67	78	90	RRP or RALP

RRP = radical retropubic prostatectomy, RPP = radical perineal prostatectomy, LRP = laparoscopic radical prostatectomy

Rx = radiotherapy, RALP = robotic assisted laparoscopic prostatectomy

2. RISK FACTORS

Reported risk factors for incontinence following RP include patient age at surgery, socio-economic status, preoperative continence status, obesity, pre-surgical bladder dysfunction, stage of disease, surgical technique (including nerve sparing, bladder neck preservation, and posterior reconstruction of Denonvilliers' musculofascial plate, anterior periurethral suspension sutures,[98,99] prior radiation therapy, preoperative length and intraoperative preservation of the membranous urethra, prior transurethral resection of the prostate (TURP), postoperative radiation or cryotherapy, and vascular comorbidities. However, various studies have come to conflicting conclusions regarding the importance of specific risk factors. Predisposing factors contributing to incontinence after TURP have been less clearly defined, probably because the incidence is so low, (and the plethora of minimally invasive therapies is reducing the popularity of TURP surgery), making the accumulation of large prospective series of this type of incontinence difficult. However, previous external beam radiation and prior brachytherapy does predispose to post-TURP incontinence (Section V and VI in this chapter).

Preoperative voiding dysfunction and pre-existing urinary incontinence have been reported as risk factors for postoperative SUI. Patients with more severe lower urinary tract symptoms, measured by validated symptoms scores, had a lower return to continence than did patients with more mild symptoms, even when controlling for age.[100] While preoperative lower urinary tract symptoms, including urgency incontinence and "overflow incontinence" may improve with de-obstruction secondary to extirpative surgery,[101] preoperative SUI does not improve following RP. Several recent cohort studies have demonstrated that preoperative sphincteric insufficiency (demonstrated by either the pre-existing clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts postoperative SUI.[102,103]Preoperative bladder dysfunction can also contribute to postoperative incontinence. Pre-existing abnormalities of detrusor function may predispose to leakage following surgery, especially in the setting of neurogenic detrusor overactivity due to Parkinson's disease, dementia or spinal cord injury.[104]

Advancing age as a risk factor is supported by several studies[77,101,105,106,107,108,109,110,111.] However, Steiner et al[112] found no correlation between age and continence status, but only 21 of the 593 patients were 70 years or older. Others have found advancing age and

the number of comorbidities to have a negative impact on the recovery time for continence during the first year after RP;[113] although, the rate at one and two years did not seem to be significantly affected.[114] Mohamad and colleagues[115] reviewed 16,524 patients who underwent RRP in public hospitals, covering 95% of all procedures in Austria between 1992 and 2003. They found that increasing age was associated with an increased risk of future AUS implantation. In those aged 45-49, 0.5% were bothered enough by PPI to merit AUS placement, while those age 70-74 were five times as likely to undergo AUS placement for PPI.[115] Similarly, Rogers et al[116] demonstrated that age affected postoperative continence status following laparoscopic RRP. In those < 50 years old, 100% achieved 0-1 pad per day continence at 1 year, which decreased to 91% and 81% for those age 50-59 and > 60 yrs, respectively (P<0.01).[116] Nilsson et al[117] reported that age at surgery predicted—in an exponential manner—the long-term risk for urinary incontinence, with an estimated relative increase of 6% per year.

Strasser and colleagues hypothesized that age related sphincteric changes may be responsible for the age-related increase in postoperative SUI, and successfully demonstrated a progressive reduction in sphincter striated muscle cells with age.[23] In addition to age, overall well-being has also been related to the risk of PPI. For example, a recent study from Italy demonstrated that both age and Charlson comorbidity index were independent predictors of return to urinary continence.[110] It is especially interesting to note that in this particular cohort study, there were no variables related to the prostate cancer itself that were significantly correlated with urinary continence. A large study from Sweden recently demonstrated that in addition to age as a risk factor (relative risk of 2.4 between the oldest and youngest quartiles), educational level also impacted incontinence, with low educational level, as compared with high educational level, being associated with a 2.5 times risk of incontinence.[117]

Obesity, especially when coupled with physical inactivity, appears to be a risk factor for PPI in men undergoing RRP. Obesity with a BMI > 30 was reported as a risk factor with an incontinence rate of 25.8% vs 8.7% in BMI <30 in a series of 252 men after RRP.[118]

Wolin et al[119] demonstrated that greater than one year after surgery, obese men were markedly more likely to have urinary incontinence (defined as any pad use) than were non obese men, while this risk was exacerbated by sedentary lifestyle, and ameliorated by at least 1 hour of physical activity per day (preoperatively). Nonobese active men were 26% less likely to have urinary incontinence than obese inactive men. In obese men who were physically active, the relative risk of urinary incontinence was 15% less than in the inactive obese men.[119]

Most large series have found no correlation between the stage of disease and incontinence rates.[106,107,120,121,122] Loeb and colleagues[123] specifically demonstrated excellent continence rates even in high-risk (high local stage) patients. However, in certain cases, the stage of disease may affect the surgical technique (ie, nerve sparing) and incontinence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage.[108] Yang et al[111] reported that neoadjuvant hormonal ablation was associated with a lower risk of urinary incontinence, and while patients with higher stage disease may have been more likely to receive hormonal ablation preoperatively, it is not clear that stage of disease was an important risk factor.

Regarding surgical technique, the many parameters involved in continence may explain difficulties in understanding the benefit of certain technical points. Perineal prostatectomy is done by only a limited number of urologists but is still advocated for markedly obese patients and the continence rate is reported as similar to the retropubic route.[83,94,124,125] Bladder neck preservation has been reported to improve continence at 1 month[126] and at 3 months[121] but no difference was found at 6 and 12 months.[127,128] Nerve sparing has no significant impact according to Steiner et al[112] and Lepor and Kaci.[80] Recently Pick et al[129] reported that nerve sparing, whether unilateral or bilateral, did not affect continence rates following RALP. However, others did find benefit.[102] In particular, Nandipati and colleagues[130] reported that in a cohort of 152 patients followed prospectively, bilateral nerve sparing surgery was associated with a shorter time to regain continence as well as improved long-term continence rates compared to non-nerve sparing surgery. They additionally found that increased age was a risk factor for post-prostatectomy incontinence. Burkhard et al[131] similarly demonstrated a positive effect of nerve-sparing surgery on postoperative continence. In a prospective cohort study of 536 patients, PPI developed in 1/75 (1.3%), 11/322 (3.4%), and 19/139 (13.7%) with attempted bilateral, attempted unilateral and without attempted nerve sparing, respectively. Attempted nerve sparing was in fact the only statistically significant factor influencing urinary continence after RRP in this cohort.[131] Based upon comparison of preoperative and postoperative urodynamics, nerve sparing appears to reduce the risk of PPI—via minimizing decreases in maximal urethral closure pressure and functional urethral length, but without affecting bladder function.[132] Two recent reports have linked preoperative sexual function with postoperative continence. While those who are sexually active preoperatively may be more likely to have their cavernosal nerves spared during surgery, it appears that the preoperative status has a significant effect on postoperative continence rather than the nerve sparing technique.[126,129,133]

Robotic-assisted laparoscopic RP has not only become a standard treatment for men with prostate cancer, but has become the most popular surgical option. In contrast to the initial robotic experience, where the body of available data on postoperative incontinence did not demonstrate an obvious differences in urinary

continence rates between open and laparoscopic/robotic approaches,[88,89,90,92,93,94,95,134,135,136] more recent reports have indeed shown a lower rate of incontinence following robotic surgery compared to traditional open surgery. While one randomized comparison of laparoscopic RP with and without robotic assistance did not show a significant difference in urinary continence,[137] there has been more recent demonstration of statistically significantly superior continence outcomes with robotic assisted laparoscopic RP compared to *open* RP.[138,139,140,141]

While no specific reconstructive technique has been definitively shown to affect long-term continence, the postoperative appearance of the bladder outlet on cystogram has been shown to correlate with early and late postoperative incontinence. Specifically, a sharper bladder neck angle with a more downwardly displaced bladder neck predicts PPI as early as 1 month, and as late as 24 months postoperatively.[142] In addition to the angle per se, the bladder neck location in relation to the superior edge of the symphysis can also predict incontinence at 12 months postoperatively. Patients in the highest tertile of bladder neck to pubic symphysis ratio (distance from superior edge of pubic symphysis to the bladder neck divided by the total pubic symphysis height) had a nearly 20% incontinence rate at 1 year postoperatively, compared to a 2.8% rate in those in the lowest tertile.[143]

Is Radical Retropubic Prostatectomy associated with higher risk of urinary incontinence in patients previously submitted to HoLEP or TURP due to Benign Prostatic Enlargement?

Suardi et al[144] evaluated the feasibility and safety of nerve-sparing radical retropubic prostatectomy (NSRRP) for localized prostate cancer after HoLEP for BOO due to BPE. Fifteen consecutive patients with prostate cancer following HoLEP underwent NSRRP. They were matched with an equal number of patients who also underwent NSRRP following TURP (TURP group) or open prostatectomy (OP group). Mean follow-up was 23.8 ± 10.5 mo. At last follow-up evaluation no statistical differences were found among the groups in terms of UI, as measured with the first question of the ICIQ-SF. The groups showed no statistical differences in UI rate. Six-month continence rates were 93.3%, 93.3% and 80% for HoLEP (N=15), TURP (N=15) and open prostatectomy (N=15), respectively (P>0.05).

3. Pathophysiology

Post-prostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction or a combination of both. Urodynamic studies are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be investigated.[124,145] Urodynamics demonstrates that sphincter incompetence occurs as the sole cause in more than two-thirds of patients, while isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10%.[146,147,148,149]

Sphincter and bladder dysfunction can coexist in at least one-third of incontinent patients. Bladder dysfunction may occur de novo after prostatectomy perhaps induced by bladder denervation; may be caused by outlet obstruction, or may be related to pre-existing factors such as age. Impaired detrusor contractility, which occurs in 29%–61% of patients (de novo in approximately 47%), and poor compliance, which occurs in 8%–39% of patients (de novo in approximately half), have traditionally been thought to resolve in the majority of patients within 8 months.[149,150] However, two recent prospective urodynamic studies have demonstrated that decreased vesical compliance can occur in up to one-third of patients following RP, and persist in 28% at 36 months, while detrusor underactivity can occur in half of the patients, and persist in 25% at 36 months.[150,151] Decreased sphincter resistance may be due to tissue scarring in some cases and reflected by a low urethral compliance, however this parameter is difficult to measure.[146] Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography, and is clinically suspected when both incontinence and decreased force of stream coexist.

The preoperative length of the membranous urethra determined on MRI has been shown to be significantly related to time to postoperative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at one year, vs 77% with or less than this length.[152] Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence.[102,153,154]. A recent elegant study of *intraoperative* stretched urethral length (from the urogenital diaphragm to the prostatic apex with cephalad retraction) and cut urethral length (length of preserved urethral stump) during RALP revealed that although in this cohort, MRI urethral length did not correlate well with continence, the intraoperative measurements correlated significantly with time to continence.[155] Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence as well as the extrinsic component responsible for active continence may be involved as has been demonstrated in a urodynamic alpha blockade test.[156] This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Postoperative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory functions.[157,158] In clinical practice, urodynamic evaluation of urethral weakness may be assessed by resistance to antegrade leakage (ALPP or VLPP), retrograde leakage, or profilometric measurement (MUCP).[159] However no such parameters have been correlated to outcomes of treatments for the correction of post-prostatectomy incontinence. It should be

noted that increasing age is a strong predictor of incontinence.[160,161,162,163,164,165] The fact that increasing age predicts incontinence reflects the natural history that atrophy of the rhabdosphincter and degeneration of neural pathways occurs with aging, thereby affecting postoperative continence status.

The state of a patient's pelvic floor may also influence continence or return to continence after RP. Physiotherapy and pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the postoperative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal.[166,167] Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. Another study showed that providing patients with instructions for pelvic floor muscle exercise alone was equivalent to biofeedback or electrical stimulation.[168] A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months.[169] On the other hand, a recent trial from Brazil did demonstrate significant difference in 12-month continence rates, quality of life, and lower urinary tract symptoms in general when randomizing patients to biofeedback-pelvic floor muscle training vs verbal instructions alone.[170] Studies in which physiotherapy was used as a treatment modality for established incontinence have shown more variable results.[171,172,173,174] A recent randomized trial of formal one-to-one pelvic- floor muscle training vs advice alone for incontinent men 6 weeks after RP failed to demonstrated any difference in continence rates at 12 months. Nor did the physiotherapy improve SUI after TURP.[175] Overall, the data indicate that pelvic floor therapy accelerates the return to continence but does not change the ultimate outcome.

No medical treatment is available to cure post-prostatectomy incontinence. Duloxetine at 60 mg per day could improve mild or moderate incontinence but half of the patients had side effects and 25% stopped the treatment because of adverse effects in two short non-randomized series. This treatment is not approved in many countries and is only a treatment option to improve symptoms in selected patients informed of side effects.[176]

4. SURGICAL AND MINIMALLY INVASIVE TREATMENTS

4.1. Urethral Bulking Agents

Urethral bulking is a minimally invasive treatment proposed for post prostatectomy incontinence, and theoretically works by adding bulk and increasing coaptation at the level of the bladder neck and distal sphincter. It can be done in an office or outpatient setting in a retrograde or antegrade fashion. Several different agents have been used for urethral bulking in men including bovine collagen (Contigen®), silicone macroparticles (Macroplastique®), ethylene vinyl alcohol copolymer (Tegress®), Dextranomer hyaluronic acid (Deflux®), and carbon-coated zirconium beads (Durasphere®). All agents share the similar problems including the need for multiple injections, deterioration of effect over time, and very low cure rates.

For collagen, "success rates" for post-prostatectomy incontinence ranged from 36-69%, with 4-20% of patients reporting being dry.[177,178,179,180,181,182,183,184] Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections were required to achieve modest rates of subjective improvement. There was no advantage of delivery technique (retrograde vs. antegrade). Several authors identified factors which negatively affect results including extensive scarring or stricture formation, previous radiation, and high grade stress incontinence and low ALPP.[178,180,181,184] One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to RP (35.2% 'social continence' vs 62.5%).[181] It appears that collagen injection did not adversely affect outcomes of artificial sphincter implantation and did not increase the complication rate.[185] Nor did collagen injection adversely affect the outcome of the bone-anchored male sling (BAMS).[186,187]The cost efficacy of injections remains to be determined. Collagen is no longer available as an injectable agent.

Other bulking agents such as polydimethylsiloxane (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and coworkers[188] treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively. They also noted that a urethral closure pressure of at least 30 cm H_2O was essential for success. Kylmala et al[189] prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving short-term continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was limited to 3 months. More recently, a Korean study with 6 month follow-up showed 43% success at 3 months following Macroplastique injection, which decreased to 32% at 6 months. Lower ALPP and a history of radiation correlated with treatment failure.[190] In a randomized trial of AUS vs Macroplastique injection in patients with minimal SUI (the majority had SUI following BPH surgery, with more than 1/3 of the cohort suffering from SUI following RRP), Imamoglu and colleagues demonstrated no difference in success with AUS vs Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique.[56] As one would expect, due to the poor efficacy of periurethral bulking agents, their use for treating PPI had decreased dramatically over the past decade, from 80% of cases in 2004, to 60% in

2010,[191] and to < 40% in 2013.[192] While the efficacy of periurethral injection is indeed limited, improvements with injection are better than those seen with more conservative management, and better than no treatment at all, with no demonstrable differences in outcome with respect to a transurethral vs periurethral injection method, and no differences in outcome between proximal urethral or bladder neck injection site.[193]

With regard to the newer (not FDA approved for male SUI) injectable bulking agents, dextranomer hyaluronic acid has been reported in men with PPI and in men with neurogenic ISD. Four of four patients with PPI failed to improve, and 1 of 2 neurogenic patients (both with detrusor areflexia, wet between catheterizations) failed.[194] With ethylene vinyl alcohol copolymer (Tegress ®**)** in a report by Hurtado et al,[195] not only was the failure rate high, but also the complication rate was unacceptable. In 17 men, who averaged 1.4 injection sessions followed at a mean of 4 months, 10 had complications, with erosion of injected material in 41.1%, and with only a minority of patients achieving a 50% decrease in leakage. Tegress® has been withdrawn from the market. Carbon-coated zirconium beads have been similarly reported to be inefficacious, with a recent report of 8 men with mild to moderate incontinence receiving a relatively large average injected volume (23.8 mL), none of whom achieved subjective or objective cure.[196]

There has been interest in the use of autologous muscle cells, stem cells, and fibroblasts as an injectable sphincter-restorative agent for PPI. Transurethral injection of living muscle stem cells to reconstitute the deficient urethral sphincter has been reported. Mitterberger and colleagues[197] demonstrated a 67% continence rate at an average of 1 year follow-up in a cohort of men suffering from PPI who were treated with transurethral ultrasound guided injections of autologous fibroblasts and myoblasts obtained from skeletal muscle biopsies. An earlier report from the same group demonstrated that men with PPI achieved a 52% dry rate with injection of adult autologous stem cells, which was superior to a similar cohort of men treated with collagen injection.[198] However, it must be pointed out that there was a retraction issued by the editors of *The Lancet*[199] for a previous article on the treatment of female SUI with autologous cells published by the same group.[200] The project was investigated by the AGES PharmMed, a department of the Austrian Government's Agency for Health and Food Safety. The editors stated that in their view "the conclusions of the official investigation pinpoint so many irregularities in the conduct of their work that, taken together, the paper should be retracted from the published record." Current research has focused on the relatively abundant adipose derived stem cells and muscle derived stem cells, which are believed to be easier to harvest (higher yield) than are autologous bone-marrow derived stem cells.[201] In a recent large scale trial of muscle derived cells for treating male sphincteric incompetence, Gerullis et al [202] demonstrated complete continence in 12% and improvement in 42% of 222 men at 1 year post injection.

Conclusion: Bulking agents remain the most minimally invasive treatment for post RP incontinence after conservative measures. All agents for which there is peer-reviewed data available, show only modest success rates with very low cure rates. Effects tend to deteriorate over time. It remains to be seen if improvements in outcomes can be achieved with alternative agents, or if the concept of urethral bulking has achieved its maximal benefit with the agents available now. It is the opinion of the committee that the use of bulking agents for the treatment of male urinary incontinence should only be utilized when other more effective treatments are contraindicated (**Level of evidence 3; Grade of recommendation C**).

4.2. Male Sling

The male sling procedure is based upon the concept of urethral support and external urethral compression, and has established itself as an accepted and efficacious treatment for PPI. The male sling is actually based on a concept similar to that described by Kaufman and associates in the early 1970s.[203,204,205] At that time a high rate of failure, septic complications and pelvic pain as well as the advent of the mechanical AUS led to the abandonment of the Kaufman prosthesis. Now with the higher prevalence of PPI and patient desire for less invasive surgery and a non-mechanical device the concept has been revisited. Procedures have been developed based on principles used to treat female stress urinary incontinence. These procedures rely on compression from the ventral side of the urethra rather than the circular compression caused by a natural or artificial sphincter. Therefore, most successful sling surgeries rely on a device that is placed under tension, occluding the urethra at rest, and during stress maneuvers.[206,207,208]

Schaeffer et al[209] described the bulbourethral sling which uses Dacron bolsters placed under the urethra, which are suspended to the anterior rectus fascia by sutures. Data on this procedure are limited to retrospective analyses from the two authors who described the procedure: it did not gain widespread popularity. In the initial report from two centers, 64 patients were included and 56% were "dry" and 8% "improved" at a mean follow up of 22.4 months.[209] Almost one-third needed secondary retightening procedures and patients with radiation fared poorly. Subsequently, Clemens et al[210] reported a questionnaire-based study of 66 men from a single institution and 41% were cured and 51% improved but mean follow up was only 9.6 months. They also reported that the

bulbourethral sling did not cause significant outlet obstruction.[211]

The long-term efficacy of the bulbourethral sling was evaluated in 2005, where 95 patients were followed retrospectively at an average of 4 years postoperatively. With follow-up questionnaires returned by 71 patients, the authors found that patients who had undergone radiation, had worse outcomes with 14% dry and 43% requiring 1 or 2 or fewer pads daily. Moderate to severe pain was reported by 12% of patients after 4 years. Patients who had not had radiation treatment had a cure rate of 42% and 72% used only 0-2 pads per day for mild leakage.[212] Others have described a bulbourethral sling using a polypropylene mesh graft with or without a porcine dermis backing (presumably to reduce the risk of erosion).[57] In two small studies of 9[213] and 16[57] patients, cure rates range from 56-69% and failure rates from 22-25% at a mean follow up of 14 months. John described the bulbourethral composite suspension where porcine dermis is secured to the bulbospongiosus muscle and a 1 cm wide polypropylene sling is placed over this and passed through the retropubic space to emerge from two suprapubic incisions (similar to the tension free vaginal tape procedure in women).[57] He reported a 69% cure and additional 6% improvement in 19 patients, with a mean follow up of 14 months. Eight intraoperative bladder perforations healed without complication.

Xu and colleagues described a bulbourethral composite suspension utilizing a suburethral polyester patch plus a narrow polypropylene tape passed from a perineal incision to a suprapubic incision. At an average of 28 months, 22 (85%) of 26 patients were successfully treated.[214]

Wadie described 2 year follow-up on a polypropylene bulbourethral sling suspended by nylon sutures and fixed in front of the rectus sheath.[215] Eighty-five percent were dry at 2 years though 25% had undergone retightening of the sling between 3 and 6 months. This sling made of easily obtainable materials might prove particularly useful in settings that do not have easy availability of some of the commercially produced slings (Figure 3).

A common method of sling fixation involved use of bone anchors. The bone anchored male sling (BAMS) obviated the need for any suprapubic incision for suture passage and fixation. In 2001, Madjar et al[216] reported on 14 patients with post RP incontinence that underwent the procedure with a synthetic or cadaveric fascial sling. At a mean follow up of 12.2 months, 86% were "cured" wearing none or 1 pad. Comiter[217] reported a 76% cure and 14% "substantially improved" rate in 21 men with post prostatectomy incontinence using polypropylene mesh with a mean follow up of 12 months.[186] In a 2005 update, the same author reported that with a median of 48 months follow-up, 65% of patients remained pad free and 15% required 1 pad per day. Urodynamic follow

Figure 3 – homemade polypropylene sling (Wadie)

up in 22 men, revealed that the sling had no substantial effects on voiding function and no one was obstructed postoperatively.[218] Onur and colleagues[219] reported on 46 men with a mean follow-up of 17 months (6-26). They used different materials for the sling (allograft dermis, allograft fascia lata, porcine small intestine submucosal (SIS) graft, synthetic mesh, and a composite of synthetic and dermis). Overall they reported 41% of patients dry and 35% improved (50% reduction in the number of pads). All patients in whom allograft or xenograft alone was used failed. A 24-month update revealed a patient satisfaction rate of 70% and a 74% improvement in leakage at a median of 24 months.[220] Giberti et al[221] reported that in 36 men followed for an average of 41 months, 62% were cured and 70% were satisfactorily improved. In the subset that had a synthetic sling implanted, a higher success rate was experienced, with 77% achieving cure. Complications included sling infection in 4.8%, and de novo detrusor overactivity in 7.1%. Carmel et al[222] reported that at an average follow up of 36 months, in a cohort of 45 men with moderate to severe PPI, 78% were improved by pad use, 76% had dry ICS 1-hour pad tests, and 72% were satisfied or very satisfied. Infection occurred in 1 patient, and pain resolved in all patients by 12 weeks postoperatively.

However, the morbidity (infection, pubic bone osteitis, perineal pain) related to bone screws coupled with the emergence of effective alternatives has decreased the popularity of the bone-anchored sling, which is no longer commercially available.

The transobturator (TO) male sling technique was introduced in 2004[223] and has become the most common approach for male sling placement, since the early reports of 2007.[53,223,224] Whereas this sling does compresses the bulbar urethra, another mechanism of action is proposed to rely on proximal urethral relocation. It is hypothesized that inefficacious coaptation of the urethral sphincter complex results from lax-

ity of posterior urethral support and relative misalignment of the proximal urethra.[225] A TO sling that restores the pre-prostatectomy configuration by realigning the mobile sphincter complex can remedy this proximal urethral descent. Following appropriate sling tensioning, the bulbar urethra is relocated proximally, by a distance of 2-3 cm, into the higher pressure pelvic outlet, functioning as a "backstop" during straining.[226] This approach relies more on rotation of the dorsal surface of the proximal bulbous urethra and indirect support of the sphincteric urethra, rather than on direct compression of the urethral lumen.[227] Membranous urethral rather than bulbar urethral placement of the sling was introduced with the TO sling with the aim of relocating the urethra in a more proximal direction. However this type of sling surgery close to the membranous urethra requires a deeper dissection compared to that needed for bulbar or perineal urethra compression slings. Over the past few years, there have been several case series reporting greater than 2-year follow-up. Success rates are generally between 50 and 80%, with cure/dry rates averaging 50%. An early report from the Cleveland Clinic showed diminished efficacy over time, with patient-determined success decreasing from 87.3% to 62.5% with the retroluminal sling, with average daily pad use more than doubling over 2 years postoperatively.[228] However, others have shown sustained efficacy over time. Rehder et al[229] followed 156 patients with varying degree of incontinence (24% 1-2 ppd, 40% 3-4 ppd, 35% ≥ 5 ppd) for a median of 36 months. 53.0 % were cured, and an additional 23.8% were improved, with 23.2% considered treatment failures. Mascle et al[230] reported their 66 patients with an average of 3 years follow-up, and 39.4% achieved continence, with an additional 40.5% improved. Interestingly, success related strongly to degree of preoperative leakage, with 94%, 74% and 56% achieving surgical success with mild (1 ppd), moderate (2-3 ppd) and severe (>3 ppd) leakage. In another report of the TO male sling with > 2 year follow-up, similar efficacy was demonstrated, with 80% success, which similarly varied with the degree of incontinence. 86% success was achieved in those with < 100 g/d leakage, vs only 40% success in those with > 400 g/d leakage.[231] Kowalik's group also showed a 60% cure rate and 13% improvement rate in 30 patients with median 39 months follow-up, also with the finding that higher pad weight (in this report > 200 g/d) predicted surgical failure.[232]

The I-Stop TOMS, another transobturator sling, differs from the AdVance sling in that it has four arms and a larger surface area of mesh placed over the bulbar urethra, and relies on tensioning each corner of the sling. In addition, the bulbar urethra is not detached from the perineum, so urethral repositioning does not occur. Rather, the sling is compressive at the bulbar urethra. A prospective multicenter study[233] was recently published with 122 patients after minimum follow-up of 12 months for 84% of them, and showed a cure rate of 60% and improvement with only one pad per day in 20%. There were no erosions or acute urinary retention. Wound infection was reported in 2% and all resolved. In a smaller cohort of 40 patients, who were followed for 2 years, 45% realized a successful outcome at 6 months, but this diminished to 38% at 24 months. There were no reported complications.[234] A different "inside-out" TO sling also positioned over the bulbar urethra[235] was implanted in 173 men, of whom 49% were cured and an additional 35% improved at a median follow-up of 24 months.[236]

For the TO sling, transient urinary retention has been reported in 3 to 23%, typically resolving by 12 weeks.[237] Perineal pain rates vary widely from 0 to > 20%, depending on the definition of postoperative pain, but most reports show significant pain in < 10% of patients, which resolves by 3 months postoperatively.[238,239,240] Serious complications requiring sling explantation are rare, and are generally reported as < 1%.[237]

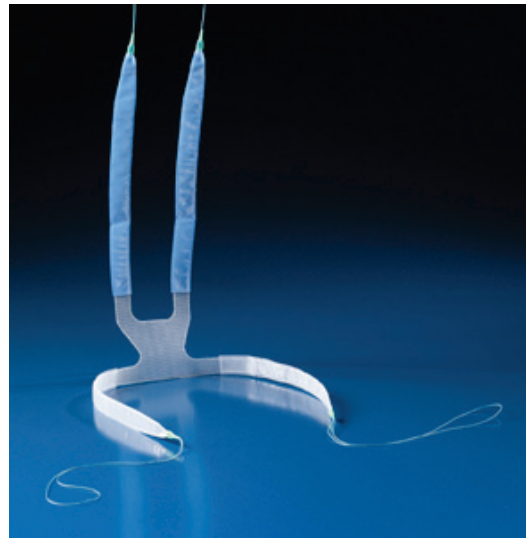

Figure 4. Virtue sling

The newest iteration of the nonadjustable male sling is the VIRTUE® Male Sling (Coloplast, Humlebaek, Denmark) -- an implantable, sub-urethral, permanent, non-absorbable support sling (Figure 4). The sling is a synthetic suburethral mesh made of knitted, monofilament polypropylene that measures 5.5 cm x 7 cm, with superior and inferior extension arms. Quadratic fixation is achieved with both transobturator and prepubic (PP) components.[224] This hybrid sling is based upon the mechanisms of action of the TO sling and the BAMS, providing a broad area of urethral compression *and* achieving proximal relocation of the membranous urethra. The sling has been shown to increase the retrograde leak pressure in 22 patients from 33.4 to 68.8 cm water after tensioning intraoperatively, with an increase in urethral resistance from both the TO component *and* the PP component.[40] In a multinational study comparing the original surgical treatment to a revised procedure with a novel fixation

mechanism, 1 year success improved from 41.9% in the unfixed cohort to 79.2% in the fixation group. Furthermore, pad weight reduction of 88.3% was realized after 1 year in the fixation group, compared to only 51% reduction in the unfixed cohort.[241] However, McCall et al[242] reported higher failure rates (68%) in the long-term (mean follow-up = 55 months). According to this retrospective series, failure was more likely in patients with external beam radiation therapy (*P*=0.02) and there was no association of procedure failure with age (*P*=0.65) or severity of incontinence (*P*=0.17). However, there appear to be differences in the surgical technique between these studies and thus a direct comparison may not be possible. Other studies are ongoing at this time.

Three adjustable retropubic slings have recently been introduced, with the objective of overcoming potential problems of overcorrection or under correction of continence: the "Argus",243 REMEEX244 and ATOMS245 slings. The Argus suburethral sling is composed of a silicone cushion attached to two silicone cone columns that are passed with needles through the obturator foramen from the perineum to both inguinal areas.246 In a multicenter trial of the Argus sling in 48 patients,246 a 73% continence rate and additional 10% improvement rate was reported after an average of 7.5 months. Erosion and infection necessitated sling removal in 10% of patients. Adjustments were indicated for persistent incontinence as well as for urinary retention.246 In an update reported of 47 patients after a mean follow up of 45 months, 66% were dry and 79% used ≤ 1 pad per day.247 Hubner's group248 reported similarly favorable results, with 79% of 101 men achieving dryness at an average of 2.2 years postoperatively. Thirty-nine percent required adjustment (10% loosening, 29% tightening) at a mean of 104 days after surgery. Erosion or infection necessitated explantation in 16% at a mean of 1 year. A report from the Netherlands249 revealed a 72% success rate for the Argus at a median follow up of 27 months. Outcome was dependent on the degree of preoperative incontinence, with surgical success in 92% of men with mild leakage (1-2 ppd), 67% in men with moderate leakage (3-5 ppd) and 67% in those with severe (> 5 ppd) incontinence. Explantation was required in 11%, due to infection, erosion, sling rupture or pain. Bladder perforation occurred in 16%, and de novo urethral stricture requiring treatment in 12%. Dalpiaz et a250 reported less favorable results, with 79% of 29 patients achieving dryness and 76% satisfaction in the short term, but the dry rate and satisfaction rates deteriorated to 17% and 28% respectively at 35 months. Complications occurred in > 80% of cases, with a 35% explanation rate, 14% de novo urgency rate, and a single instance each of urethral stricture and ureteral injury. In a retrospective cohort study of 16 men status post AUS explantation for erosion,251 who were treated with an Argus sling or repeat AUS, men receiving the AUS had a better outcome. Of those who underwent repeat AUS implantation, 63% were cured, and an additional 25% were improved, with only 12% failing. Notably 75% of the Agus patients failed to improve. The most recent report of the Argus sling involved a prospective 2-center study of 42 patients with varying degrees of leakage (range 53-885 g/d) who had a transobturator adjustable device. At a mean follow-up of 28.8 months, results of this sling were similar to the results of the retropubic device: 61.9% were dry, 26.2% of patients were improved, and 11.9% failed. Median adjustments were 1.7 per patient, and there were no instances of acute retention. Three wound infections were managed surgically, but did not require device explantation.252

The REMEEX adjustable sling is composed of a monofilament suburethral sling connected to a suprapubic mechanical regulator with two monofilament traction threads. The mechanical regulation part, the varitensor, is a subcutaneous permanent implant, which is placed over the rectus fascia 2 cm above the pubis; the implant allows adjustment of suburethral pressure from outside the body by means of an external manipulator.[244,253] In a prospective multicenter Phase II trial of the REMEEX adjustable sling, 51 patients were followed for an average of 32 months (range: 16-50). With 90% of patients requiring at least 2 adjustments, a continence rate of 64.7% was achieved, with an additional 19.6% reporting improvement over baseline.[Error! Bookmark not defined.] More recent, but maller studies have also shown promising results. Navalon Verdejo et al[254] reported that 3 of 5 men were dry at an average of 1.4 months, with the other 2 patients experiencing marked improvement. Four of 5 patients experienced recurrent SUI, which was resolved after surgical re-adjustment via the varitensor. A study with lower success rates was reported from Spain with a cohort of 14 men at an average of 18.6 months postoperatively, 42% are dry and 33% are improved.[255] However, bladder perforation occurred intraoperatively in 29%, sling explantation was required in 21%, urinary retention occurred in 36%, and readjustment was necessary in 83%.

The newest adjustable sling is the ATOMS system, composed of a transobturator-placed mesh tape with a soft inflatable silicone cushion, connected to a refillable inguinal titanium port. Adjustments are made via inflation of the silicone cushion rather than by manipulation of the sling arms. In a single center cohort study of 36 patients, only 38.9% achieved social continence. Furthermore, an explantation rate of 27.7% precludes the widespread adoption of this experimental device.[256]

Sling results are shown in Table 4[49,50,57,209,212,213,214,216,217,218,219,220,221,244,246,257,258,259,260]

BAMS = bone-anchored male sling

4.2.1 Adjustable vs Nonadjustable Slings

While there are few studies comparing the nonadjustable vs the adjustable male sling procedures, overall, the two types of slings appear equally efficacious. Author-reported success for the fixed slings generally ranges from 54-91% (average=76%) for the fixed sling compared to 28-100% (average=78%) for the adjustable models. Whereas the adjustability does not appear to increase the overall efficacy of the surgery, it does, by definition, increase the need for surgical revision/tightening. In one nonrandomized study comparing outcomes of an adjustable (Argus) vs nonadjustable (AdVance) sling, more patients chose the adjustable device (25 vs 19). With mean follow-up of 36 and 33 months respectively, there was no statistically significant difference in continence or satisfaction rates. However, the Argus group had a 24% surgical revision rate, vs only 5% in the AdVance group.[261] Thus, it does not appear that adjustability improves continence compared to a fixed male sling placed with proper tension with adequate fixation.

4.2.2 Sling Complications

Due to the small size of most reported cohort series of BAMS patients, the precise complication rate is not known.[259] However, reports from the largest cohorts of patients reveal an infection rate ranging from 0-6%, and a urethral erosion rate of 0-2%.[50,217,259] Bothersome scrotal pain or numbness affects 16%-72% of patients postoperatively, but has been reported to resolve in nearly all patients by 3 months.[217,221] Postoperative urinary retention was reported in 2-12% of patients. In most cases, it was self-limited and resolved in within 2 weeks[54,220,222,260,262] or rarely required loosening after one month.[50]

Infection of the perineal incision/mesh occurred in 3-12%. These infections usually required removal of the implanted sling. Some superficial infections were successfully treated with antibiotics. In men with postoperative mesh infections, 76% (19/25) required surgical explantation of the sling.[54,217,221,222,259,262,263] The majority of infections occurred early; however, late infections at 3 months and 1 year have been reported.[54,222]

Urethral erosion is a well-defined complication in the female SUI population. It has not been frequently reported with any type of male sling; although, there are case reports for erosion of the bone-anchored sling, the retroluminal sling, and the adjustable sling, yet no such instances of erosion have been reported for the quadratic sling.[253,247,264] Pre-existing risk factors for sling erosion have not been established, but have been ascribed to unrecognized iatrogenic urethral injury.[265] It has therefore been suggested that inside-out trocar passage minimizes the risk of iatrogenic urethral injury.[266]

Abnormal postoperative pain or paresthesia is thought to be from compression or intraoperative disruption of the perineal nerves, or from healing around the newly placed bone screws. This complication is difficult to characterize because there is no standard level of pain that is considered abnormal. While some series acknowledged that the majority of patients experience mild pain for 1-3 months after surgery,[259] others reported only those with severe pain that required explantation of the sling.[260] The pain generally resolves within 3 months [217,219,222,259,262] although persistent pain beyond 3 months has been reported.[50,54] Sling removal has been reported in two patients for persistent pain.[50,54]

De novo detrusor overactivity or urinary urgency has been reported in 1-14% of patients, and can be treated with oral anticholinergics when necessary. One patient required sling explantation due to this complication.[54]

While the bone-anchored sling is rarely performed anymore, bone screw dislodgement can happen as a late complication and has been reported in 3 patients.[217,262,267] This caused recurrent incontinence and in such rare instances, the bone anchor may be replaced, and the sling tension can be re-established.

The most common complications reported with the TO sling are perineal pain and urinary retention and studies are needed to establish the best rates between success and side effects among different slings. Pain beyond the normal perioperative period has been reported to affect 0-20% of patients, and urinary retention has been reported in 3-21% of cases. While incision or explantation for retention is rare, the need for catheterization can persist for up to 12 weeks,[238,268,269] with rare instances of retention lasting > 3 months.[270] Less commonly experienced is wound infection, with only rare sling infection or erosion requiring explantation.[264,269,271] Unlike the BAMS, however, there are occasional instances of worsening incontinence following TO sling placement, which likely occur if the sling is not adequately fixed in position, and allowed to migrate proximally and posterior to the urethra, thereby exerting a pulling effect that opens the dysfunctional urethral sphincter.[271,272]

Rates of recurrent incontinence following successful sling surgery are generally low.[50,217,220,273] However, up to 13% of patients who undergo sling placement

will ultimately receive an AUS.[192] Rather than routinely offering AUS for sling failure, there have been recent cohort studies regarding repeat sling surgery in the patient who has failed primary sling placement. Soljanik et al[273] reported a cohort of 35 men undergoing a second TO sling. Success rate at 6 months was 79% (46% dry, 33% improved), and was maintained at 76% at an average of 16.6 months, demonstrating that the TO sling may be an effective treatment for managing SUI after a prior failed sling surgery. There was one urethral injury and a 23.6% rate of urinary retention, neither of which adversely affected the surgical outcome. Of note, all patients had a positive repositioning test, and were deemed appropriate candidates for repeat sling placement.[273] Martinez et a[274]l reported their cohort of men who received a salvage TO sling, and noted that in men who either did not realize sling efficacy or who had early sling failure (< 6 months), success with salvage surgery was lower (20% cure, 20% improved) vs the success rate in those who had initially achieved continence, but developed recurrent leakage later (> 6 months). This latter group realized a 62.5% cure and 12.5% improvement rate at 1 year following repeat sling surgery.[274]

4.2.3 Predictors Of Success

As the male sling has realized increased popularity, and has become the most common procedure offered for the treatment of PPI,[192] there is a growing body of literature identifying those factors that predispose to sling failure. Several cohort studies have demonstrated that prior radiation therapy is associated with diminished efficacy of the male sling, probably due to urethral fibrosis and inadequate urethral coaptation.[53,212,219,221,236,253,275,276,277] A history of prior urethral stricture,[278] pelvic radiation,[209,259,279,280] or prior incontinence surgery[218,251,259,281] decreases sling efficacy.

Urodynamic predictors of failure include the presence of a short functional urethral length, a low maximal urethral closure pressure and abdominal leak point pressure,[282] and a negative repositioning test.[283] Pretreatment severity of incontinence measured by the degree of leakage also appears to influence sling results. Several reports indicate that those with more severe leakage do not achieve similar continence rates when compared to those with milder leakage.[219,221,259,263,284,285] Fischer and colleagues[50] were able to quantify, in prospective fashion, that leakage greater than 423 gm on preoperative pad weight predicted an inferior outcome, compared to those men with less leakage on preoperative pad weight test. In their report, 62 patients with SUI were followed prospectively. All patients were rigorously evaluated with 24-hour pad test, urodynamics and validated incontinence questionnaires. Success was determined by the Patient Global Impression of Improvement. Overall, 36/62 (58%) of surgeries were successful at a mean follow-up of 15 months. The only preoperative predictive factor was 24-hour pad weight. If pad weight was less than 423 gm, there was a 6-fold greater success rate compared to those with a preoperative pad weight of greater than 423 gm.

Finally, there are technique-associated drivers of success. The use of organic (resorbable) material is less efficacious than synthetic (permanent) sling material.[219,221,259,286] The treatment of male SUI with a suburethral sling requires tension that can only be maintained with the use of synthetic material. In addition, poor suture fixation of the TO sling and failure to adequately tunnel the sling arms are also related to poor efficacy.[266,278] Similarly, the quadratic sling without proper fixation has a substantially lower success rate than does the sling with properly fixated prepubic and transobturator sling components.[266]

Conclusion

In the intermediate term, the male sling appears to be a reasonable option. Slings have surpassed the artificial sphincter as the most common surgical treatment for PPI. The European Association of Urology Guidelines has concluded that there is limited short-term evidence that fixed slings cure or improve post-prostatectomy incontinence in patients with mild to moderate incontinence (LOE 3) and that men with severe incontinence, previous radiotherapy or urethral stricture surgery may have poorer outcomes (LOE 3). Additionally, there is no evidence that one type of male sling is better than another (LOE 3) and there is no evidence that adjustability of the male sling offers additional benefit over other types of sling (LOE 3). However, in the UK, the National Clinical Guidelines Centre in The Management of Lower Urinary Tract Symptoms in Men has stated that implanted compression devices and slings can be offered to men with SUI within the context of a randomized clinical trial.[287]

The best candidates appear to be those with lower and moderate degrees of incontinence, who have neither had previous radiation nor AUS placement. With non-circumferential urethral compression, the male sling appears to have a lower risk of urethral erosion and atrophy than does the AUS in the intermediate term. In men with mild to moderate degrees of SUI, or for patients demanding a less invasive procedure or non-mechanical device, the male sling has established itself as a viable alternative to the artificial sphincter. When given a choice of surgery, patients have been reported to overwhelmingly choose the male sling over an artificial urinary sphincter. Kumar et al[6] reported that in men with moderate PPI (pad weight 100 to 400 gm/24 hours) who were recommended to receive an AUS or a male sling, 92% opted for the sling. Interestingly, even when the surgeon recommended an AUS for severe leakage (> 400 gm/24 hours), 25% still opted for the sling. Intermediate and long-term data support the BAMS and transobturator male sling as durable treatments for PPI, while short-term outcomes of the quadratic sling

are also favorable. (**Level of evidence 3; Grade of recommendation C**)

4.3. Artificial Urinary Sphincter

The artificial urinary sphincter remains the most effective long-term surgical treatment for post RP incontinence due to sphincteric insufficiency (Figure 5). However, due to the cost, the perceived cumbersomeness of the device with resultant patient reluctance to have or inability to use a mechanical implant, and the fear of complications, it is not suitable for all patients. In addition the development of less invasive techniques (as described above) potentially gives patients new options for treatment. Ultimately the choice of AUS will be based upon patient dexterity, economics, degree of incontinence, previous incontinence surgery, and expectations from surgery. Patient preference was tested in a study by Kumar et al.[6] Based on the magnitude of their incontinence patients either had an AUS (high grade incontinence) or sling (low grade incontinence) or a choice between the two (moderated grade incontinence) recommended. Outcomes, length of experience and complications were reviewed with the patients. Of interest, all recommended to have a sling chose a sling, 75% recommended to have an AUS had an AUS while of those given a choice 92% chose a sling. This sheds some light on patient preferences in this area.

The AUS has the longest track record of success in the treatment of PPI. Two older studies have reported that about half of the patients with severe incontinence will undergo AUS implantation.[288,289] However, these studies were conducted before male slings and bulking agents became popular, and sling surgery has since surpassed the AUS in number of procedures performed annually. To this end, it is likely that the advent of the male slings has increased the rate of surgery in men with milder incontinence who may not otherwise have opted for an artificially sphincter. The success rates for AUS as defined by a continence status of zero to one pad per day ranges from 59% to 90%,[290,291] as shown in Table 5.[60,290,292,293,294,295,296,297,298,299,300,301]

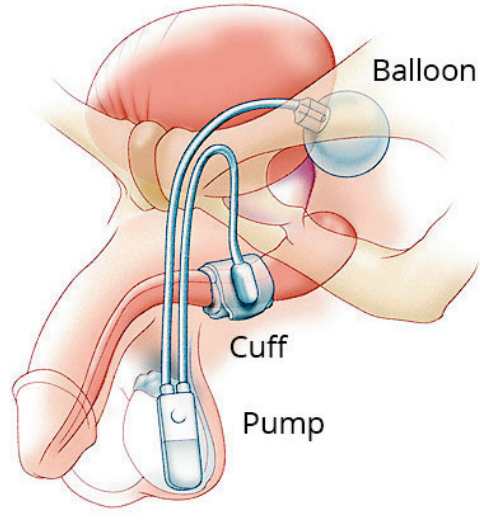

Figure 5. Artificial urethral sphincter

TABLE 5. Results of the Artificial Urinary Sphincter in Post-Radical Prostatectomy Incontinence

Authors	N	Follow-Up (yrs)	0 or 1 pad/day
Fleshner & Herschorn[294]	30	3	87%
Goldwasser et al[299]	42	1.2	82%
Gousse et al[306]	71	7.7	59%
Haab et al[298]	36	7.2	80%
Hoy et al[319]	48	24	88.2%
Kim et al[300]	124	6.8	82%
Klijn et al[297]	27	3	81%
Lai et al[301]	218	3.1	69%
Lim et al[320]	13	29.8	72.7%
Madjar et al[296]	71	7.7	59%
Martinez-Salamanca et al[975]	32	1	96%
Martins & Boyd[293]	28	2	85%
Montague[292]	66	3.2	75%
Mottet et al[295]	96	1	86%
Perez & Webster[290]	49	3.7	85%
Trigo Rocha et al[60]	40	4.5	90%

Just as reported rates of incontinence following prostate cancer surgery depend on the definition of incontinence, continence rates with the AUS can vary with the definition of continence, the method of evaluation, and the length of follow-up. The lowest rates are from patient administered questionnaires when pad free rates range from 10-72%.[293,302,303,304,305,306] Nevertheless, high satisfaction rates of 87% to 90% are consistently reported, even without total continence.[294,298,302]

One potential downside of the AUS is the need for periodic revisions in a number of patients. Revision and explantation rates due to mechanical failure, urethral atrophy, infection and erosion vary considerably among studies with respectively reports of 8-45% and 7-17%.[306] In a large cohort reported by Lai and colleagues,[301] non-mechanical failure decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff and mean time to reoperation was 26.2 months (mean 2-68 months). With a Kaplan-Meier analysis, the overall 5-year expected product survival was 75%. Only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years. Actuarial freedom from revision at 5 years was estimated at 50%-75%. Interestingly, there do not appear to be any urodynamic factors that predict AUS failure in men with ISD. Whereas the male sling has been shown to have inferior success rates in patients with severe leakage, the AUS has been reported to have predictable success regardless of the degree of incontinence and regardless of detrusor hypocontractility, detrusor overactivity, low abdominal leak point pressure, or diminished compliance.[62] While the success of the AUS in treating incontinence is not adversely affected by preoperative detrusor overactivity, the rate of persistent overactive bladder symptoms may be high (71%), and patients must be counselled accordingly.[307]

The long-term efficacy of the AUS was demonstrated by Fulford et al[308] who reported that at 10-15 year follow-up, 75% of patients with an implanted AUS either had died or died with a functioning device. Revisions include replacement of the malfunctioning part, cuff replacement, repositioning or downsizing due to urethral atrophy, a second or tandem cuff[309,310] or transcorporal cuff placement.[311] Transcorporal cuff placement, which involves inserting the cuff through the corporal bodies to avoid perforating the dorsal aspect of the urethra, can be particularly useful for patients with prior radiation or urethral erosion; however potency, if present, may be compromised. Some have advocated tandem cuffs not only as a salvage procedure, but also as a primary procedure for men with severe incontinence.[312,313] However, O'Connor et al reported no difference in continence outcome and a higher revision rate in patients undergoing double-cuff implant vs single-cuff after longer follow up.[314]

There is conflicting evidence regarding whether or not there is an increased revision rate for patients who received pelvic radiation.[291,293,315] A recent report, however, showed that the relative risk of erosion is significantly higher in those who had radiotherapy compared to those who did not – RR 4.05, 95% confidence interval (CI) 1.1-15.3 – and that this risk of erosion has not diminished despite improvement in radiation technique and equipment.[316] The results of continence for radiated patients are variable with some studies showing lower success rates[290,315] while others do not.[305] A recent report on the artificial sphincter in patients with a "fragile urethra" (history of radiation, prior urethroplasty or prior AUS) demonstrated outcomes similar to those reported for low risk patients – with continence achieved in 77% and improvement in 97%, with explantation secondary to erosion in only 7%.[317] It has been recommended that such patients have a lower pressure reservoir and/or longer period of deactivation time.[293]

5. EVIDENCE BASED COMPARISON OF AUS AND SLINGS

There are few comparative studies of the artificial sphincter and the various male slings, and no prospective randomized trials comparing the devices. However, there have been some recent cohort studies comparing outcomes of the AUS with those of specific male slings in certain patient populations. While no one device is preferred in all patients in all clinical situations, there are some recommendations made in the literature regarding the preferred treatment in certain patient populations depending on prior radiation, prior incontinence surgery, degree of urinary incontinence, and bladder contractility.

Adequate urethral tissue compliance is necessary for successful urethral compression and/or proximal repositioning with a sling. Radiation and previous AUS explantation, both of which may result in a relatively non-compressible urethra, are associated with diminished sling efficacy. It has been reported that 13% of men who have sling surgery will ultimately be treated with an artificial urinary sphincter.[192] There is no evidence, however, that the efficacy of the AUS is diminished in those with prior sling placement. While there are trials of repeat sling surgery in those who have failed initial sling placement,[274,273] the AUS has a substantially higher success rate than does repeat sling placement, as the risk of persistent incontinence is six times higher with repeat sling than with AUS implantation.[318] It is, therefore, the Committee's recommendation that with the exception of the occasional patient with persistent mild to moderate SUI following prior sling, with a positive repositioning test, AUS implantation is the treatment of choice for persistent PPI because it can provide the circumferential urethral compression necessary for adequate coaptation even in the setting of diminished urethral compliance.

In men who have not been radiated and have not had prior incontinence surgery, factors such as degree of leakage, proximal urethral mobility, and detrusor con-

tractility can help determine the preferred surgical approach. In a retrospective review of 124 patients with mild to moderate PPI (≤ 5 pads per day), 76 of whom underwent TO sling surgery vs 48 who underwent AUS placement, Hoy et al showed relative equivalence in surgical outcome. Specifically, there was no statistical difference in continence (88.2% vs 87.5%), satisfaction (93% vs 92%) or complication rate (19.7% vs 16.7%). However, those complications associated with the AUS were more severe than those following sling surgery.[319] In a comparison of men with mild-moderate PPI receiving AUS (N=20) or adjustable TO sling (N=20), Lim et al[320] reported no statistically significant difference in efficacy (72.7% vs 85% success). However, there was a greater rate of pain reported in the adjustable sling group (30% vs 7.7%), and sling explantation was required three times more often in the sling group.

In those with mild to moderate leakage and a positive repositioning test or adequate urethral mobility on video urodynamics, a compressive or transobturator sling is a reasonable approach, with lower complication rates compared to AUS placement and without an adverse effect on future AUS placement. With detrusor underactivity, the TO sling may be preferred versus a compressive sling, given its non-compressive mechanism of action. In the setting of detrusor underactivity in this group with moderate incontinence, AUS is preferred. With leakage > 400 g/day (moderate to severe), AUS is the recommended option, however a compressive sling is also a reasonable alternative in the patient who does not desire an AUS.

Conclusion

The AUS (AMS 800) remains the most predictably successful surgery for the treatment of PPI secondary to sphincteric insufficiency in patients with severe incontinence, in those who have had external beam radiation treatment and in those who have had prior sling or AUS implantation (**Level of evidence 2; Grade of recommendation A).** It has the largest body of literature reporting long-term success and this success and high patient satisfaction seem to outweigh the need for periodic revisions in some patients. Intermediate term data with the male sling demonstrates that the sling is equally efficacious with a lower rate of severe complications in patients with mild-moderate SUI, provided that those patients have not failed previous AUS surgery, have not had radiation treatment, and have normal bladder contractility. **(Level of evidence 2; Grade of recommendation B)**

6. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of PPI, either with benign or malignant disease. Therefore, at present guidelines as to timing of the surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. Observational studies of men following prostate cancer surgery typically demonstrate improvement in continence from the early postoperative period until the end of the first year.[119] In addition, it is common for clinical trials of non-operative management to follow patients for up to 12 months postoperatively, usually with improvement in both the intervention and the control groups during that year of follow up.[170] In a prospective cohort study of men undergoing RRP, Lepor and Kaci[80] demonstrated continued recovery of continence up to 24 months postoperatively, from 80.6% at 3 months to 95.2% at 12 months, plateauing at 98.5% at 24 months. Other cohort studies have demonstrated a plateau in continence rates at 12 months.[321,322] Since continence may improve up to 12 months postoperatively, and possibly even until 24 months, it is generally recommended that behavioral/conservative management be utilized during the first year after prostate cancer surgery. However, a recent consensus group recommended that in patients experiencing no improvement in SUI symptoms at 6 months it is reasonable to proceed with intervention at that point.[866]

There have been some studies evaluating the effect of early interventional treatment for incontinence. Schneider and colleagues[323] demonstrated a beneficial effect on the earlier return to continence with early injection of periurethral bulking agent. Results were better in the subgroup of 34 patients that were injected early (mean 23 days postoperatively) compared to 10 patients treated at a mean of 26 months postoperatively. It could not be demonstrated, however, that long-term continence is improved by early injection of bulking agent. Similarly, Jones and colleagues[324] demonstrated in a comparative cohort study of RRP patients treated either with or without a simultaneous suburethral sling, that sling placement at the time of RRP resulted in an earlier return to continence. There was no difference after 24 months. **(Level of evidence 4; Grade of recommendation C)**

IV. INCONTINENCE AFTER PROSTATECTOMY FOR BENIGN DISEASE

1. INCIDENCE AND RISK FACTORS

The incidence of urinary incontinence after prostatectomy for benign disease has been reviewed and described in the AHCPR "Benign Prostatic Hyperplasia" Clinical Practice Guidelines.[325] The following rates of

stress incontinence and total incontinence, respectively, were reported:

- Open surgery (retropubic or transvesical prostatectomy): 1.9% and 0.5%.
- TUIP (transurethral incision of the prostate): 1.8% and 0.1%.
- TURP (transurethral resection of the prostate): 2.2% and 1.0%.

These figures were based on studies reported before 1990. Several other series were published after 1990. These series were reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence.[7,326,327] A clear description of the method of follow-up and assessment of the continence status was indicated in only about one third of these studies. The incidence of incontinence after open surgery, TURP, TUIP and HoLEP is low: the reported percentages ranged between 0 and 8.4%. Since the method of assessment of the continence status and the definition of incontinence is rarely stated it is actually not possible to make a distinction between stress, urgency and mixed urinary incontinence. On the other hand, the category urinary incontinence represents a heterogeneous group of adverse events, including total and partial urinary incontinence, temporary or persistent incontinence.[328] There is generally no clear indication that the incidence is affected by patient age or (resected) prostatic volume.[326] However, a recent study out of Brazil did demonstrate that the rate of urinary incontinence following BPH surgery is higher in older patients. Most of the increased incidence in incontinence was due to bladder dysfunction rather than to sphincter insufficiency. In a retrospective chart review from Wendt-Nordahl and colleagues,[329] the incidence of incontinence following TURP was reported to have decreased over 17 years, from 3.3% in 399 patients operated on between 1987 and 1997, compared to 1.3% in 550 patients operated on from 1997-2004. It is not clear whether this statistically significant ($P < 0.05$) difference was due to improvement in surgical technique or patient characteristics. However both the earlier and later incontinence rates are consistent with those in the AHCPR and AUA guidelines reports.

In 2003, the AUA published guidelines for the management of "benign prostatic hyperplasia".[330] The estimated frequency of incontinence following TURP was 3% (from 19 trials that included > 5000 patients). However, the Veterans Affairs Cooperative Study, reported an incontinence rate of only 1% in TURP patients, which was not different from the watchful waiting arm.[331] The AUA conducted a meta-analysis of RCTs comparing TURP with TUIP or transurethral electrovaporization, which did not reveal any statistically significant differences in incontinence rates.[330,332,333,334,335,336] According to the 2010 AUA updated guideline,[328] urinary incontinence was reported at rates between 0.5% and 8% after open prostatectomy, with several studies[337,338] reporting much lower rates of permanent incontinence.

However, this update[328] provided limited additional information on incontinence. Randomized controlled studies involving HoLEP compared to TURP presented controversial information. Urinary incontinence rate was similar in one study,[339] while in another series[340] it was reported as increased in the HoLEP population. The AUA Panel recognized that this rate was higher than expected but felt the general urologist's experience with HoLEP was less than other technologies and the report warranted observation.

In the past 2 decades, a wide range of innovative transurethral procedures have been introduced in urological practice and challenged the supremacy of the two standard surgical options (monopolar transurethral resection of the prostate and open prostatectomy). These alternative transurethral procedures comprise laser therapies (enucleation, vaporization, and resection techniques) and bipolar devices permitting bipolar TURP or bipolar enucleation.[341]

Transurethral holmium laser enucleation of the prostate (HoLEP) has become a standard treatment for BPO. Review of RCTs by the AUA as well as a meta-analysis of early RCTs comparing TURP with HoLEP did not reveal any significant differences in incontinence rates.[330,336,342,343,344,345,346,347,348] While incontinence did not increase with age in men undergoing HOLEP with morcellation, it was noted that the overall complication rate—including bladder mucosal injury, urethral stricture disease, and bladder neck stenosis was higher in patients with prostate volumes > 50 g.[349] Moreover, it does not appear that either bipolar resection of the prostate or photovaporization of the prostate are associated with a substantially different rate of urinary incontinence than are other BPH surgeries.[350] While incontinence following PVP is comparable to that of other BPH surgeries, and more often than not improves over 12-36 months postoperatively with conservative management, the rate of postoperative dysuria is higher than that of TURP, recently reported at a rate of 10.1%.[351]

Concerning HoLEP, Vavassori et al[349] reported the outcomes of a prospective study assessing safety, efficacy, and medium-term durability of this technique combined with mechanical morcellation. Three hundred and thirty patients were followed for 3 years. Transient stress urinary incontinence was reported in 7.3% of patients. Incontinence typically resolved spontaneously within 3 months except in two patients who experienced persistent stress urinary incontinence at 36-month follow-up.

Nam et al[352] investigated the factors associated with occurrence of recovery from transient urinary incontinence (TUI) in 391 patients who underwent HoLEP. TUI after HoLEP occurred in 65 patients (16.6%), 52 patients of whom (80.0%) showed recovery within three months. Stress and urgency urinary incontinence and postvoid dribbling occurred in 16 patients (4.1%), 29 patients (7.4%), and 33 patients (8.4%), respectively. Age (odds ratio [OR]=3.494; 95%

CI=1.565 ~7.803; *P*=0.002) and total operation time (OR=3.849; 95% CI=1.613~9.185; *P*=0.002) were factors that significantly affected the occurrence of TUI.

Summary of Comparative Studies Published in the Last Decade

Electrovaporization With Monopolar Energy vs TURP

According to a systematic review[353] and meta-analysis conducted by the Ontario Health Technology Advisory Committee, which included twelve RCTs comparing electrovaporization using monopolar energy with TURP (mean sample size of 104; range 50–235), 622 and 623 patients were randomized to electrovaporization and TURP respectively. Mean follow-up ranged from 6 months to 5 years. Rates of urethral stricture and UI were also similar between the techniques. UI occurred in 3.9% and 3.7% of electrovaporization and TURP patients, respectively. Overall incidence of 'irritative' urinary symptoms was 16.3% in electrovaporization and 11.7% in TURP patients.

HoLEP vs TURP

A meta-analysis included 4 RCTs,[345,346,348,353,354] with sample sizes ranging from 61 to 200, comparing HoLEP to TURP. Overall, 233 and 228 patients were randomized to the HoLEP and TURP arms, respectively, and were followed for 1 year postoperatively. The mean prostate size reported by these studies ranged from 53.5 to 77.8 mL in HoLEP patients and from 49.9 to 70 mL in TURP patients. Stress incontinence occurred in four patients (1.7%) who underwent HoLEP and in three TURP patients (1.3%). Rigatti et al[354] reported that 25 (44%) of the HoLEP group and 17 (38.6%) of the TURP group also developed urgency incontinence. Two of the trials reported that postoperative 'irritative' voiding symptoms (described as burning) were more frequent in the HoLEP arm compared with the TURP arm. Rigatti et al[354] reported 'burning symptoms' in 33 (58.9%) of the HoLEP patients and 13 (29.5%) of the TURP patients. Gupta et al[345] reported a higher rate of 'dysuria' in the HoLEP arm (10%) compared with the TURP arm (2%).

Another systematic review and meta-analysis was conducted by Tan et al[340] and included four studies. No statistically significant differences between pooled estimates were noted between HoLEP and TURP for stress urinary incontinence (1.5 vs 1.5%; *P*=0.980).

Wilson et al[355] compared HoLEP with TURP for men with bladder outlet obstruction (BOO) secondary to BPH with a minimum of 24-month follow-up. Sixty-one patients were randomized to either HoLEP or TURP. All patients had BOO proven on urodynamic studies preoperatively (prostate size 40-200 g). UI was present in 48% of HoLEP patients and 38% of TURP patients preoperatively (not including post-micturition dribbling). Six of the 15 incontinent patients in the HoLEP group and eight of 11 in the TURP group regained continence postoperatively. Only one patient (in the HoLEP group) had new onset SUI noted at 12 months, which had resolved by 24 months. One patient in the TURP group had UUI at 24 months, which did not require treatment.

A RCT[356] with a 4-year follow-up (N = 120) compared HoLEP with TURP. Incontinence occurred in two patients (3.3%) in the HoLEP arm and in one patient (1.7%) in the TURP arm. The incidence of postoperative dysuria was not reported in this study.

HoLEP vs Transurethral Electrovaporization of the Prostate

A study by Gupta et al[345] compared the results of HoLEP, TVR, and TURP. One hundred and fifty patients (50 in each group) were prospectively randomized. Patients in all three groups had comparable characteristics before surgery. Mean operating duration and intraoperative irrigant used for TVR was less than for HOLEP or TURP, and blood loss with HOLEP and TVR was less than with TURP (all $P < 0.001$). Postoperative irrigation, nursing contact time, and catheter duration were significantly less for HOLEP than TURP or TVR, and for TVR than TURP. One patient in the HoLEP arm developed incontinence, compared with none in the TVR arm. Transient dysuria occurred more frequently in TVR patients: five (10%) in HoLEP vs nine (18%) in TVR patients.

Potassium Titanyl Phosphate vs TURP

One RCT[357] (N = 100) with long-term follow-up (3–6 years) compared laser prostatectomy using KTP with TURP in smaller size prostates. The rate of UI was the same in both arms (one patient in each) and none of the patients in this study developed postoperative 'irritating voiding' symptoms to such a degree that additional medications were required beyond those routinely provided upon discharge.

Monopolar vs Bipolar TURP

Cornu et al[341] conducted a systematic review and meta-analysis of functional outcomes and complications following transurethral procedures for lower urinary tract symptoms resulting from benign prostatic obstruction (BPO). A total of 69 RCTs (8517 enrolled patients) were included. At 12-month follow-up, the UI rates (defined in most studies as SUI that appeared after the intervention) were similar following M-TURP and B-TURP.

Greenlaser Laser Photovaporization of the Prostate (PVO) vs TURP

More recently, Bachmann et al[358] published a randomized controlled trial comparing TURP to GreenLight XPS PVP for men with BPO. A total of 291 patients were enrolled at 29 sites in 9 European countries. Patients were randomized 1:1 to undergo GreenLight PVP or TURP. Of the 291 enrolled patients 281 were randomized and 269 received treat-

ment. At 12 months 4 patients treated with GreenLight XPS and 4 who underwent TURP had persistent UI.

Pereira-Correia et al[359] assessed urodynamic parameters and voiding function in BPH patients who underwent PVP (N=10) vs TURP (N=10). In this small case-series, PVP group had a higher postoperative rate of UI when compared to the TURP group ($P < 0.04$). Five (50%) patients in PVP group developed UUI, which was not associated with detrusor overactivity in the urodynamic evaluation (first month after surgery), but had spontaneous resolution between 3 and 12 months postoperatively.

In summary, the incidence of UI after open surgery, TURP (monopolar and bipolar), TUIP, and laser therapies (including enucleation, vaporization, and resection techniques) is low, and does not differ appreciably among the various techniques. Lower urinary tract symptoms, such as dysuria and urgency, seem to be prevalent in the early postoperative period after novel laser therapies.

2. TIMING OF SURGICAL INTERVENTION

There are no clear data on timing of a surgical intervention for the treatment of incontinence, as mentioned above in the section on post-RP. Therefore, at present, guidelines as to the timing of surgery cannot be formulated. A certain period of watchful waiting supplemented with conservative measures, particularly pelvic floor physiotherapy, seems to be a reasonable option. More recently, a RCT[360] showed that a Pilates exercise program proved to be as effective as conventional pelvic floor muscle exercises (PFME) to speed up continence recovery in patients with post-RP UI, and could be considered for patients who do not adhere to conventional treatment. Thus, conservative management may be tried for periods of up to 6-12 months depending on whether there is any progress noted by the patient. (**Level of evidence 4; Grade of recommendation C**).

In addition, a study by Filocamo et al[361] demonstrated that pelvic floor muscle exercises, with or without duloxetine, may speed up recovery of urinary continence in selected patients. (**Level of evidence 1; Grade of recommendation A**).

3. SURGICAL TREATMENT OPTIONS

3.1. Artificial Sphincter

The literature on this subject was reviewed for the 1st, 2nd, and 3rd International Consultations on Incontinence.[7,326,327] Candidates for treatment with the artificial urinary sphincter (AUS) are patients with incontinence due to intrinsic sphincter deficiency that have normal bladder compliance.[362] Detrusor overactivity is not a contraindication.[307] The AUS has been placed around the bulbar urethra via a perineal route or transverse scrotal routes[363] or around the bladder neck.[7,326,327] The above mentioned review of the results obtained with the AUS indicated that more than 70% of the men treated with the AUS for this indication are dry or almost dry after a follow-up of more than 2-3 years. However, most series on the AUS include both men with post-prostatectomy incontinence related to benign and malignant disease.[326]

In summary, the AUS is a successful surgical treatment option for post-prostatectomy incontinence. It is the most commonly performed surgery for post-prostatectomy incontinence, with the longest follow-up and therefore longest record of success. **(Level of evidence 2; Grade of recommendation A)**

3.2. Injectable Agents

Most series include post-prostatectomy incontinence after treatment for benign and malignant disease, with the majority after prostate cancer surgery. For collagen, “success rates” range from 36-69%, with 4-20% of patients reporting being dry.[177,178,179,180,181,182,183,184] Study results are inconsistent with both TURP[364] and RP[365] showing better outcomes.

Other bulking agents such as polydimethylsiloxane PDMS (Macroplastique®) have shown some initial success, but results also deteriorate over time. Bugel and co-workers[188] treated 15 patients. They noted rapid deterioration of initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months respectively. As mentioned previously in the section on post-RP incontinence Kylmala et al[189] prospectively studied 50 patients with mild to moderate SUI (average 48 cc on 1 hour pad test), with 12% achieving continence following 1 injection, and an additional 20%, 18%, and 10% achieving continence with 2, 3, and 4 injections respectively. Follow-up, however, was only 3 months. In a randomized trial of AUS vs Macroplastique injection in patients with minimal SUI (the vast majority had SUI following BPO surgery, with less than 1/3 of the cohort suffering from SUI following RP), Imamoglu and colleagues[56] demonstrated no difference in success with AUS vs Macroplastique. However, in patients with more severe incontinence, AUS was superior, with minimal improvement following transurethral Macroplastique. There has also been some initial work with sphincteric injections of muscle stem cells.[197,198]

Bulking therapy fails in up to 75% of men. Of those who are improved only a minority actually becomes dry with short-term follow-up. Although bulking therapy may be slightly more efficacious in treating SUI following TURP compared to SUI following prostate cancer surgery, bulking is of limited value in those men with all but minimal SUI and should only be used when other treatments are contraindicated. **(Level of evidence 3; Grade of recommendation C).**

3.3. Male Sling Procedures

Since Frangenheim[366] described his first successful urethral sling suspension for post-traumatic stress urinary incontinence in 1914, various sling materials and surgical methods have been reported. Rectus fascia, as described by Frangenheim,[366] has distinct advantages over alloplastic materials with respect to erosion and infection risks. Allograft off-the-shelf-materials like lyophilized fascia lata have a higher infection risk than does autologous fascia, whereas the use of synthetic materials like polypropylene mesh or polytetrafluoroethylene slings are associated with a higher incidence of urethral erosion.[367] According to various published techniques, the sling can be placed either underneath the bladder neck, the urethral bulb or the membranous portion of the urethra. The principle of continence support is similar for all sling procedures and comprises passive compression of the urethra, which is dependent on the applied sling tension.[257] This mode of action favours sling procedures as a treatment option for intrinsic sphincter deficiency. However, the sling tension needed for restoration of continence has not been standardized, with tensioning techniques ranging from perfusion sphincterometry, to a cough test, to visual approximation,[219,368] and therefore the success of the procedure probably depends heavily on the surgeon's experience and the degree of sphincteric incompetence. Overcorrection with consequent urinary retention (especially in the setting of detrusor underactivity) and under correction with persistent or recurrent incontinence are certainly possible, which may adversely affect continence, bladder emptying, and patient satisfaction. Most series of sling surgeries deal with a preponderance of men following prostate cancer surgery. Therefore, it is difficult to draw conclusions about any differences in sling efficacy between those with SUI following BPH surgery vs those with SUI following RP due to small numbers of BPH patients most the cohort series.

V. INCONTINENCE AFTER EXTERNAL BEAM RADIOTHERAPY AND SURGERY FOR PROSTATE CANCER

The risk of incontinence after external beam radiotherapy (EBRT) for prostate cancer is variable and ranges from 0 to 23.9%. Lawton et al[369] reported a risk of urinary complications of 7.7% in more than 100 patients, proportional to dose. Perez et al[370] found incontinence in only 5 of 738 patients. Shipley et al[371] reviewed more than 2500 cases with an incontinence rate of 0.5%. Similar incidences have been reported in more recent series. Madalinska et al[81] reported an incidence of 6-7%. With three-dimensional conformal radiotherapy, Weil and colleagues[372] reported no incontinence in 168 consecutive patients and Hanlon et al,[373] in a series of 195 men, found that post treatment urinary symptoms were no different from a control group without cancer. With conformal radiotherapy, Sandhu et al[374] reported a 9% incidence of stress incontinence in 110 patients. The impact of EBRT followed by prostatic boost, for a total of 66-70 Gy, was evaluated. Scalliet and co-workers[375] reported urinary incontinence in 16% of 230 patients, however, Fransson and colleagues[376] reported an increase in urinary incontinence on a patient-administered symptom bother scale 3 years after treatment in 153 men compared to pretreatment status. The increase was from a mean of 0, at the start to 2 out of 10 at 3 years. Ponholzer et al[377] reported incontinence in 18.8% of a group of 82 men who were surveyed 4.4 year after EBRT for prostate cancer. Furthermore urinary incontinence worsened from year 2 to year 6 in a cohort of 147 men treated with 3D conformal RT.[378] Budaus et al[379] conducted a review of radiation series published from 1999-2010 and concluded that early storage symproms are commonly reported but long-term incontinence is not.

Stereotactic body radiation therapy (SBRT) is an innovative form of radiation therapy that is disseminating into practice for the treatment of prostate cancer. Compared with the more standard intensity-modulated radiation therapy (IMRT), SBRT is technologically more intensive and delivers higher doses of radiation per treatment, with an entire course of treatment delivered in up to five visits. In comparison, since IMRT typically delivers a complete course of radiation in 7 to 9 weeks, SBRT may be less expensive overall. The accelerated radiation therapy course associated with SBRT may also mean higher radiobiologic doses than standard fractionated IMRT, which may lead to greater local cancer control[380] and possibly greater toxicity. Yu et al[380] reported in a retrospective national US Medicare sample, that at 24 months, the odds ratio of requiring a workup for either urinary incontinence or obstruction was 2.23 GU of SBRT vs IMRT. Furthermore, Halpern et al[381] reported using the Surveillance, Epidemiology, and End Results (SEER) program and Medicare linked data, that after 2 years, urinary incontinence was seen in 23.9% of patients treated with SBRT vs 19.9% treated with IMRT.

Pre-radiotherapy transurethral prostatectomy (TURP) appears to be a risk factor for incontinence. Jonler et al[382] reported an incontinence rate of 11% with pretreatment TURP. Green et al[383] and Lee et al[384] also reported a higher risk of incontinence with pretreatment TURP vs those without with 5.4% and 2% respectively. In a recent systematic review Ishiyama et al[385] reported that among the 14 papers of the prior-TURP group, 13 demonstrated higher incontinence rates in patients with TURP compared with patients without TURP. Four papers demonstrated a statistically significant increase of incontinence in patients with TURP. One paper also reported a higher incontinence rate with TURP vs no-TURP after EBRT (8% vs 1.5%).[386]

Salvage or adjuvant radiotherapy is frequently given after radical prostatectomy and the impact on continence is controversial. Petrovich et al[387] reported no difference in incontinence in 2 cohorts of patients, one with and one without adjuvant radiation. In a follow-up study the same group reported no late toxicity.[388] Fontaine et al[389] also reported no change in continence status in 16 of 17 men after salvage radiation. However, Petroski et al[390] reported that postoperative radiotherapy worsened continence in 26% of 129 patients followed for a median of 5 years. Sowerby et al[391] reported urinary incontinence at 3 years in 24.5% of 162 men who underwent adjuvant radiation and 23.5% of 490 men who underwent delayed or salvage radiation for prostate cancer. On the other hand, salvage radical prostatectomy following external beam radiotherapy has been generally reported to have a high incidence of urinary incontinence[392,393,394,395] possibly because of radiation induced fibrosis of the external sphincter.[393] In a recent systematic review of 27 series of salvage prostatectomy, Matei et al[395] reported a 47.8% average incontinence rate (range 19%-79%). The incontinence rate was not lower with laparoscopic or robotic approaches. Cozzarini et al[396] demonstrated that older age and greater radiation dose in the salvage setting, and younger age and hypertension in the adjuvant setting, resulted in worse urinary dysfunction

1. SURGICAL TREATMENT

Results of surgical treatment of incontinence in this setting are based on retrospective clinical series. In the past the most commonly published treatment modality was the artificial urinary sphincter as therapy for sphincter damage. As discussed and referenced in the following paragraphs, the series published contain both patients who had and had not received radiotherapy and collagen injections have also been reported in various case series.

Historically there has been a highly variable revision rate of 22% to 55% reported for the artificial sphincter following radiotherapy (Table 6[293,290,291,301,304,315,397,398,399]).

There are also variabilities in reported differences between radiated vs non-radiated patients. Most recent studies have shown similar outcomes after radiation[291,301,400] except for a Canadian study which demonstrated that the relative risk (RR) of erosion was significantly higher in those who had radiotherapy compared to those who did not (RR 4.05, 95% CI 1.1–15.3).[316] Bates et al[401] conducted a systematic review of surgical revision outcomes of 1886 patients from 15 studies and continence outcomes in 949 patients from 11 studies while comparing radiated and non-radiated patients. The AUS revision rate was higher after RP + radiation vs. RP alone, with a random effects risk ratio of 1.56 (95% CI 1.02-2.72; *P*<0.050). However, the authors pointed out that if the largest reported studies which contained approximately 60% of the patients were pooled the relative risk for surgical revision changes to 1.51 (95% CI 0.52-4.38; *P*=0.440) or non-significant. Furthermore, in a large recently reported series of 489 men with 181 having had radiation, Rivera et al[400] reported that on univariate and multivariate analyses radiation therapy was not associated with increased rates of device infection/erosion or urethral atrophy and there was no difference in device survival between radiated and non-radiated individuals (Table 6).

Although recent clinical studies may not have shown significant differences in outcomes, there are theoretical radiation effects on the lower urinary tract that are relevant. There may be radiation induced vasculitic fibrosis of the urethra.[293] Radiation may also induce detrusor overactivity or poor compliance leading to urgency incontinence.[401] Recurrence of bladder neck contracture may be more common.[301] Radiation has also identified as a co-morbidity associated with erosion[402] and infection.[403] In order to avoid problems it is generally recommended that the cuff be inserted outside the radiated field.[404]

Collagen injection has also been reported for incontinence after radical prostatectomy and adjuvant radiation[179,183,364,405,406,407] or after salvage radical prostatectomy following radiotherapy.[186,408] Continence results are poorer compared to those without radiation.[365] Lee et al[190] reported similarly poor results with Macroplastique with success in 1of 4 radiated patients after 6 months.

The male perineal bone-anchored sling has been reported in patients following adjuvant RT. In Comiter's group with the perineal compression sling 3 with radiation had no adverse sequelae.[186] Similarly, in the series of Onur et al[219] radiation did not cause a worse outcome. However, Schaeffer et al[209] reported that prior irradiation was the only identified factor that predisposed to failure. Their success rate following a single sling procedure was only 29% (2/7) for irradiated patients, and the corresponding rate for non-irradiated patients was 68% (39/57).[209] They postulated that the sling acts by compressing and elevating the urethra, thereby increasing urethral resistance to abdominal pressures. Theoretically, radiation-induced fibrosis of the urethral and periurethral tissues would make compression and elevation more difficult by reducing tissue compliance and mobility..

TABLE 6. The Artificial Sphincter for Incontinence After Radiotherapy

Authors	N	Revision Rate After Radiotherapy		Continence
Martins & Boyd[293]	34/81	38% for whole group		88%
Wang & Hadley[397]	16	25% (infection and erosion – 12.5%)		87%
Perez & Webster[290]	11/75	55%		63%
Gundian et al[398]	15/56	22%		90%
Elliott & Barrett[304]	46/313	22%		—
Manunta et al[315]	15/72	53% (infection and erosion – 20%)		73%
Gomha & Boone[291]	28/86	25% (similar to a non-radiated control group)		64%
Lai et al[301]	60/176	20% v 32% for non-radiated group		69%
Sathianathen et al[399]	29 radiated 48 non-radiated	10.3% 12.5%		86.2% 87.5%
Rivera et al[400]	181 radiated 308 non-radiated	Device survival (1 y, 5 y) 92%, 77% 90%, 74%	*P=0.24*	N/A N/A

Multiple studies with AdVance slings have shown worse results after radiation,[53,409,410,411,412] although Kretschmer et al[413] recently reported no adverse effect of radiation on outcomes with AdVance XP in 7 previously radiated patients with mild to moderate incontinence after a mean follow-up of almost 3 years

Experience with the Argus adjustable retropubic sling was reported in 22 men by Hubner et al.[248] After a mean follow-up 1.5 years, 2 were removed for infection/erosion and the rest were dry. The ATOMS adjustable sling was reported in 31 men with moderate to severe post-prostatectomy incontinence and radiation.[414] After a mean of 17.8 months 58% were dry, 29% were improved, and 13% failed. A mean of 3.8 fluid adjustments were administered to the whole cohort of 99 men.

Adjustable balloons (proACT™) have been used in the post-radiation patient with stress incontinence but reported risk factors for failure and complications were prior external beam radiotherapy.[55,415] Kocjancic and colleagues[416] reported a continence rate of 67% in non-radiated patients compared to 36% in radiated patients.

In summary, despite the reported higher incidence of complications of the artificial sphincter in post-prostatectomy patients after radiation in a number of studies, it has provided acceptable treatment benefits. Injectable agents have yielded poor results. Other techniques such as slings may be adversely affected by radiation. Adjustable slings may be considered but more evidence in the post-radiation patient is needed. **(Level of evidence 3; Grade of recommendation D)**

VI. INCONTINENCE AFTER OTHER TREATMENTS FOR PROSTATE CANCER

1. BRACHYTHERAPY OF THE PROSTATE

Brachytherapy is a form of radiation therapy in which radioactive materials (seeds) are placed directly into the prostate gland. The incidence of incontinence following this modality is given in Table 7[417,418,419,420,421,422,423,424,425,426,427,428,429,430] and is usually related to the treatment of post-brachytherapy urinary retention.

Many series have reported retention to be associated with larger initial prostate volumes.[431] In a systematic review of brachytherapy series, Crook et al[426] reported the incidence of retention to be 1-14%. Many patients require prolonged or permanent alpha blocker or a TURP.

Moack et al[430]	—	25.3	3.1

[a]Implant plus external beam radiation

[b]Any incontinence

The main risk factor for incontinence after brachytherapy is TURP. Hu and Wallner[423] reported on the incidence of urinary incontinence after TURP/TUIP following prostate brachytherapy for prostate cancer. Of 10 patients who underwent the outlet relaxing procedures for refractory urinary obstruction, 7 developed some degree of permanent urinary incontinence. They surmised that the cause may be multifactorial and may include physical damage to the urinary sphincters and the radiation dose to the urethral region. More recently Mock et al[430] reported that in the 79 men who required a channel TURP out of a total of 2495 patients, 20 (25.3%) had urinary incontinence compared with 3.1% of those who underwent seed implantation only (P<0.001).

Surgical therapy when required has usually included the artificial sphincter.[424,432] High dose brachytherapy that is administered over a short period of time may have reduced toxicity.[433] Urethrorectal fistula is another complication that has been reported in 1.8% of patients in a large U.S. medicare retrospective review.[424] Salvage brachytherapy leads to a higher rate of urinary tract complications.[394,434]

2. CRYOSURGICAL ABLATION OF THE PROSTATE

Cryosurgical ablation of the prostate is used for clinically localized prostate cancer either as primary treatment or after unsuccessful external beam radiation therapy. The frequency of the main lower urinary tract complications are listed in Table 8[435,436,437,438,439,440,441,442,443,444,445,446,447,448,449] The artificial sphincter has been mentioned as one of the treatments for incontinence.[446,449] Cryotherapy is an adverse factor for bulking agents. Urethrorectal fistulae can also occur in up to 5% of treated patients.[449] Severe incontinence and fistulae that occasionally result may have to be treated with extirpative surgery and diversion.[450]

3. HIGH-INTENSITY FOCUSED ULTRASOUND

Transrectal high-intensity focused ultrasound (HIFU) is another minimally invasive treatment for prostate cancer. HIFU destroys prostate cells by coagulative necrosis of the tissue without damaging the structures intervening between the transrectal probe and the target tissue.[451] Reports of efficacy also include morbidity. In a systematic review involving 37 articles/abstracts, Rebillard et al[452] reported that stress incontinence occurs in 6-28%, urethra/bladder neck stenosis in 1-31%, and rectourethral fistula in 0-3% of treated patients. With improvements in techniques the risk of severe complications may be decreasing.[452,453] In a systematic review from 2000-2011, Cordeiro et al[454] noted that the rate of incontinence ranged from <1-34.3%. Dickinson and colleagues[455] recently reported that 105/189 (56%) patients from a UK multicenter registry were leak free and pad free at 5 years after HIFU.

[a]***Previously radiated/not previously radiated***

VII. INCONTINENCE AFTER NEOBLADDER CONSTRUCTION FOR BLADDER CANCER

The incidence of continence after neobladder construction following radical cystectomy for bladder cancer ranges from 85 to 100% during the day and 51 to 100% at night (Table 9).[456,457,458,459,460,461,462,463,464,465,466,467,468,469,470] Most patients achieve daytime continence after one year and nightime continence after 2 years. Clifford et al[470] recently reviewed their experience in 188 patients. They reported, with validated questionnaires, that daytime continence increased from 59% at <3 months to 92% at 12-18 months. Nighttime continence increased from 28% at <3 months to 51% at 18-36 months.

Most of the published reports do not comment on specific surgical management and imipramine is mentioned as treatment only occasionally. Martins and Boyd[293] reported on 8 patients treated with the AUS for persistent sphincter weakness incontinence. Six of these underwent revisions, 3 for infection and/or erosion and 3 for inadequate cuff compression. They cautioned against the use of the AUS and suggested alternatives such as intermittent catheterization at night. However, O'Connor and colleagues[471] reported a successful outcome, after AUS, with no complications in 5/5 men with incontinence after neobladder, with a mean follow-up of 22 months and Simma-Chiang et al[472] reported success in 11/12 men 22 months after AUS implant. Vainrib et al[473] reported on the use of the AUS in 36 patients with a mean follow-up of 40 months. Data were available in 29 patients. Post AUS, incontinence persisted in 8 (27.6%) patients and 60% needed revisions over time. The bone-anchored sling has been reported for one case[474] and the AdVance sling for 2 cases[240] Injectables have only been reported in women following neobladder construction.[475]

In summary there are not enough data upon which to recommend definitive surgical therapy, although the artificial sphincter is reasonable. **(Level of evidence 3; Grade of receommendation C-D).**

VIII. INCONTINENCE AFTER TRAUMATIC INJURIES OF THE URETHRA AND PELVIC FLOOR

Incontinence following posterior urethral injuries occurs in 0-20% of patients[476,477] and is thought to be due to the extent of injury rather than to the method of management.

The data on surgical treatment are all retrospective case series and the most commonly published surgical therapy is the AUS. The series published contain both patients with and without traumatic injuries. Perez and Webster[290] reported on 27 patients after urethral or bladder neck strictures.

TABLE 9. Continence After Neobladder Construction for Bladder Cancer

Authors	N	Follow-Up (mos)	Continence (%)	
			Day	Night
Alcini et al[456]	34	12	100	83
Cancrini et al[457]	89	24 (22% with SUI)	97	83

Studer et al[459]	100	24	92	80
Benson et al[460]	32	25	94	74
Abol-Enein and Ghoneim[461]	60	24	90	80
Rogers and Scardino[462]	20	24	90	55
Hautmann et al[463]	211	66	85	85
Hautmann et al[464]	363	57	95	95
Steven and Poulsen[465]	166	32.4	100	100 (after 5 years)
Abol-Enein and Ghoneim[466]	353	38	93.3	80
Carrion et al[467]	56 ileum 57 colon	41 41	91 86	68 68
Nieuwenhuijzen et al[468]	62 60 (sexuality preserving)	>12 >12	90 96	67 67
Yadav et al[469]	42	27.2	100	93.8
Clifford et al[470]	188	18-36	92	51

The revision rate was 41% and the continence rate was 85%. In a subsequent report from this centre on reoperations the patients with traumatic injuries were not discussed separately.[478] In Montague's[292] series, 22 out of 166 patients had incontinence after trauma. He did not separate the results of this group from those of the other patients. Martins and Boyd[293] reported on only one patient out of 81 with a traumatic urethral injury. This patient was dry and required no revisions. Venn at el[404] reported on 2 with pelvic trauma out of a total of 70. Mundy and Andrich reported successful AUS implant in 7 out of 8 patients after reconstruction for pelvic fracture-related injuries.[479] **(Level of evidence 3; Grade of recommendation C).**

Bladder neck reconstruction, by excising the scar and narrowing the calibre, was reported by Iselin and Webster[480] in 6 patients who had incontinence with an open bladder neck on cystourethrography, following urethroplasty for traumatic strictures. Bladder neck closure with a Mitrofanoff catheterizable abdominal stoma has also been reported as treatment following severe urethral or bladder trauma.[481] **(Level of evidence 3; Grade of recommendation C)**

For patients with severe bladder neck strictures and incontinence after prostate surgery, Meulen et al[482] and the group from Baylor[301,483] reported on the use of a Urolume stent with a bulbar artificial sphincter. The Urolume stent is no longer available. A novel approach which has yet to be tested in more studies involves the use of a non-permanent Allium urethral stent.[484] The stent is a self-expandable coiled metal structure that is covered with a polymeric coating. It is inserted transurethrally and can be removed by unravelling it with an attached tab. The study involved 14 men with recalitrant postoperative posterior urethral stenosis and stress incontinence. The stent was left indwelling for 6 months and then removed. After another 6 months the artificial sphincter was inserted if restenosis had not occurred. After a mean of 13 months following AUS placement, 13/14 did not restenose and all are dry. None of the men had undergone radiation.

Alternative management with perineal urethroplasty and subsequent artificial sphincter placement in 6 patients was reported by Simonato et al[485] Patil et al[486] reported on 8 patients with recalcitrant posterior urethral stenosis and defunctionalized bladders. Seven had radical prostatectomy (6/7 with radiation) and one had traumatic disruption. They were treated with cystectomy, neobladder creation and urethral pull-through for the AUS was subsequently implanted. After a median of 58 months all were socially continent with a median of 2 revisions. Palmer et al[487] reported their series of 20 men with posterior urethral stenosis and long strictures treated with a ventral buccal mucosa graft and gracilis muscle flap. Five men were incontinent. Of 3 who

subsequenstly had an AUS, 2 had it removed due to infection.

In summary, the AUS provides a reasonable outcome in appropriate cases. Since there are few reports of alternative therapies the C recommendations were based primarily on expert opinion as to what is reasonable surgical therapy in very difficult cases. **(Level of evidence 3; Grade of recommendation C)**

IX. CONTINUING PEDIATRIC PROBLEMS INTO ADULTHOOD: THE EXSTROPHY-EPISPADIAS COMPLEX

1. INITIAL MANAGEMENT OF THE EXSTROPHY-EPISPADIAS COMPLEX

1.1. NATURE OF THE EXSTROPHY BLADDER

In considering the management of incontinence in adults who were born with exstrophy or isolated epispadias, it is helpful to understand the nature of the bladder plate and the muscles around it. There is slowly accumulating data that show that they are not identical to normal. Less is known about changes over time either in those closed in the first few days of life or having had a delayed primary closure (DPC).

The bladder plate is smaller than a normal bladder and so can only achieve a normal capacity if it can grow, or stretch without losing its proper structure. Microarray analysis shows that the bladders are developmentally immature. The number of myelinated nerve fibers in the detrusor is reduced in newborn exstrophy bladders compared to that of control neonates who had died from cardiac causes.[488] The innervation of the muscle as defined by the muscarinic and other neuropeptide receptors are the same as in controls.[489,490]

The muscle appears structurally normal when stained for actin and myosin, but there are functional changes which persist in cell culture. Cellular proliferation is normal and there is a near normal response to stretch in vitro.[491,492,493] At birth, there is an excess of collagen in relation to smooth muscle which improves with age but never reaches the same ratio as normal controls: by the time reconstruction is completed smooth muscle in exstrophy children is 31.5% of the bladder wall and 56.5% in normal controls.[494,495]

These findings, taken together, suggest that the bladder has less ability to stretch or achieve good compliance, the detrusor is less efficient and the response to medication may be different from that in other conditions. Some promising basic research has suggested that mesenchymal stem cells obtained from bone marrow may be used to grow smooth muscle for use in augmenting bladders such as that in exstrophy.[496] This is not a clinical reality at present.

Control of the bladder outlet depends on proper function of the pelvic floor musculature and of the urethral sphincters. In exstrophy infants who have not had an osteotomy, the pelvic floor muscles have normal bulk, but abnormal orientation, especially in their relationship to the urethra.[497] They are unable, therefore, to contribute to urethral continence at the primary closure. Varma et al have described wrapping the levator ani as a loop in front of the urethra.[498]

The existence of the urethral sphincters is uncertain. There is no histological study to show their presence or innervation. However, some muscle found dorsally around the urethral plate and spread over the corpora has been described as sphincteric. It has been wrapped around the urethra at primary reconstruction.[498] Electromyographic studies of continent children have shown normal electrical traces even when such formal reconstruction has not been done.[499]

The prostate is a flat plate of normal size, lying behind the urethra and not wrapped around it.[500] Growth of the prostate at puberty will not improve continence.

A further problem with the assessment of outcomes of exstrophy reconstruction is that there is no satisfactory definition of continence. In a review of the literature, Lloyd et al[501] identified six definitions of continence, the commonest of which was 'three hour dry interval'. Most worryingly, 1372 of the 2681 children in the studies reviewed were said by the authors to be continent even though no definition was given in 68% of the studies!

A dry interval of three hours implies that the bladder has a fixed capacity beyond which the pressure becomes higher than that of the fixed outflow resistance. Providing the child recognizes this point, a visit to the lavatory will avoid incontinence. This is not true continence but a means of managing poor bladder control. The evidence base is three at best.

Epispadias is a more rare condition. There are very few data on the bladder and sphincters for this diagnosis alone. In general the bladder is of better volume and there may be some active sphincter function in those at the better end of the spectrum.

1.2. Early Management

The early reconstruction of bladder exstrophy is clearly important but not a subject for this chapter. Only an outline will be considered. Techniques have gradually evolved over the last 100 years since the first (transiently) successful closure described by Trendelenberg in 1906.[502] A most important development, at least in Western countries has been the concentration of cases in a small number of highly specialized centers. Although reasonable results have been reported from general pediatric units, the best results, as with other complex surgery, are found in high volume units.[503,504,505]

Broadly, there are three approaches to early reconstruction:

- Staged repair, originally described by Oesterling and Jeffs.[506] Here the principle is to close the bladder in the first operation. The bladder neck and epispadias repair are then done as a second stage. This has evolved into the modern staged repair of exstrophy (MSRE).
- Complete primary repair of bladder exstrophy (CPRE) often attributed to Grady et al[507] The objective is to close the bladder and bladder neck and to repair the epispadias in one operation. Although more than one operation is often needed, the important principle is to create bladder outflow resistance as early as possible. This should allow proper development of bladder volume and compliance. A further bladder neck reconstruction may be needed in up to 40% of children.[508]
- Single stage radical soft tissue mobilization (RSTM), usually called the Kelly operation.[509] The entire anterior pelvic contents with blood and nerve supply are mobilized from the pelvic sidewall, reconstructed and repositioned more posteriorly in the pelvis. There is no osteotomy, but the radical mobilization allows abdominal wall closure without osteotomy.

Each of these is subject to many modifications by different surgeons, which makes comparison of results difficult. Not surprisingly, there are no controlled trials. If only reported outcomes are considered continence rates in children have improved from close to zero in 1906 to about 90% in specialist centers.

Patients who are now the subjects of adult follow-up will have been operated between 20 and 30 years ago and often longer. Only a handful of adults who have had the RSTM have been reported. It is often difficult to tell which of the other two techniques have been used when reviewing adult outcomes and, in terms of management of persistent incontinence, it probably does not matter.

1.3. Late Bladder Function

There are very few data on the continence rate in adults, and there are no controlled trials. In the small number of studies in adults, the type of original reconstruction is usually ignored.

For the children who have done well, there is some evidence that continence may not be maintained into adulthood. In a follow-up of 56 patients for a minimum of 20 years, 13 were found who were continent and voiding naturally at 10 years old. However, by 20 years old, only three were still in this situation. The remainder were augmented or on clean intermittent catheterization (CIC) or both. The patients had been operated in the 1960s and early 1970s by older techniques than are currently used. In a further review from the same unit of a cohort 15 years later and with at least 20 years of follow-up only one of 50 patients was voiding normally.[510,511]

When specifically sought, the incidence of lower urinary tract symptoms (LUTS) is high. Taskinen et al[512] used the Danish Prostatic Symptom Score (DAN-PSS) in an investigation of 32 patients aged 16 to 44. All of seven men and two of four women who had not had an augmentation had disturbing incontinence. Amongst those with epispadias alone, six of eight men and four of five women had disturbing incontinence. Seven of the 19 exstrophy patients had had an augmentation, five of whom were completely continent and two lost small volumes on rare occasions. Moderate or severe symptoms that could be attributed to over active bladder were found in 80% of patients, but there were no urodynamic data. Surprisingly, only one of 17 patients who expressed an opinion wanted further surgery, especially if it would result in the need for CIC.

Late failure has several possible causes. Perhaps the most important is that the outflow resistance generated by bladder neck reconstruction is mainly fixed with little or no sphincteric action. Voiding is, therefore, always against obstruction. Deterioration in bladder function would come either from detrusor failure or from overactivity. Borer et al found detrusor overactivity in six of 13 children (46%) who had had a staged repair but in none of 19 who had had CPRE.[499]

Another problem was identified by Yerkes et al[513] In an investigation of 18 children who were said by themselves and their parents to be ‘continent and voiding well’, none were, in fact, voiding normally. Apart from infections, stones and a dry interval of two hours, there were major objective bladder dysfunctions in all patients. Seventy-two percent had a residual urine of at least a third of bladder capacity; 70% had a flow rate below 10 mL/sec; 30% had staccato stream; and 36% voided by Credé’s maneuver.

Finally, there is the problem of the definition of continence discussed above. When free from the discipline of childhood it quickly becomes apparent that the coffee, sodas and alcohol that soon become a part of an adolescent’s life, expose the fact that a ‘dry interval’ is no longer ‘continence’.

1.4. Renal Function

Most of the reported upper urinary tract anomalies that have been reported in association with exstrophy are clinically insignificant, such as duplex ureters. In 462 children who had renal ultrasounds only 1.5% had an anomaly that could affect renal function.[514]

Subsequent renal damage and renal failure are a consequence of the surgical management. Although older figures estimate renal damage at 15% to 20% for the initial reconstruction (or diversion), current figures are much better.[515]

At birth, the mean estimated glomerular filtration rates (eGFR) are the same as in normal babies. There is then a dip, corresponding to the primary closure in the MSRE: from eight days old to 56 days the mean eGFR, corrected for surface area, does not increase while that of normal babies increases by about 50%

to 60%. Beyond 56 days the exstrophy babies begin to catch up and are not significantly different from normal by two years old.

When the same patients were reviewed at least one year after their bladder neck repair, there was still no difference from normal in the *mean* eGFR.[516] Unfortunately, the *mean* value obscured the fact that 20% of the kidneys were damaged, some quite seriously. Hydronephrosis was seen in two kidneys severely, five moderately and two mildly out of 44 kidneys at a mean age of 15 years. One patient had an eGFR of 61 mL/min/1.75m^2 which would almost put him in the high risk group for late end stage renal failure. DMSA scans were not done in these children so there is no information about scarring.[516]

Similar results have been reported from Canada after major secondary surgery such as bladder neck closure or augmentation. In 57 patients at a mean age of 11.5 years, 18 (32%) had some hydronephrosis. DMSA showed renal scarring in 14 (27%). Damage was seen after all types of surgery regardless of whether or not a bladder neck closure was done. However, only one patient *without* hydronephrosis had scars. One developed mild renal failure and one required a renal transplant.[517]

Although end stage renal failure is rare in patients with exstrophy, most series mention one or two cases. It is most unfortunate that it is usually a consequence of reconstructive surgery and infection, in spite of vigorous attempts to prevent it. The most important parts of the long term supervision are to control infection and to react promptly to even small signs of renal damage, especially hydronephrosis.

2. MANAGEMENT OF PERSISTING INCONTINENCE

Although the need for long-term care of children born with the major genitourinary anomalies has been advocated by some for many years, it is only recently that the need has been generally recognized. A process of transition from paediatrics, through adolescence and into adult life now is accepted as essential standard of care in the US and Europe.[518,519,520]

2.1. Investigation

Complete objective evaluation of bladder function is particularly important in patients with exstrophy as the description by patients and parents is unreliable.[513]

Urodynamic studies in adults are best done using a small co-axial suprapubic catheter. It is inserted under general anesthetic so that an endoscopic examination of the urethra and a measurement of the true bladder capacity can be made at the same time. Imaging during the urodynamic study which is done a day or two after the insertion gives good views of the outlet and its function. The studies can be repeated without the need to insert a new catheter. The volume of the bladder measured under general anesthesia has some predictive value.

Validation of CMG findings in exstrophy is only available for children. Dave et al[521] investigated 31 children one year after a modified bladder neck reconstruction. Fifteen had satisfactory continence defined as a dry interval of two hours or more, no stress incontinence and no more than two episodes of nocturnal enuresis per week. The continent children had a better bladder capacity at 162 mL compared to 113 mL for those with poor continence or 55mL for the totally incontinent. End filling pressure was around 31 cmH_2O for the continent children vs 48 or 41 cm for the other two groups. Unstable detrusor contractions were seen in a third of the continent group and were associated with a lower than average bladder capacity and less good compliance than in the other continent children. As in other conditions of bladder abnormality, end filling pressures over 40 cm H_2O were associated with hydronephrosis (two thirds of patients).

A leak point pressure (LPP) of at least 10 cm H_2O is needed to generate bladder expansion. Despite a LLP over this level, some children still have severe dribbling incontinence because of detrusor over activity. Their bladders did not expand because the detrusor was constantly emptying it.[522]

The role of electromyography (EMG) of the sphincters has been reported but not correlated with management or outcomes.[499] In Dave et al's[521] patients only 12 children voided with sustained detrusor contractions and only five voided effectively. Ten children had persistent EMG activity during voiding, but no other detectable neurological abnormality. Eight of them had significant residual urine volumes.

2.2. Medical Management

The near normality of the detrusor innervation at least in infants born with exstrophy, suggests that standard anti-muscarinic drugs should be effective for overactivity. Several reviews mention that oxybutynin or other anti-muscarinic agents can be used but without any data.

There have been no disease specific controlled trials, least of all in adults. In children, there has been an uncontrolled trial of imipramine using both clinical and urodynamic criteria to assess response. All of 17 children (mean age 7.9 years) had urodynamically proven detrusor overactivity, small poorly compliant bladders and incontinence. Imipramine 1.5-2.0mg/kg was given for a mean of 9.5 months. There was a 40% increase in bladder capacity and a 25% reduction in end filling pressure. Eleven of 17 children had a clinically significant improvement in continence; all of eight children with partial continence (1-2 hour dry interval by day but enuretic) became dry day and night with a dry interval of more than 2 hours. Three of nine children with severe incontinence improved.[523] In an editorial comment on this paper, Gearhart[524]

stated that he used oxybutynin 0.5 mg/kg in combination with imipramine, which 'gave even better results'. No further data were given.

2.3. Bulking Agents for Bladder Outflow

The fixed bladder outflow resistance can be increased with injectable bulking agents. It does not matter which of the commercially available products is used but autologous fat does not seem to work. The only published results are in children. There is no standard technique of injection and the objective is to put in enough of the agent to produce visual occlusion of the bladder neck area using 2.5 to 7.5 mL.

In two recent series, 17% and 42% respectively became continent, though Alova et al[525] in reviewing the literature, concluded that 50% of children became dry. Injections can be repeated but only one patient became dry beyond four attempts (he became dry after six injections).[526,527] Best results are seen in those who are partially dry and have a bladder capacity above 70 mLs. It is important to note that in one of these series, two of 16 patients who were partially continent were rendered completely incontinent by the injections.[527]

2.4. Bladder Neck Reconstruction

There are few data on the outcomes of bladder neck reconstruction in adults with exstrophy, especially if done without augmentation. Occasional adult patients are included in series primarily on children.

In a group of older children (3.2 to 15.5 years) the group at the Hospital for Children, Great Ormond Street reported very modest results. There were 20 boys and ten girls most of whom had had several operations apart from the initial bladder neck reconstruction, including injection of bulking agents, augmentation and Mitrofanoff procedures and yet still remained wet. Sixty percent became dry by day (80% of girls and 50% of boys), but only 50% by night. None could void urethrally and only five could self-catheterize urethrally.[528]

The results in isolated epispadias are better with all of five patients (11 to 36 years old) becoming dry compared to two of four with exstrophy. All patients had failed previous injection of dextranomer (Deflux®) based agents and it was said that this did not compromise the bladder neck surgery.[525]

Bladder neck reconstruction without augmentation carries the additional risk that the bladder will expand but will develop instability and poor compliance. This will lead to hydronephrosis and renal deterioration. Grimsby et al[529] have made the very important observation that there is a cumulative incidence of complications after bladder neck reconstruction without augmentation. Seventy percent of children had required further surgery for continence by seven years and the same percentage had new or worsening renal scarring up to ten years. Although none of the children had exstrophy, the observation remains valid – early success is not a cure and may just be changing one problem for an even worse one.

2.5. Artificial Urinary Sphincters

The patient with exstrophy has, by definition, a reconstructed bladder neck and urethra. Such structures are not well suited to the support of an AUS cuff. It is also common for incontinent patients to carry a residual urine and so, with an AUS, would need to use CIC. Again, data on this procedure in adults with exstrophy are limited and often included in series of patients with different diagnoses. In one series of 112 patients without spina bifida, there were 12 with exstrophy and four with epispadias aged four to 17 years old. The AMS 880 AUS was used with 5.5 to 7.5 cm cuffs and 61–70 cm H_2O balloons. The cuff eroded in three of 12 exstrophy patients. Only four were dry and able to void spontaneously all of the time.[530] Herndon et al[531] reported a 20% erosion rate in patients of any diagnosis who had had a bladder neck repair.

Various tissues and devices have been used to provide passive artificial outflow resistance. Pedicled gracilis muscle has been wrapped around the exstrophy urethra and gave continence in all of five children with CIC.[532] Lima et al[533] described a silastic ring around the urethra which can be expanded by injecting saline through a sub-cutaneous port. In six of 12 patients the cuff eroded. The other six were dry, but one developed hydronephrosis and had to have the device deactivated. Five voided normally and the sixth who had had an augmentation previously, relied partially on CIC.

2.6. Bladder Augmentation

In childhood, the reported need for augmentation is 0% to 70%.[534] Only a few patients will be able to void to completion from an augmented bladder, the majority requiring CIC. Follow-up urodynamic studies have compared the use of ileum as a patch and sigmoid colon as a patch or cup. The best reduction in detrusor pressure is achieved with a patch of ileum compared to sigmoid (mean decrease of 81% vs 27%).[535] There was no significant difference in the volume achieved which is not surprising as it is only related to the size of augment applied.

In adults with incontinence, either new or persisting from childhood, full evaluation is essential. Augmentation will not create reliable continence if the bladder outflow is inadequate nor is it likely to permit spontaneous voiding: only one of seven adult patients with an augmented bladder in the series reported by Taskinen and Suominen could void.[512] The patient has, therefore, to accept that CIC through one channel or another is the probable outcome. The ability to pass a catheter through the urethra must be checked before the augmentation is done. If it is not possible, the urethra will need to be adjusted to make it possible or a suprapubic catheterizable channel will be needed.

Similarly, if the outflow resistance is inadequate a plan is needed to strengthen it. However, a redo bladder neck repair at the same time as an augmentation has a low success rate, especially with a small bladder.

If the surviving bladder is very small and the outlet incompetent it may be better to abandon it altogether. Reconstruction can be done with isolated intestine and a supra pubic catheterizable stoma (see below).

The techniques of intestinal augmentation and the long-term consequences are beyond the scope of this chapter. The problems are well known, but to date no satisfactory alternative has been found and certainly not one that would dispense with need for CIC. It has proved possible to grow urothelial and muscle cells from fragments of exstrophy bladder and from mesenchymal (and other) stem cells.[491,496] Clinically, several autografts and xenografts have been tried, most recently small intestinal submucosa, but have not produced reservoirs of useful size.[536]

2.7. Diversion

Even in the most prominent exstrophy centers diversion is sometimes needed. The only question is how many failed attempts to create a normally working bladder mandate some diversion from this ideal goal? In Baltimore, 91 of 704 children (13%) required such procedures. If it is correct that normal continence and voiding are not always preserved in adulthood, the number will rise.

There is a school of thought that the results of exstrophy reconstruction in the long run are so poor that early diversion should be the initial management.[537] Gobet et al[538] have reported good outcomes with up to 69 years of follow-up with a primary standard ureterosigmoidostomy. With the use of a de-tubularized rectal pouch, such as the Mainz II, and an understanding of the long-term complications continence rates of 95% day and night are reported.[539] This could be the management of choice in countries with limited facilities for reconstruction.[540] Surveillance for the development of anastomotic neoplasms from the tenth year after construction is mandatory.[541]

At the simplest level, a catheterizable supra pubic stoma may be put into the bladder, usually with an augmentation. Ideally, the urethra is left open so that there are two channels for CIC. However, if the urethra cannot be made continent, it can be closed. In males the closure must be at bladder neck level so that antegrade ejaculation is possible. In an assessment of outcomes of this management 96% were reliably dry by day and 86% by night (82% of patients were adults at the time of review). The well-known complications of this type of diversion occurred in 39% including the need for redo of the bladder neck closure in one patient.[542]

If the remaining bladder is too small to be useful or has been removed, any of the standard continent diversions can be used. In females, there is a particular advantage in this because the reservoir can be put to the side of the abdomen. This will usually, but not always, leave it clear of the uterus and out of harm's way during the C-section which is usually the safest means of delivery for those with exstrophy.[543]

A conduit diversion is only needed in the most exceptional circumstances such as uncontrolled hydronephrosis or non-compliance with CIC. In four of five patients described by Baradaran et al,[544] reconstruction to a continent system was possible when the underlying problem had been corrected.

3. RECOMMENDATIONS

The published studies to date are retrospective case series with levels of evidence at best 3 with a Grade of Recommendation of C. The expert opinion of the Committee has resulted in the following recommendations regarding the evaluation and treatment of persisting incontinence in adulthood. **(C)**

Patients with exstrophy-epispadias complex should be evaluated and managed in specialized centers.

Persisting incontinence should be evaluated with urodynamics including measurement of bladder capacity and its treatment should be individualized based on urodynamic findings.

A universal definition of continence should be established.

Anti-muscarinic drugs are the first option for detrusor overactivity.

Bladder neck bulking agents may be effective but continence is unlikely to be achieved if 4 injections have failed.

Standard techniques for enlargement of a small or high-pressure bladder are appropriate.

Redo bladder neck reconstruction has a high failure rate and is very unlikely to allow complete, spontaneous voiding. Urethral CIC may be difficult or impossible.

AUS also has a poor outcome because of erosion, chronic retention and CIC difficulties.

Suprapubic continent diversion with or without augmentation and with or without bladder neck closure is the best choice for exstrophy patients with urethral failure. Rectal diversion (eg, a Mainz II pouch) should be considered especially in countries with limited medical facilities.

Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications. Appropriate transitional arrangements must be made to ensure that this is achieved.

Comparative studies, including quality of life and psychological assessment, should be undertaken if possible.

X. DETRUSOR OVERACTIVITY AND REDUCED BLADDER CAPACITY

1. REFRACTORY URGENCY INCONTINENCE AND IDIOPATHIC DETRUSOR OVERACTIVITY

The overactive bladder (OAB) syndrome refers to the symptoms of urgency, with or without urge incontinence, usually with frequency and nocturia.[545] Detrusor overactivity (DO) indicates the urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked. Idiopathic Detrusor Overactivity (IDO) exists when there is no defined cause. Neurogenic Detrusor Overactivity (NDO) is seen when there is a relevant neurological condition. Ahlberg et al[546] found that 82% of patients initially considered idiopathic on careful searching actually had pathology potentially leading to the problem. Refractory OAB indicates OAB symptoms that have failed conservative and medical management.

Idiopathic detrusor overactivity is a normal situation early in life. Children have urgency incontinence as a stage in acquiring bladder control. The incidence of detrusor overactivity during mid-life years (20 to 60) has been estimated as 10%.[547] In the asymptomatic elderly, detrusor overactivity once again becomes common, occurring in 50% of men over 70.[548] In the symptomatic elderly, over 75 years old, it can reach 90% in men.[549] DO may be a cause of severe storage symptoms such as frequency, nocturia, urgency and urgency incontinence. Conservative treatment of these symptoms such as bladder training and pharmacotherapy is discussed in other sections. Magnetic stimulation via a variety of techniques has been reported as a noninvasive treatment of DO.[550,551] Bradshaw et al[552] demonstrated an effect on cystometry with magnetic stimulation and found an improvement in urodynamic parameters but no consistent change in OAB symptoms. Almeida et al[553] in a prospective urodynamic controlled study of 91 women with UI, found an improvement on DO only in patients with initial bladder contractions greater than 15 cm H_2O. There are no other specific data available.[554] The use of intravesical neuromodulatory drugs such as capsaicin and resiniferatoxin was extended to DO of non-neurologic origin after the suggestion that its etiology involved the enhancement of the C-fiber mediated spinal micturition reflex[555] and emerged as a minimally invasive procedure: the results are shown in Table 10.[556,557,558,559,560,561,562,563]

TABLE 10. Intravesical Capsaicin and Resiniferatoxin for Detrusor Overactivity (Males and Females)

Authors	N	Improvement	Duration of Effect	Drug and Dose	Side Effects
Cruz et al[556]	3 IDO (total of 16 including 3 males)	71% continence (overall total of 14) and 21% improvement	Up to 18 months	Capsaicin 125 mL of 30% alcohol in saline containing 1 mM	Intense burning sensation
Kuo[557]	13 IDO (41 total)	5 (38.5%)	2 to 9 months	RTX 10 mL of 100 nM RTX in 10% ethanol for 40 min	
	18 previous TURP	11 (61.1%)	Average 5 months		
Kuo[561]	23 (19 ended)	11 of 19 (58%)		10 nM RTX weekly 3 to 4 times	4 withdrew due to side effects. Significant worsening of emptying
Kuo et al[562]	17 IDO	Vehicle 2 (9) 22% RTX 5 (8) 63%	6 months	Vehicle or 4 weekly 10 nM RTX	Randomized double blind placebo controlled. 6 withdrew after first instillation
Liu and Kuo[567]	28	14 (50%)		10 nM RTX weekly for 4 weeks	Transient receptor potential vanilloid subfamily 1 overexpressed in the responders

Authors	N	Improvement	Duration of Effect	Drug and Dose	Side Effects
Palma et al[558]	25 females with idiopathic urgency incontinence	10 (40%) disappearance of urgency incontinence	1 month evaluation only	50 nM RTX	No mention of retention
Rios et al[563]	58 females with IDO	43% RTX 35% Placebo vehicle improvement equal (*P*=0.439)	1 month first evaluation	50 nM RTX or 10% ethanol saline solution	Randomized double-blind placebo controlled
Silva et al[560]	13 IDO (2 men, 11 women) (12 incontinent)	11 improved (91%) in incontinence 3 (25%) dry	3 months follow-up	100 mL 50 nM RTX solution 10% ethanol in saline for 30 minutes	No retention or other problems
Silva et al[568]	17 IDO (out of 23)	Vehicle 9 (39%) RTX 14 (60%)	Pre-test with vehicle only followed by RTX	Vehicle followed by 100 mL 50 nM RTX (patients enrolled in 2005)	No separation of NDO and IDO
Yokoyama et al[565]	10 (4 men)	5 (2 dry) 50%	3 months follow-up	100 mL 50 nM RTX for 30 minutes	Neurometer before and at 30 days

IDO = idiopathic detrusor overactivity, RTX = resiniferatoxin, TURP = transurethral resection of prostate

NDO = neurogenic detrusor activity

In spite of promising and controversial results, it is still considered experimental and more clinical studies are necessary for it to be licensed,[564] but recent publications on this subject could not be found. The mechanism of action is still under study. The mean bladder perception threshold is increased only in patients with clinical improvement.[565] The complexity of the mechanism is demonstrated by the presence of vanilloid receptors not only on sensory fibers but also in bladder urothelium and smooth muscle cells[562] and by ineffectiveness in treating OAB from idiopathic causes or suprapontine lesions with no vanilloid-sensitive fiber-mediated reflex.[566] It has been suggested that over expression of transient receptor potential vanilloid subfamily 1 in the bladder predicts the response.[567] A well designed double-blind placebo controlled study revealed no difference between placebo ethanol 10% saline solution and 50 nM resiniferatoxin, nevertheless both treatments showed improvement in symptoms of women with IDO.[563] Some placebo-controlled studies either did a quasi randomization[568] or did not explain how it was done.[562] Patients with increased bladder sensation without DO presented some improvement in symptoms in a small non placebo controlled series.[569] There are no recent clinical series published and at present time and the use of resiniferatoxin has been restricted to animal studies.[570,571] **(Levels of evidence 1 – 4; Grade of recommendation D, two level 1 studies have contradictory conclusions**).[562,567] For symptoms that are refractory to conventional means, 3 interventional treatments have been reported: botulinuntoxin-A detrusor injections, neuromodulation, and bladder augmentation. Attempts to determine the effectiveness of management among individuals with different pathophysiologic profiles found no trends in treatment efficacy according to any sub-type of bladder overactivity.[572] A prospective study comparing satisfaction in patients that underwent onabotulinuntoxina injections or augmentation cystoplasty (AC) was favorable to AC, but the conclusion was weakened due to no randomization.[573]

1.1. Botulinum Toxin a Injection in the Bladder

The minimal invasiveness of this method makes it very attractive but long-term results in IDO are lacking Table 11.[574,575,576,577,578,579,580,581,582,583,584,585,586,587,588,589,590] The effects of its use are still not fully recognized,[591,592] with possible systemic consequences,[593,594,595] such as generalized muscle weakness in a number of patients treated for neurogenic bladder overactivity, and the development of resistance to the drug.[596,597,598] The FDA conducted a safety review of botulinum toxin products and issued a report that included a “Boxed Warning” highlighting the possibility of life-threatening distant spread of the toxin, a Risk Evaluation and Mitigation Strategy (REMS) with a medication guide to help patients understand the risks and benefits, and changes to the established drug names to reinforce individual potency and lack of interchangeability of the different products and to prevent medication error.[599] Most of the initial experience comes from its use in neurogenic bladders.[600,601,602,603]

TABLE 11. Botulinum Toxin A Detrusor Injection Results

Authors	N	Type of Patients	Dose	Punctures (N)	Results	Comments
Harper et al[574] Level 3	13 men 26 women	Neurogenic and idiopathic origin (not described separately)	200 idiopath 300 neurog	20 to 30 sparing the trigone flex cysto.	Increase max bladder volume 174 to 589 mL	
Loch et al[575]	30	Neurogenic and idiopathic	200 U	20 injections sparing the trigone	Significant improvement in 67% of the patients ≥ residual urge	No description of gender or whether NDO
Radziszewski et al[576] Level 3	6 women 6 men	Only idiopathic	Up to 300 U	10-15 injections sparing the trigone	1 months follow-up 100% success no residual	Short follow-up inexact criterion of success
Rackley et al[589] Level 3	18 women	IDO	200-300 U (Botox)	Each 100 U in 1 cc saline, 0.1 cc injections	Improvement 40% frequency 30% urgency	6 months follow-up
Rapp et al[577] Level 3	29 women 6 men	6 neurogenic	300 U	30 injections including trigone	34% resolution 26% improvement	40% failure
Kuo[578] Level 3	12 women 18 men	12 neurogenic	200 U	40 injections sparing the trigone	26% resolution 46% improvement	26% failure
Chancellor et al[579] Level 2/3	2 men 8 women	Only idiopathic	100-300 U	20-30 injections only in bladder base and trigone	80% improvement	Control group-11 neurogenic with 73% improvement
Rajkumar et al[585] Level 3	15 women	IDO	300 U (Botox)	30 mL – 30 injections	93% improvement	Not randomized prospective study 6 patients with PVR > 130 mL
Popat et al[584] Level 3	31 (18 women and 13 men)	IDO	200 U (Botox)	20 mL – 20 injections	57% dry at 4 months	19% needed CISC
Kessler et al[590] Level 3	11 (no gender information – 8 men in total of 22 patients)	IDO	300 U (Botox)	30 mL – 30 injections sparing the trigone	91% dry 5 months duration	Prospective study comparing IDO with NDO 4 high PVR with CSIC (36%)
Werner et al[976] Level 3	26 women	Only IDO	100 U (Botox)	30 mL – 30 injections	65% dry at 12 weeks 60% dry at 36 weeks	36 weeks follow-up

Schmid et al[582] Level 3	23 men 77 women	Only IDO	100 U (Botox)	30 mL – 30 injections	88% improved 8% poor results	12 weeks follow-up, 4% urinary retention
Kuschel et al[581] Level 3	26 (only women)	Only IDO with incontinence	100 U (Botox)	30 mL – 30 injections	11/26 improved (42%), 4 no need further treatment	2-year follow-up, 3 complications (1 no response and 2 high PVR)
Jeffery et al[580] Level 3	25 (only women)	Only IDO	500 U (Dysport)	20 mL – 20 injections	63% dry – 1 week, 32% dry – 3 months	Prospective first study with Dysport
Lee et al[583] Level 3	13 men 5 women	10 IDO and 8 NDO	50-200 U (NTX component of purified Type A neurotoxin)	20-40 injections including trigone indigocarmine together to check leak	89% improved	3 months follow-up, 6% retention with IC for 12 months
Sahai et al[588] Level 2	34 (16 BTX and 18 placebo), does not discriminate gender	Only IDO	200 U (Botox) or sale (as placebo)	20 mL – 20 injections	Normalization—<u>Frequency</u> – 36% BTX, 11% placebo <u>Urgency</u> – No difference <u>Incontinence</u> – 50% BTX, 0% placebo	12 weeks follow-up, randomized placebo controlled double blind trial, difficult voiding 75%, IC 38%
Kuo[586] Level 2	45 (gender not specified)	Only IDO	100 U (Botox)	Injections in detrusor, suburothelial or bladder base	Success 93% detrusor, 80% suburothelial, 67% bladder base	Prospective randomized 3 months, 4 retentions, 14 difficult void
Ghalayini & Al-Ghazo[587] Level 3	16	IDO	500 U (Dysport)	500 U diluted in 30 mL saline – 30 injections	80% of patients satisfied	Prospective study, 9 months follow-up, 1 retention and 4 with PVR > 120 mL – 5 ICath
Mohanty et al[977] Level 3	35 women	IDO	200 U (Botox)	20 mL – 20 injections sparing trigone	85.7% improvement, no adverse effects	Case series, no retentions
Kuschel et al[581] Level 3	26 (women)	IDO	100 U (Botox)	30 mL – 30 injections	11 re-injections	Case series
Brubaker et al[677] Level 1	43 women (28 BTX and 15 placebo)	IDO	200 U (Botox)	20-30 injections, sparing trigone	Study stopped—43% (12 pts) with large PVR	Randomized double blind placebo controlled

Authors	N	Type of Patients	Dose	Punctures (N)	Results	Comments
Flynn et al[978] Level 2	22 women (7 placebo and 15, 2 does of Botox)	IDO	200 or 300 U (Botox)	10 injections, sparing trigone	6 weeks results only – (improvement) 26% PVR > 200 mL, 18% infection	Randomized double blind placebo controlled (immediate results)
Sahai et al[674] Level 1	34 (both sexes)	IDO	200 U (Botox) (16 pts) or placebo (18 pts)	20 mL with 20 injections	QoL improved with Botox	Randomized double blind placebo controlled
Lie et al[979] Level 3	9 women 10 men	IDO	200 U (onabotulinumtoxinA)	20 mL, 20 sites sparing trigone	More efficacious in female	Case series, 5.2% retention
Dmochowski et al[676] Level 1	313, randomized to 6 groups (both sexes)	IDO	Placebo and Botox 50, 100, 150, 200, 300 U	20 injections of 0.5 cc, sparing trigone	All benefits but placebo and 50 U groups, 100 U best result (14.5% PVR > 200 mL)	Randomized double blind placebo controlled
Granese et al[980] Level 3	68 women	IDO	100 U (Botox)	20 sites, sparing trigone	All with objective and subjective improvement	35% required IC (residual > 100 mL)
Dowson et al[981] Level 3	100	OAB and IDO	Botox most 200 U	20 sites, up to 10 injections	47% discontinued treatment	IC 35%, UTI 21% (include cases from Sahai et al, 2009)
Kanagarajah et al[629] Level 3	5 men 27 women	IDO without urodynamic detrusor overactivity	Botox? 100 or 150 U	10 to 15 sites	84% improved more than 50% of symptoms	5 UTI, 3 IC
El-Azab et al[573] Level 3	13 men 18 women	IDO	Botox 100 or 200 U (16) or bladder augmentation (15)	20 injections sparing trigone or 20 cm ileal segment augment	More satisfaction with AC than with oBTX therapy	No randomized and different doses
Shakeri et al[640] Level 3	15 women 15 men	NDO (12), IDO (18)	500 U (Dysport)	20 injections sparing trigone	Satisfaction in 58% IDO and 77% NDO	1 UTI in each group
Abeywickrama et al[612] Level 3	33 women	Only IDO, repeated injections	Dysport initial 500 U, 3 or more injections	20 sites injections sparing trigone	Sustained improvement maintained in all injections	2 UTI and IC, 750 U next injection if return < 6 months
Abdelwahab et al[982] Level 1	63 women 17 men	Idiopathic OAB	Botox randomized 100 or 200 U	20 sites injections	At 6 months, comparable results	More dysuria and UTI in the 200 U group

NDO = neurogenic detrusor activity, IDO = idiopathic detrusor overactivity, PVR = postvoid residual

CISC = clean intermittent self-catheterization, NTX = neurotoxins, IC = intermittent catheterization

BTX = Botulinum toxin type A (Botox), QoL = quality of life, OAB overactive bladder, UTI = urinary tract infection

In 2011, OnbotulinumtoxinA was first approved by countries in North and South America and Europe for treatment of urinary incontinence in people with neurologic conditions as spinal cord injury or multiple sclerosis. Lately, approval was extended to idiopathic detrusor overactivity. Information about its use in children is scarce.[604] DasGupta et al[605] published a systematic review on its use in children. They found 225 children in ten peer-reviewed publications with 165 pediatric patients with neurogenic overactivity (6 studies), 21 patients with idiopathic overactivity (1 study) and 39 patients with voiding dysfunction (3 studies). Only 11 male children with idiopathic OAB were included, limiting conclusions on this subject. Blackburn et al[606] reported the use of Dysport in 27 pediatric patients 6 to 16 years, being only 7 males. They concluded for efficacy in a dosage of 15 iu/kg.

A randomized study comparing the results of botulinum toxin (BTx)-A injections to intravesical resiniferatoxin in NDO showed superior clinical and urodynamic benefit with the use of botulinum toxin.[603] The need for reinjections seems to be overcome by the significant improvement in quality of life of these patients,[607,608,609] nevertheless discontinuation has been reported to be up to 63% after 36 months of treatment.[610] Malde et al[611] conducted a retrospective telephone interview on 72 patients regarding satisfaction after treatment. Among them, only 49 continued to receive injections and 57% would consider BTx-A a lifelong management option. In general, there is an impression that efficacy after multiple reinjections seems to be maintained.[612,613,614] Cost-effectiveness with botulinum toxin A in patients with detrusor overactivity is becoming an important issue with its increasingly widespread use.[615] The number of BTx treatments in the UK has increased dramatically from around 50 in 2000 to 4088 in 2010, making costs an important matter to be considered.[616,617,618] A 3-year cumulative cost analysis of BTx vs augmentation cystoplasty favored botulinum toxin injections,[619] but longer follow up may change this. The use of BTx-B (Myobloc – RimabotulinumtoxinB) is less efficient, with duration of action of about 10 weeks.[620]

The optimal site of injections, including or not including the trigone, is still under debate.[621] In 2007, Kuo[586] published a study comparing the injections into the detrusor, suburothelial area, and bladder base, with the last location improving urgency but not increasing capacity. In 2011, Kuo[622] did a single blind, randomized, parallel, actively controlled trial testing 100 U of OnabotulinumtoxinA with patients assigned to receive injection into one of the three following sites: bladder body, 100 U; bladder body, 75 U plus trigone, 25 U; and bladder base, 50 U and trigone, 50 U. He concluded that the injections are a safe and effective treatment for IDO regardless of the injection sites. Manecksha et al[623] performed a study with 500 U of AbobotulinumtoxinA in 22 patients randomized to trigone-included or trigone-sparing detrusor injections. Benefits of trigone included injections were superior to trigone sparing injections for the treatment of refractory IDO and did not cause VUR in this study, besides some question about the power of the study.[624] A case series of 56 women with IDO underwent submucosa-only injection of 200 U of OnabotulinumtoxinA at 30 sites, showed success in 85.7% at 2 months and 54.3% at 12 months.[625] Initial results of bladder instillation of 300 units of OnabotulinumtoxinA and 50 mL of 50% DMSO in aqueous solution in women with IDO, showed safety and some efficacy that merit further research.[626] Many studies on idiopathic overactive bladder have been done in women.[580,581,612] Data are still lacking on dose, concentration, site(s), numbers of injections, long-term efficacy and side effects though the manufacturer recommended dose of Onabotulinumtoxin A is 100 units divided in 20 injections within the bladder, sparing the trigone. Le Maux et al[627] conducted animal experiments showing similar inhibiting effects of aboBoNTA despite the number of sites injected, but this conclusion needs clinical confirmation. Administration of BoNTA through liposome encapsulated formulations is also beginning to show some therapeutic potential.[628] Attempts to determine whether poor responders could be predicted from preoperative urodynamic parameters showed only a very high maximal detrusor pressure over 110 cm H_2O as an unfavorable predictor when using 200 units.[588] Kanagarajah et al[629] showed good outcomes in patients with OAB without urodynamic detrusor overactivity, proposing the need for further studies in this situation. Studies in women suggest a longer duration of action than its mere motor-nerve blocking potency can explain.[581] Therefore, a dual mechanism of action has been proposed. In addition to binding to cholinergic terminals, it might also affect afferent nerve transmission, thereby decreasing urgency.[630,631] Kuo[632] evaluated retrospectively the results of 100 U OnabotulinumtoxinA injection in 174 patients (89 males). Patients who had sensory effects had significantly greater long-term success rates compared to those with motor effects alone. He concluded that improvement of urgency severity seems to be significantly associated with the long-term success of BoNT-A treatment for IDO. There are five commonly marketed forms of BTx-A: Botox (Allergan Pharmaceuticals, Irvine, CA, USA), now referred to as OnabotulinumtoxinA, Dysport (Ipsen Biopharm Ltd., Wrexham, UK), referred to as AbobotulinumtoxinA, Xeomin® (Merz Pharma, Frankfurt am Main, Germany), referred as IncobotulinumtoxinA, Prosigne® (Lanzhou Biological Products Institute, Lanzhou, China), and Neuronox (Medy-tox, South Korea) which currently does not have a known non-proprietary names. The FDA Import Alert 65-02 from October 6, 2015 stated that the following were the only U.S. licensed botulinum toxin products at that time: Botox, Dysport, Myobloc and Xeomin. Botox and Dysport require different doses to achieve similar results, in a proportion of approximately 1:3.[633,634] Other forms of BTx-A do not have enough data in urology to be considered for this report, including Xeomin (IncobotulinumtoxinA) (Merz, Germany), Prosigne (Lanzhou Institute of Biological Products, China),[635] and Neuronox (Medy-tox, South

Korea). They have different constituents and excipients, different complex sizes, and they are stored under nonequivalent situation, making immediate comparison inappropriate.[636] AbobotulinumtoxinA for refractory IDO was published in 2007 with similar results to OnabotulinumtoxinA.[580] Recently, a series of 22 patients with IDO underwent injection of 500 U of AbobotulinumtonA and were randomized to injections including or excluding the trigone.[623] Similar results were obtained regarding side effects (18% retention and no reflux) with the trigone-included group showing better results. Another large case series of 234 patients either with various types of neurogenic bladder dysfunction (NBD) or IDO underwent respectively 500 U and 250 U of AbobotulinumtoxinA including 57 men with IDO. Success was 91% for NBD and 93% for IDO, with 12% retention only in the male patients.[637] In a study using a type A neurotoxin, produced in a medical school laboratory and purified by a procedure using a lactose gel column, Lee at al[583] reported improvements in 89% of patients treated for incontinence due to IDO and NDO. Malki et al[638] retrospectively reviewed cases with doses switched from 300 to 200 U, maintaining 79% of effectivity. Only 9% (all NDO) reverted back to receiving 300IU. Mangera et al[639] did a systematic review on management of lower urinary tract diseases comparing OnbotulinumtoxinA and AbobotulinumtoxinA. They identified good-quality studies for OnabotulinumtoxinA in adults and lack of such studies for AbobotulinumtoxinA, although this does not imply that OnabotulinumtoxinA is more effective than AbobotulinumtoxinA. Recently, the use of AbobotulinumtoxinA in a small series of IDO and NDO, showed satisfaction in 58% and 77% respectively.[640] A new series with AbobotulinumtoxinA has been published since them.[612] Many studies with botulinum toxin detrusor injection use different outcome measures for results and are variable in reporting the presence of residual urine and the need for intermittent catheterization, but 6-75% of cases may develop a high post void residual urine.[581,583,585,588] A retrospective study looking at risk factors for adverse events in a series of 217 patients treated with OnabotulinuntoxinA showed an overall 63.3% success, with male gender, base line PVR ≥ 100 mL and dosage >100 U as predictors of urinary retention or difficulty voiding. Liao and Kuo[641] reviewed 61 frail elderly patients submitted to 100 U onabotulinuntoxinA because of IDO, among their large group of patients. Frail elderly was defined as age greater than 65 years and 3 or more of certain criteria, including unintentional weight loss, self-reported exhaustion, weakness, slow walking speed and/or low physical activity. Large post-void residual urine volume (greater than 150 mL) was significantly higher in the frail elderly group than in the other groups (60.7% vs 39.7%, *P*=0.018). Besides being an alternative for treatment of refractory DO, currently available data do not support superiority of any specific treatment plan, and therapy options should be tailored to the specific patient and physician preference.[642] Higher doses such as 200 units in IDO resulted in incomplete emptying, necessitating intermittent catheterization in 6 out of 16 patients (37.5%) in one study.[588] Sahai suggests a careful follow up of the patients after the injections, starting IC in symptomatic patients if post void residual urine is more than 100-150 mL.[643] Many reports do not separate genders and mix neurogenic and idiopathic etiologies. A large number of publications are reviews of the literature.[614,644,645,646,647,648,649,650,651,652,653,654,655,656,657,658,659,660,661,662,663,664,665,666,667, 668,669,670,671,672,673] There is a randomized double blind OnabotulinumtoxinA placebo controlled trial showing favorable difference against saline injections for frequency and incontinence, but not for urgency.[588] Quality of life analysis showed improvement even with the occurrence of 38% of urinary retention.[674] In a dose-finding randomized double blind placebo controlled study with a total of 313 IDO patients of both sexes, all OnabotulinumtoxinA dosages (50-300 U) were better than placebo, but the 100 and 150 U dosages were best in regard to the balance between efficacy and side effects.[675,676] In women, a placebo controlled randomized study with 200U of OnabotulinumtoxinA for IDO showed a 60% clinical response, but was terminated early due to 43% of patients having increased PVR.[677] Point-counterpoint about the use of BTx-A as a first or second line treatment for OAB[678,679,680,681] favors a first approach for oral medications. The knowledge of long term effectiveness and costs will better clarify this point.

CONCLUSIONS

- **Efficacy of botulinum toxin A for IDO**: **level 1 of evidence, Grade of recommendation A** (for OnabotulinuntoximA). Fewer studies for AbobotulinuntoximA and the lack of studies for other A toxins do not allow similar recommendation.
- **Dosage of botulinum toxin A for IDO:** between 100 and 150 U (for OnabotulinuntoximA). No studies for other types. **Level 1 of evidence; Grade of recommendation A.**
- **Location of injection**: the majority of studies use 20 or 30 injections, and spare the trigone (Table 11). Alternative sites such as submucosal or including the trigone, have **levels 2 and 3 of evidence. Grade of recommendation C.**
- **Predictability of complications**: Risk factors for retention or difficulty voiding are: male gender, baseline PVR ≥ 100mL and a dosage >100 U, **frail elderly population**. **Level 3 of evidence; Grade of recommendation C** (for OnabotulinuntoximA – for other types, no conclusion possible).

The committee cautions that although the efficacy and safety of botulinum toxin A for IDO has been established there are still gaps in the available data. Its use in men remains not as widely reported as its use in woman; the issue of voiding difficulty and the need

for intermittent catheterization has not been addressed in men. Furthermore the recommendations cannot be extended to other toxins due to lack of studies.

1.2. Electrical Stimulation and Neurostimulation

Electrical stimulation of the genital area was first used to control incontinence due to DO of different etiologies on an empirical basis.[682] Later, it was suggested that reflex sphincteric contraction induced by electrical stimulation can promote an inhibitory effect on detrusor activity, thus suppressing DO.[683] Many studies of external electrical stimulation for bladder inhibition of idiopathic urgency incontinence have been published, mainly in female patients[684,685,686,687,688,689,690,691] The results vary from 45% to 85% success, with a mean of 38%, and 26% improved. Electrodes implanted in the pelvic floor, have not yielded good results.[689]

Sacral neurostimulation has been reported as an alternative therapy for urgency incontinence, urinary retention, chronic pelvic pain, and for simultaneous urinary and fecal incontinence.[692] Good results utilizing sacral neurostimulation in neurogenic bladder dysfunction were published as early as 1991.[693,694] The working mechanism of neurostimulation in the treatment of lower tract dysfunction is still unknown.[695,696] A suggested mechanism is somatic afferent inhibition of sensory processing in the spinal cord,[697,698] therefore, it may be a centrally acting treatment modality different from botulinum toxin, which is an end-organ therapy that specifically targets the bladder.[699]

Long-term results suggest a sustained effect on restoring voiding in appropriately selected cases, but a revision rate up to 42% at 5-year follow up remains a problem.[700] The largest sacral neurostimulation database reported noted an overall patient satisfaction with treatment of between 60-80% and loss of efficacy was the major problem, occurring in 17% of patients[725]. The 14-year revision rate from a single center was 39%, which decreased by up to one-third after the introduction of design improvements such as the tined lead.[701] In this group, the main reason for revision was loss of efficacy in 58.5% of cases. Battery change was necessary in 8% of patients and the mean battery life was 101.8 months. On-demand stimulation as suggested by Orlemans et al[702] may improve this revision rate. Its use in refractory idiopathic urgency incontinence has been limited to mostly women. Bosch and Groen[703] presented results of chronic implantation in 15 women and 3 men, with an average age of 46 years. Significant improvements in voiding frequency, average voided volume, number of incontinence episodes and number of pads used were found, with no deterioration in response to stimulation with time. However, with subsequent experience in 14 men only 2 patients had a partial response and the rest ultimately failed.[704] Shaker and Hassouna[705] implanted 18 patients with refractory urinary urgency incontinence, but only 2 were in men. Groen, Bosch and van Mastrigt[706] reviewed 33 implanted women and found no effect on urethral resistance and bladder contraction strength as consequence of the depressant effect of sacral (S3) nerve neuromodulation on detrusor overactivity. Groenendijk et al[707] in a retrospective study for the Sacral Nerve Stimulation Study Group, reported urodynamic aspects of 111 patients implanted, but only 8 men were included. They found a better result on urgency incontinence in patients without DO. The difference was not significant. This tendency was also found by South et al[708] in 67 women implanted. Clinical or urodynamic values to predict the outcome of sacral nerve stimulation have been difficult to define. Evaluation of 19 women suggested that urethral instability seemed to be a good parameter to predict a favourable outcome.[709]

Some studies do not specify the etiology of the DO and neurogenic and non-neurogenic causes are grouped together.[705] Some reports focus on technical or specific aspects of the procedure and the same patients may be included in different publications.[707,710,711,712] Implantation in children may be feasible in selected cases[713,714] and poorer results are expected in older women. The outcome in older men is unknown since there are no reports.

Table 12[590,700,715,716,717,718,719,720,721,722,723,724,725] shows recent studies.

Some reports are literature reviews[696,726,727,728] or detail technical modifications.[729,730] There is one systematic review on efficacy and safety of sacral nerve stimulation for urgency incontinence, but 13 of the articles analyzed are abstracts and it is also difficult to ascertain whether the same patients are included in different publications.[731]

There are some publications with level 1[715,716] or 2[704,718,719] evidence and with a grade of recommendation of B. However, due to relatively few men in the clinical trials, and poor results in one of the prospective trials, its general applicability to men with urgency incontinence may be limited. The scenario remains unchanged after about 26,000 patients implanted.[732] In a recent review, Apostolidis[733] concluded that further research is needed to improve patient selection, identify prognostic factors, clarify the mechanism of action, and reduce complications and revision rates. Smits et al[734] studied 20 patients who had discontinued BTx-A because of lack of efficacy (3 had success with Botox but preferred a more permanent solution) and later underwent sacral neuromodulation. Fourteen patients had a successful trial and were implanted and at one year 79% of these patients were satisfied with the treatment. **(Use of neurostimulation for treatment of refractory urinary urgency incontinence in non-neurogenic patients - Level of evidence 3. Grade of recommendation C).**

TABLE 12. Neuromodulation for Treatment of Refractory Urgency Incontinence Due to Detrusor Activity (Both Sexes)

Authors	N	Success (Dry)	Improved	Control Group (N)	Study and Comments
Schmidt et al[715]	34	47%	29%	42	Prospective randomized
Weil et al[716]	21	56%	19%	23	Prospective randomized
Bosch et al[717]	34 women 6 men	38% 16%	21% 16%		Prospective longitudinal

Grunewald et al[719]	18	39%	33%		Prospective
Aboseif et al[720]	5 men 38 women	77%			Not clear about etiology
Hedlund et al[721]	13	61.5%			2 men included, both dry
Kessler et al[590]	91 (71 with UI)		70%		Average follow-up 2 years. Gender not specifically discriminated (about 13% males)
Groen et al[723]	60 women	15%	62%		Longitudinal study, 5 year follow-up
Chartier-Kastler et al[724]	1170 OAB		85%		Multicenter prospective observational, 85% females
Davis et al[725]	172		77%		8% complication

UI = urgency incontinence, OAB = overactive bladder

1.3. Surgical Treatment by Detrusor Myectomy and Augmentation

Previously used treatments of surgical bladder denervation, open bladder transection, cystolysis, endoscopic phenol injections, hydrostatic bladder distention did not yield good results.

Bladder autoaugmentation or detrusor myectomy has been reported as an alternative to augmentation in neurogenic and non-neurogenic dysfunction. Table 13[735,736,737,738] shows results of this treatment in patients with non-neurogenic detrusor overactivity. There are few long-term results available.[737] The use of a silastic intravesical balloon as a scaffold after myectomy seems to improve results in neurogenic patients, but was not tested in IDO.[739] Additional and longer-term experience is still required to properly assess this procedure. **(Level of evidence 3; grade of recommendation C-D)**

Enterocystoplasty results are detailed in Table 14,[736,740,741,742,743,744,745,746] which includes both male and female patients. Some publications are not clear about the type of surgery specifically done in IDO and about the gender. Good results vary from 58% to 88%, with an average of 77%. Approximately 10 to 75% of patients require intermittent catheterization for bladder emptying. Ileum was the most frequently used bowel segment followed by sigmoid colon, although no scientific reason for the use of any particular segment was given. The surgery, as reported in other sections, has a significant complication rate and should be considered carefully when applying it to these patients. A study of 40 patients with neurogenic and idiopathic OAB showed sustained good results with a medium follow up of 13 years.[747] **(Level of evidence 3; grade of recommendation C)**

2. REDUCED BLADDER CAPACITY

Fibrosis of the wall produces a low-volume low-compliant bladder, leading to diminished functional capacity. Symptoms of frequency and nocturia occur as a result of progressive decrease in bladder volume, but urinary incontinence may also be the consequence of a very small capacity, especially if accompanied by urethral weakness. The diagnosis can be suggested by the micturition chart, and confirmed by urodynamics. The causes can be congenital or acquired. Acquired causes include multiple surgeries, inflammatory processes (chronic cystitis, interstitial cystitis, tuberculosis, schistosomiasis, and chemical cystitis) or following radiation.

Bilharzial contracted bladder is a problem that is primarily limited to endemic areas in Africa and the Middle East. Schistosoma haematobium migrates to the veins of the vesical and pelvic plexuses, where the female begins to lay eggs, promoting an initial inflammatory response. As a result, granulomatous lesions form in the lamina propria. Mucosal reactions vary from hyperplasia to polypoid cystitis. A contracted bladder occurs in 2% of cases.[748] Bladder augmentation seems to offer reasonable results in these cases.

Similarly, small fibrotic bladders due to other etiologies can be treated successfully with enterocystoplasty. The results of this surgery are presented in Table 15.[746,749,750,751,752,753,754,755,756,757 758,759,760,761,762,763,764,765,766,767,768,769,770,771,772,773,774,775,776] The results are similar in all etiologies except for radiation. The poorer results after radiation may be due to other tissue damage in the surgical area. New conformal techniques for radiotherapy may improve results in the future, so that the need for augmentation cystoplasty decreases. A new cause for reduced bladder capacity is the long-term ketamine abuse leading to bladder inflammation and volume reduction in about one third of patients.[777] The treatment outcome of augmentation enterocystoplasty was better than those patients with conservative treatment.

Almost all of these studies do not distinguish bowel segments or separate males from females in reporting results. Therefore, it is not possible to correlate any particular aspect with the chance of success or failure. However, overall the results seem reasonably

good with the exception of patients who have undergone radiation. **(Level of evidence 3; Grade of recommendation B).**

XI. URETHROCUTANEOUS AND RECTOURETHRAL FISTULAE

Urethrocutaneous or rectourethral fistula may have congenital, inflammatory, neoplastic or traumatic origins. It is important to recognize the varying etiologies because each type may require a different surgical strategy. All reports except one are retrospective case series. The report by Shakespeare et al[778] is from a prospectively collected database of patients treated with radiotherapy for prostate cancer. They noted that some of the men who had undergone brachytherapty had a biopsy of the anterior rectal wall by gastroenterologists prior to developing the fistula. They recommended that the anterior rectal wall not be biopsied in patients with a history of prostate brachytherapy unless there was a high clinical suspicion of malignancy **(Level of evidence 3; grade of recommendation C).**

1. URETHROCUTANEOUS FISTULA (UCF)

1.1. Acquired UCF

Hidden foreign bodies have been described as a rare cause of both strangulation of the glans penis and UCF. Tash and Eid[779] presented the case of a 30-year-old man who developed a UCF and penile shaft necrosis after a condom broke during intercourse. Neither the patient nor several physicians could identify the retained ring of condom, which had been buried under newly epithelialized skin. He underwent removal of the foreign body under general anesthesia, followed 5 months later by a formal UCF repair.

Urethroperineal fistula, as a complication of open perineal prostate cryosurgery, occurs as an immediate perioperative complication in 10.7%.[780]Thomas et al[781] retrospectively evaluated 250 patients after radical perineal prostatectomy and revealed only one (0.4%) urethroperineal fistula. Fahal et al[782] published an unusual complication of mycetoma. The patient had an infection with Actinomadura madurae that involved abdominal wall, perineum and urethra. This resulted in urinary extravasation with a UCF.

1.2. Management of UCF

The diagnosis of UCF is made by physical examination, retrograde urethrography (Figure 6), urethroscopy, fistulography, urethral ultrasound or color Doppler imaging. Urethral sonography provides additional information about any involvement of the surrounding tissue, location of vessels and associated abnormalities such as a periurethral abscess.[783] Treatment of UCF usually requires urethroplasty techniques with modifications involving fistula excision and multiple layer closure.[784] **(Level of evidence 3; Grade of recommendation C)**

Figure 6. Voiding cystourethrogram after incision.

2. RECTOURETHRAL FISTULA (RUF)

Culp and Calhoon[785] described five basic groups of RUF according to the etiology: congenital, iatrogenic, traumatic, neoplastic, and inflammatory. This classification is the most current, even today over 50 years later.

2.1. Congenital RUF

Endo et al[786] described the results of the Japanese Study Group of Anorectal Anomalies (JSGA) to determine the relative incidence of specific types of these anomalies in Japan. They included discussion of RUF regarding the relationship between the fistula levels and the blind end of the rectum, low type deformity, rare types, and associated anomalies. A total of 1,992 patients (1,183 boys and 809 girls) registered from

1976 to 1995 were analyzed according to the pathogenesis of anorectal malformation in the field of molecular genetics. They reported that more than 20% of RUF should be categorized as intermediate or low deformity from the position of the rectal pouch. A significant preponderance of Down´s syndrome in the deformities without fistulae suggests that investigation of associated anomalies and congenital diseases may provide further insights. The purpose of Rintala's study was to compare the long-term outcome of sacroperineal-sacroabdominoperineal pull-through (SP-SAP) to that of posterior sagittal anorectoplasty (PSARP). In boys with high anorectal anomalies, PSARP was superior to SP-SAP pull-through in terms of long-term bowel function and fecal continence.[787]

In 2011, the German network for congenital uro-rectal malformations evaluated postoperative urological complications in 267 patients with anorectal malformations (recto-urethral fistula in 21 cases). According to type of operation, the highest number of postoperative urologic problems was reported after abdominosacroperineal pull-through.[788]

2.2. Acquired RUF

Acquired RUF may occur after pelvic trauma, surgery of the prostate or rectum, pelvic cancer, radiation (either external beam or brachytherapy), cryosurgery, prostatic hyperthermia, prostatic high intensity focused ultrasound (HIFU), inflammatory bowel disease affecting rectum, or rarely prostatic inflammation. Loran et al[789] reported a patient with a RUF after a repeat transrectal prostate biopsy.

Benchekroun and co-workers[790] report a series of 11 RUF observed over a 25-year period. The etiologies were surgical trauma (5 cases), fracture of the pelvis (2 cases), inflammatory lesions (3 cases), and one fistula was congenital. Colostomy was performed in two patients, surgical closure of the fistula was performed in seven patients: abdominoperineal (3 cases), perineal (2 cases), transperitoneal (1 case) or by transanosphincteric incision (1 case).

In 1972, Smith and Veenema[791] reported their 20-year experience with 160 patients undergoing radical retropubic prostatectomy (RRP) with an incidence of 15 rectal injuries. Only four fistulas developed in this group.

Roberts et al[792] published a series of 11,452 men who underwent open (RRP) or laparoscopic (LRP) radical prostatectomy. Rectal injury occurred in 18 men—12 in the RRP group (0.12%) and six in the LRP group (0.47%). When recognized intraoperatively and primarily repaired, rectourethral fistula was prevented in 87.5% of men. Primary repair performed with vascularized tissue interposition prevented rectourethral fistula development. In men with unrecognized rectal injury, the rectourethral fistula tended to persist and eventually required delayed surgical repair. Thomas et al[793] reported that rectourethral fistulas developed in 13 of 2,447 patients (0.53%) after RP. In seven of 13 patients (54%) a rectal lesion was primarily closed at radical prostatectomy.

With conservative management in three patients, all three healed spontaneously. None of these patients had fecaluria. Three of the nine patients (33%) experienced spontaneous fistula closure after temporary colostomy and transurethral catheterization. In this group, six patients (67%) required additional surgical fistula closure, which was successful in all. Surgical fistula closure (1) without colostomy in presence of fecaluria failed.

The most common single cause of RUF in the series of 23 male patients published by Tiptaft et al[794] was a fracture of the pelvis and iatrogenic causes (two cases after transurethral prostatic surgery, two cases after open prostatectomy, and three cases after urethral instrumentation. Noldus et al[795] reported 23 (3.9%) rectal injuries during 589 RRP and cystoprostatectomy procedures. Eastham and Scardino[796] summarized the incidence of rectal injury during RRP in 3834 patients with an average of 0.7% (range 0.2-2.9%). The incidence of RUF, as an immediate perioperative complication of open perineal prostate surgery, is 1.4 %.

Nyam et al[797] reviewed records of all patients who were diagnosed with RUF between January 1981 and December 1995 and 16 males were identified. All patients were interviewed by telephone for follow-up. The mean age was 68 years and the mean follow-up was 80 months. Adenocarcinoma of the prostate in 15 patients and recurrent transitional cell carcinoma of the bladder in one patient were the underlying malignant diseases. Nine patients had had a RRP with two fistulas after radiation, two after brachytherapy, and three after a combination of radiation and brachytherapy. One patient formed a fistula after cystectomy and dilation of a stricture. This heterogeneous group of patients received multiple therapies including initial colostomy (7 patients), transanal repair (2 patients), parasacral repair (2 patients), transperineal repair (2 patients), coloanal anastomosis (3 patients), and muscle transposition (3 patients). Four of the patients required a permanent stoma.

Badalament et al[798] managed one patient (0.4%) with a urethrorectal fistula after cryoablation therapy for prostate cancer. Zippe[799] reviewed preliminary results of prostate cryosurgery and reported a 2 to 5% incidence of RUF. Porter et al[780] found a 2.5% rate of RUF in 210 patients after TRUS-guided prostate cryosurgery and no urethroperineal fistulae. Ismail et al[800] reported the experience of using salvage targeted cryoablation of the prostate (TCAP) in 100 patients for the recurrence after radiotherapy. The mean follow- up was 33.5 months and RUF occurred in 1%.

Montorsi et al[801] reported a RUF after transrectal prostatic hyperthermia (43°C) in patients with advanced prostatic cancer after multiple treatment sessions. The fistula was cured after a urethral catheter was left in place for one month. Kleinberg et al[802] summarized results of 31 patients with stage T1 or T2

prostatic carcinoma following CT guided transperineal I125 implants and reported that only one patient developed a prostatorectal fistula that was managed with an ileal conduit.

Fengler and Abcarian[803] published their experience of eight patients with RUF in the course of treatment of prostate cancer (3 fistulae after radiation therapy alone, 3 after prostatectomy and 2 after both surgery and radiation therapy). Larson et al[804] evaluated 5719 patients after radiation for prostate cancer. Ten had documented RUF. Lane et al[805] treated 21 men with RUF following primary external beam radiotherapy and one after adjuvant external beam radiation therapy for prostate cancer. Time from the last radiation treatment to fistula presentation was 6 months to 20 years. Four patients underwent proctectomy with permanent fecal and urinary diversion. Successful fistula closure was achieved in the 9 patients who underwent urethral reconstruction. Chrouser et al[806] identified a total of 51 patients with a history of external beam radiation for prostate cancer that subsequently had a urinary fistula. Of 20 patients meeting inclusion criteria, 30% received external beam RT alone, 30% received brachytherapy and 40% had received combined external beam RT/brachytherapy. Most fistulas (80%) were from the rectum to the urinary tract with an average diameter of 3.2 cm. Of patients with rectal fistulas 81% had a history of rectal stricture, urethral stricture, rectal biopsy, rectal argon beam therapy or transurethral prostate resection after radiation. All patients with rectourethral fistulas who achieved symptomatic resolution required urinary and fecal diversion.

Shakespeare et al[778] reviewed the potential factors in fistula development and identified three cases (0.2%) of RUF among 1455 patients treated with prostate brachytherapy (BT), occurring at 19-27 months following BT. All these patients had BT monotherapy and had been investigated with endoscopy and low rectal biopsy. They concluded that gastrointestinal specialists should not perform biopsy of the anterior rectum in patients who have had BT unless there is a very high clinical suspicion of malignancy. Marguet et al[807] described 6 cases of RUF in patients treated with BT plus external beam radiotherapy for localized prostate cancer and subsequent rectal biopsies or rectal surgery. Four patients underwent hyperbaric oxygen therapy, which failed. Three patients underwent fecal diversion with gracilis interposition flaps, and two underwent pelvic exenteration. They also concluded that biopsy of rectal ulcers in the clinical setting of combined radiotherapy should not be performed.

Chang et al[808] published a case of prostatic malakoplakia masquerading as a rectal tumor due to formation of a fistulous tract to the rectal muscular layers. Cools et al[809] reported a very uncommon type of fistula between the large bowel and the prostatic urethra due to Crohn's disease. Felipetto et al[810] described a prostatocutaneous fistula as a complication of pseudomonas prostatitis.

Transrectal high-intensity focused ultrasound (HIFU) destroys prostate cells by coagulative necrosis of the tissue. Recent reports of efficacy also include morbidity. Rebillard et al[452] reported RUF in 0-3% in a review involving 37 articles/abstracts.

Netsch et al[811] reported a retrospective analysis of 363 patients with PCa who underwent HIFU. A total of 8 patients (2.2%) developed RUF. The occurrence after 1 HIFU session was 1.17%, after salvage HIFU 4.5% and after repeated HIFU sessions was markedly elevated (13.63%). Spontaneous closure of RUF did not occur.

Buckley et al[812] concluded that there has been a major shift in the cause of RUF from primarily surgical to approximately 50% resulting from radiation/ ablation therapy. Surgically induced RUFs typically are small, located in bladder neck/trigonal region and can be closed primarily. Radiation/ablation induced fistula are large (>2 cm), involve the prostatic urethra and are fibrotic often requiring a combination of onlay grafting and interposition muscle flap for closure. The anterior, perineal sphincter-sparing approach may be the optimal approach for closure of most RUF (simple or complex). Lacarriere et al[813] noted that the use of radiotherapy had a major impact on its prognosis. The flap, which seemed to have the best results, was the gracilis muscle flap.

Hanna et al[814] reviewed outcomes after surgical treatment of RUF in radiated and nonirradiated patiens. Patients who had irradiated RUF underwent more complex operative repairs, including gracilis interposition flaps (38%) and pelvic exenterations (19%), whereas nonirradiated patients most commonly underwent a York-Mason repair (50%). There were no statistically significant differences in RUF or in postoperative and functional outcomes. Only 55% of irradiated patients had their stoma reversed vs 91% in the nonirradiated group.

Beddy et al[815] examined whether choice of operation and results of surgery for RUF in 50 patients are influenced by prior radiotherapy. Radiation was received by patients for prostate or rectal cancer, and other patients developed a fistula following prostatectomy, Crohn's disease or pelvic fracture (without radiation). Prior to definitive surgery, 30 patients underwent fecal diversion and 37 underwent urinary diversion. Definitive surgery was approached predominantly abdominally in radiated patients and perineally in nonradiated patients successful primary fistula repair was more frequent in the nonradiated group compared with the radiated group. Permanent colostomy and urinary diversion were more often required in radiated patients.

Linder et al[816] also evaluated the impact of pelvic radiation (BT, external beam radiation) and ablative therapy (cryotherapy or high intensity focused ultrasound) on the surgical repair of RUF.Patients with prior radiation/ablation were significantly more likely to require permanent colostomy and permanent urinary diversion as part of fistula management.

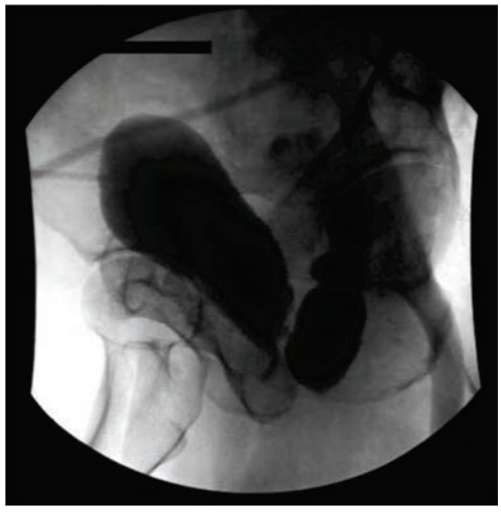

Figure 7. Cystogram demonstrates a rectourethral fistula that occurred after a laparoscopic radical prostatectomy

RUF following laparoscopic radical prostatectomy in 10 patients was reported by Chun et al.[817] Spontaneous healing of the fistula was noted in 6 patients following diversion (urinary ± fecal diversion).

2.3. Diagnosis of RUF

RUF may be strongly suspected from the patient's history (fecaluria, abnormal urethral discharge, pneumaturia, leakage of urine from the rectum during micturition). Rectal examination, proctoscopy, careful urethroscopy, intraurethral injection of methylene blue dye, radiopaque contrast agent placed into the bladder and then voided usually appears in the rectum on X-ray, are the most important diagnostic steps (Figure 7).[783,818]

Sa et al[819] evaluated the value of three-dimensional spiral computed tomography/cysto-urethrography (CTCUG) in diagnosing posterior urethral strictures associated with RUF. The accuracy in determining the RUF was higher with CTCUG (93%) than with conventional urethrography (71%).URFs.

2.4. Therapy of RUF

Small fistulae may resolve spontaneously with urinary and/or fecal diversion. Therefore, an initial trial of conservative therapy is reasonable. Selected patients with chronic fistulas who are poor surgical candidates may also be managed conservatively with antibiotics, pads and symptomatic care. Timing of repair is often individualized, mainly according to the etiology, delay in diagnosis, size of fistula, whether it is the first or subsequent repairs, and the general condition of patient.

Diversion of urine (suprapubic cystostomy) is generally recommended as well as correction of any urethral stricture distal to the fistula. Fecal diversion, with colostomy is used by some as a mandatory part of double diversion or selectively by others.[793] Gibbons[820] stressed the need for a diverting colostomy for 3-4 months.

However, as surgeons obtained more experience, bowel preparations became standardized, and effective antibiotics were developed, and the enthusiasm for colostomy diminished. Currently, colostomy is recommended in circumstances where antibiotics alone cannot control the inflammation and infection associated with the fistula or when the fistula involves radiated tissue. Low residue diet is also useful for healing. Suitable drainage (perineal and urethral splinting) is stressed.

2.5. SURGICAL APPROACHES

Surgical management for rectourinary fistulas remains a reconstructive challenge. Two-layer closure of the urethra and rectum with suture lines at right angles and with interposition of soft tissue (eg, omentum,[821] gracilis muscle,[822] or scrotal flap[823]) has been described. Surgical approaches include transabdominal, transvesical, or direct exposure of the RUF.

There are only a few guidelines to direct the surgeon to the most successful and least morbid technique. Rivera et al[824] staged RUF as: stage I, low (less than 4 cm from anal verge and nonirradiated); stage II, high (more than 4 cm from anal verge and nonirradiated); stage III, small (less than 2 cm irradiated fistula); stage IV, large (more than 2 cm irradiated fistula); and stage V, large (ischial decubitus fistula). Diverting colostomy was performed for stages III to V 6 weeks before definitive therapy. Some of the patients in addition to the RUF will also have urethral strictures that have to be managed. Reconstruction of both aspects to restore functional anatomy is possible with complex reconstructions.[825]

Hechenbleikner et al[826] searched MEDLINE (PubMed, Ovid) and the Cochrane Library by using the term RUF. All studies were retrospective. Of the 569 records identified, 26 articles were included.Four hundred sixteen patients were identified, including 169 (40%) who had previous pelvic irradiation and/or ablation. Most patients (90%) underwent 1 of 4 categories of repair: transanal (5.9%), transabdominal (12.5%), transsphincteric (15.7%), and transperineal (65.9%). Tissue interposition flaps, predominantly gracilis muscle, were used in 72% of repairs. The fistula was successfully closed in 87.5%. Overall permanent fecal and/or urinary diversion rates were 10.6% and 8.3%. Most high-volume centers (>25 patients) performed transperineal repairs with tissue flaps in 100% of cases.

The surgical approaches including the numbers of reported patients are listed in Table 16.[785,790,791,794,795,803,818,823,827,828,829,830,831,832,833,834,835,836,837,838,839,840,841,842,843,844,845,846,847,848,849,850,851,852,853,854, 855,856,857,858,859]

2.5.1 Perineal Approach

In 1926, Young[827] dissected the rectum away from sphincters, divided the fistula, closed the urethra, and mobilized the rectum further cephalad in such a fashion as to pull the affected rectum caudally out of the anus where it was then transected and discarded, suturing the proximal rectum to the anal skin. Subsequently Lewis,[828] in 1947, described suturing the levator muscle fibers together in the anterior midline when possible.

Goodwin et al[829] reported a series of 22 RUF approached perineally. They extensively mobilized the rectum posteriorly and the bladder anteriorly through wide perineal exposure allowing interposition of the levator ani muscles between the urinary tract and rectum. Singh et al[860] described the management of a delayed post-traumatic RUF repaired via transperineal access without rectal or sphincteric transgression. An example of a preoperative and postoperative urethrogram is in Figure 8. Pratap et al[832] described a simultaneous perineal and abdominal approach in a series of 8 patients with traumatic perineal injuries who had both complex urethral disruptions and RUF.

Samplaski et al[833] reported transperineal repair with gracilis muscle interposition in 13 patients with complex RUFs of varying etiologies. One patient developed recurrence. They demonstrated low morbidity, high success rates, and reasonable bowel and bladder function postoperatively.

Selph et al[834] confirmed that patients who require placement of an AUS after a perineal RUF repair seem to fare just as well as patients who undergo primary AUS implantation with no increased rate of complications postoperatively.

Voelzke et al[835] divided the fistula cohort of 23 patients into 2 groups, including postoperative and energy ablative fistulas, respectively. They recommended rectal sphincter preserving transperineal repair as a successful surgical method to repair postoperative and energy ablative rectourethral fistulas. An interposition muscle flap should be considered in the

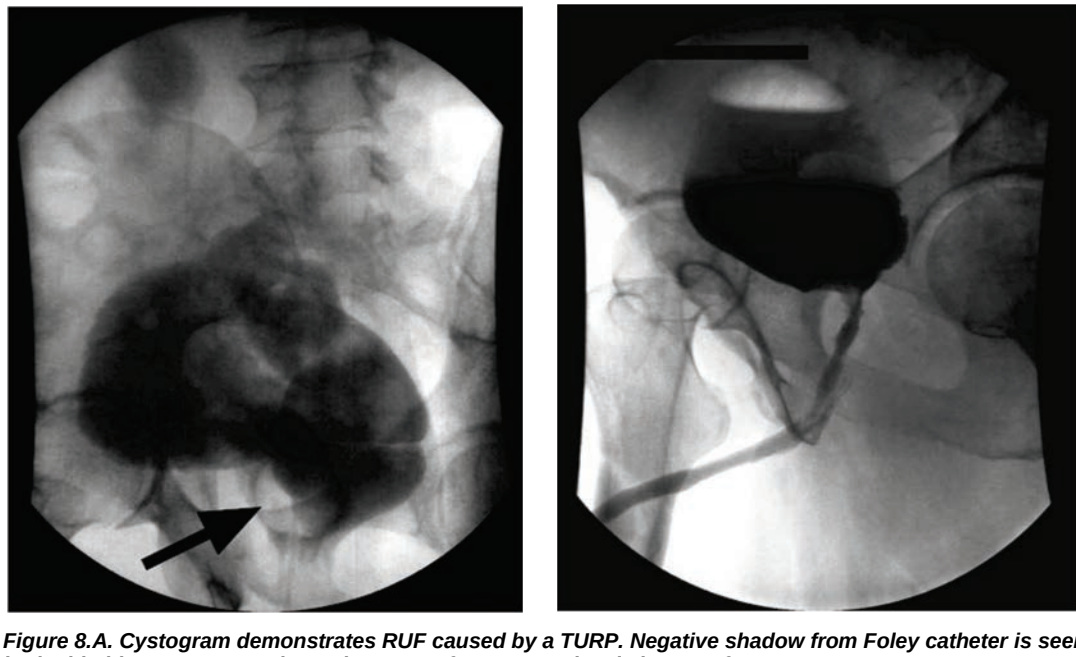

Figure 8.A. Cystogram demonstrates RUF caused by a TURP. Negative shadow from Foley catheter is seen in the bladder. B. Retrograde urethrogram after transperineal closure of RUF.

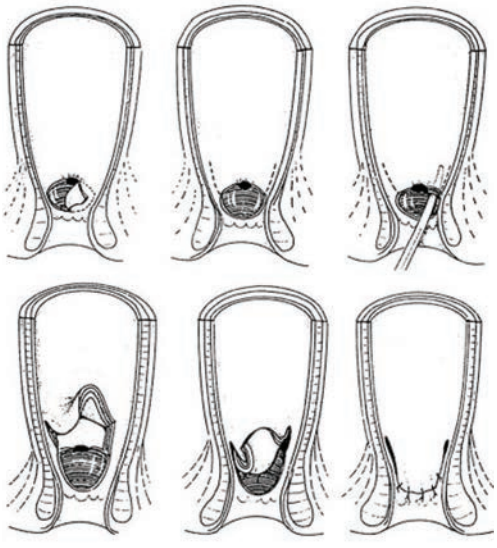

Figure 9. Rectourethral fistula repair. Full thickness rectal wall is mobilized to close in a "vest over pants" technique to close the fistula.

setting of energy ablative rectourethral fistulas to increase successful outcomes.

2.5.2 Posterior Sagittal Approach

Kraske in 1885[861] described a posterior midline incision extending to the left paramedian aspect of the coccyx and sacrum that involved partial removal of the sacrum in addition to coccygectomy. His method did not involve division of the sphincters, but rather sweeping the rectum laterally to ultimately facilitate resection and reanastomosis of a tumor-bearing rectal segment, thereby preserving fecal continence. In 1962, Kilpatrick and Thompson[836] used this approach when the rectum was completely mobilized circumferentially proximal and distal to the fistula. The RUF was then divided, sparing as much as possible on the urethral aspect. The rectal part of the fistula was excised and closed in two layers, and the urethra was repaired and stented with a catheter.

2.5.3 Posterior (Parasacrococcygeal) Transsphincteric Approach

In 1969, Kilpatrick and Mason[838] updated this method and advocated a more radical method of dividing the rectal sphincters to give direct access to the RUF. The procedure (the York-Mason approach) is simpler than some complicated transabdominal or transperineal approaches to RUF. It is still used because it allows direct visualization of the fistula via parasacrococcygeal (transsphincteric) incision especially to fistulae in the mid to lower rectum.[803] After the skin incision the mucocutaneous junction is marked with sutures and the internal sphincter is exposed. Division of the sphincter mechanism and posterior rectal wall allows exposure of the fistula. Each sphincter muscle is tagged with color-coded sutures. The next step of this procedure is the incision around fistula, followed by excision of the fistulous tract exposing the catheter in the prostatic urethra. The undermining of rectal wall allows sufficient mobilization.

After closure of the prostatic urethra it is recommended that the full-thickness rectal wall flaps are close in a "vest over pants" technique (Figure 9). It is important to make sure that the suture lines do not overlie each other. The procedure is completed by suture of the rectal wall and approximation of the sphincter muscles (Figure 10). Fengler and Abcarian[803] reported healing of RUF in all of 8 patients with the York-Mason approach. Bukowski et al[840] managed 7 acquired recurrent RUF (3 after prostatectomy, 3 after trauma and 1 after perineal abscess) using York-Mason technique and a similar experience was described by Fournier et al[839] in the management of a case of the urethroprostato-rectal fistula after a gunshot wound.

Stephenson and Middleton[837] modified the York-Mason repair and reported their experience with posterior sagittal, transanal, transrectal repair of RUF in 15 patients. The transsphincteric, transanal surgical approach provides many advantages, including easy access and identification of the fistula tract, good surgical exposure, adequate resection back to well vascularized tissue, and access to several vascularized

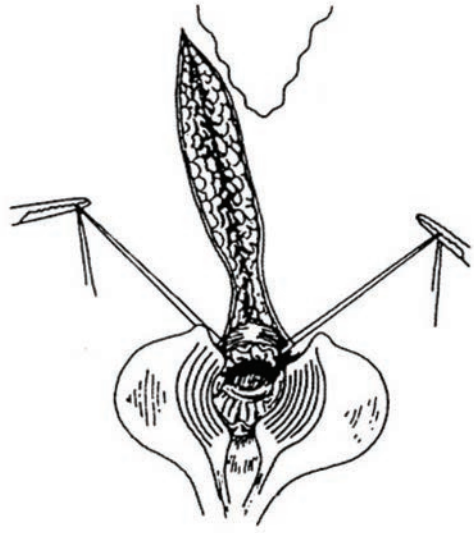

Figure 10. York-Mason approach to a rectourethral fistula via a parasacrococcygeal (transsphincteric) incision. Sutures are used to mark the sphincters. The speculum has been placed at the bottom of the incision and the anterior rectal wall is visible.

flaps for interposition between the repaired urinary and gastrointestinal tracts.

Culkin[852] reported preliminary experience with the transsphincteric, transanal surgical approach to correct acquired urethrorectal fistula in five men. Mean patient age was 56.6 years (range 37 to 72). The etiology was surgical (radical prostatectomy) in 3 cases, traumatic in 1 and idiopathic in 1.The time from the diagnosis of urethrorectal fistula to surgery was 4 weeks to 4 years. Five men underwent excision and closure of a urethrorectal fistula with diverting colostomy. In 4 men (80%) urinary continence subsequently returned with adequate sphincter tone, while in 1 (20%) with perineal trauma and active proctitis the fistula recurred 6 weeks after surgery.

Dal Moro et al[841] reviewed a 15-year experience using the York-Mason posterior sagittal transrectal approach to iatrogenic RUF in 7 patients. In one patient with Crohn's disease the fistula recurred 11 years after the first surgery. The colostomy remained in place only in one patient with Crohn's disease and in another with ulcerative rectocolitis.

Erickson et al[842] reported a novel surgical technique used to repair a rectourethral fistula associated with two short-segment urethral strictures located in the anterior and posterior segments of the urethra in a patient with prior unsuccessful repairs. The anterior urethral stricture was reconstructed with a ventral onlay of buccal mucosa in the exaggerated lithotomy position. In a modified prone position, the rectourethral fistula was repaired using the transrectal transsphincteric (York-Mason) technique and the posterior urethral stricture with a radial forearm fasciocutaneous free flap which was anastomosed to the inferior gluteal artery and vein. The coexistence of a rectourethral fistula and distal urethral stricture requires simultaneous repair, because the urethral pressure from the distal obstruction may compromise fistula closure. Lorente et al[843] reported early successful closure in 10 patients with the posterior transsphincteric York-Mason technique, with good recovery of urinary and fecal continence. Pera et al[844] reported on 5 patients successfully treated after RP with the York Mason technique.

They reported minor morbidity and no impairment of continence.

Rouanne et al[845] reported 10 male patients with RUF due to radical prostatectomy who underwent York Mason repair between 1998 and 2009. All patients initially received both a urinary and a bowel diversion as the first step of the treatment. The second step consisted of a modification of the York Mason technique in which the approach began with a parasacrococcygeal incision extending from the coccyx to the anal verge. The mean time from surgery to York Mason repair was 15 (range, 4-42) months.

Kyrklund et al[846] aimed to define the long-term bowel functional outcomes following PSARP (posterior sagittal anorectoplasty) for RUF. They used validated

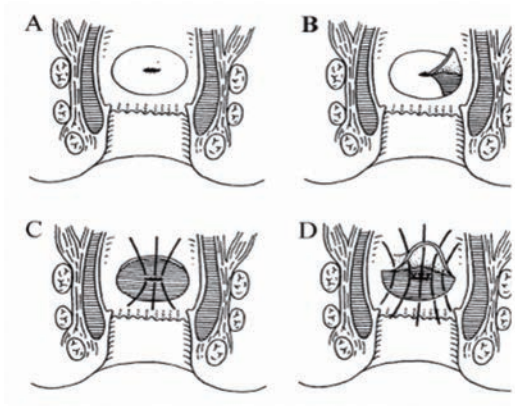

Figure 11. Transanal repair of rectourethral fistula.

D. Rectal mucosal flap sutured with absorbable suture.

Bowel Function Score (BFS) questionnaires mailed out to patients. Approximately one third of 34 respondents reported voluntary bowel movements (VBMs) and complete continence and 24% were reliant on anterograde continence enema (ACE) washouts, and 1 patient had a colostomy. Their results suggest that in the long-term, functional symptoms remain highly prevalent among patients treated for RUF with PSARP. However, the majority can be expected to achieve social continence.

Forest et al[847] retrospectively analyzed the data of 17 patients treated surgically for RUF with the York Mason technique between 2000 and 2012. All patients had a bowel diversion before surgery. They observed four recurrences of RUF (23.5%).

Alam et al[848] from India prospectively reviewed the records of all the patients who developed RUF. A total of 18 patients were included and in all cases faecal and urinary diversion were done preoperatively. In 8 patients repair of fistula was done through the perineal approach where excision of the fistulous tract with anastomotic urethroplasty and repair of rectal wound was performed. Out of these 8 patients tunica vaginalis flap was applied in 3 and dartos pedicle flap in 5 cases; in the remaining 6 patients transrectal York-Mason repair was done. No patient developed urinary or faecal incontinence. Transrectal York-Mason repair is easier to do with less morbidity and complication while perineal approach with graft interposition may be done in cases where anastomotic urethroplasty is needed along with fistula repair.

Pfalzgraf et al[849] assessed fistula recurrence rate and health-related quality of life (HRQL) after repair in a

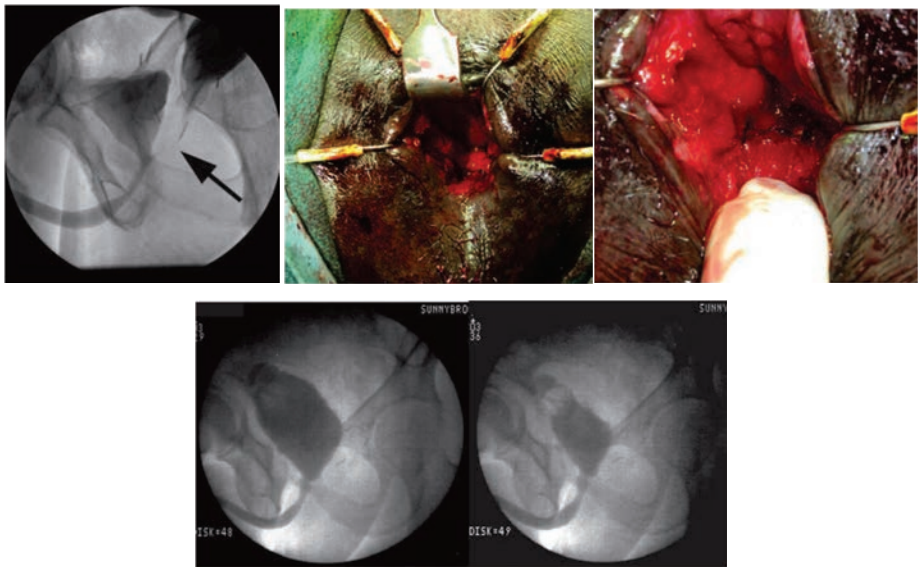

Figure 12.

retrospective study of 17 patients treated for RUF after RP between 1993 and 2008.Fistula closure was abdominal in 10 patients, perineal in five and combined abdominal and perineal in two, some with tissue interposition. Perineal or abdominal fistula repair yields excellent success rates and high patient satisfaction.

Transanal Approach

Parks and Motson[851] popularized the addition of a full thickness local flap of anterior rectal wall as an adjunct to fistula repair through the intact anal canal (Figure 11[862] and Figure 12). They modified the transanal technique by denuding the rectal mucosa lateral and distal to the fistula, and mobilized the rectal wall away from Denonvilliers´ fascia proximal to the fistula for four centimeters. Tiptaft et al[794] also used a special anal retractor for this surgery.

With the Latzko procedure the RUF is closed in three layers with absorbable suture. A transurethral catheter is placed for 3 weeks. Noldus et al[795] reported 23 patients (3.9%) with rectal injury during 589 RP and cystoprostatectomies. Of these 23 patients, 12 developed a RUF. Seven fistulas closed spontaneously with prolonged catheter drainage. The remaining 5 fistulas were all successfully closed with the transanal Latzko procedure.

Al-Ali et al[818] treated 30 men with RUF caused by war wounds. He used the method of posterior transsphincteric anterior rectal wall advancement as the treatment of choice. Double diversion (end sigmoid colostomy and suprapubic cystostomy) for one month was performed in all patients. Double diversion alone resulted in 'spontaneous' RUF healing in 47% of patients but 53% required reconstruction. Early repair was recommended for large fibrous fistulas. Undiversion was done after two months when the urethra and anorectal canals were normal.

Joshi et al[853] successfully used a rectal advancement flap in five patiens with RUF.

Keller et al[854] introduced an algorithm-based treatment approach for RUF. Selective fecal diversion is possible, and the majority of patients who require definitive intervention can be treated with a transanal or transperineal(endorectal, dartos, or gracilis) approach. Only six patients (20%) required permanent urinary diversion or drainage catheters, but long-term urinary dysfunction is frequent. Healing rate was 90% and recurrence rate 0%.

2.5.4 Anterior Transsphincteric, Transanal Surgical Approach (ASTRA)

In 1973, Gecelter[855] performed a midline perineal incision to gain access to the urinary tract after placing the patient in exaggerated lithotomy position. The anal sphincter was incised anteriorly, tag sutures carefully placed, and the rectal incision was carried to the fistulous tract, which was excised and repaired in multiple layers with transposition of tissue as available. Castillo et al[863] reviewed their first 110 consecutive laparoscopic extraperitoneal radical prostatectomies and reported 3 RUF. Only one was cured with conservative management. The other 2 patients were repaired by ASTRA.

2.5.5 Endoscopic Approach

Wilbert et al[857] reported two patients with RUF who were repaired endoscopically transanally. The patients were positioned prone and the rectoscope mounted to the operating table was inserted into the rectum .The fistula was visualized and the opening excised to the level of the perirectal tissues with cautery. The rectal wall was mobilized full thickness with scissors and closed primarily in two layers with a microscope. The patient was then placed in lithotomy position and the urethral side of the fistula was coagulated and injected with fibrin.

Bardari et al[858] used cyanoacrilic biological glue to close one prostato-perineal fistula complicating an abdominoperineal resection of rectum and one persistent neobladder-ileal fistula. The biologic sealant was administrated endoscopically through an open-end 6F ureteral catheter. Quinlan et al[864] presented the case of an iatrogenic fistula in a 71-year-old man treated by a transanal endoscopic microsurgical (TEM) approach, without recourse to a stoma. Bochove-Overgaauw et al[865] reported successful repair of 1 of 2 RUF with transanal endoscopic microsurgery (TEM): the RUF occurred after laparoscopic radical prostatectomy. Pigalarga et al[859] described a case of successful repair of iatrogenic RUF through a multidisciplinary approach consisting of cystoscopy, urethral stent placement, colonoscopy, and transanal endoscopic microsurgery assisted rectal advancement flap.

2.5.6 Other Modifications

Youssef et al[830] successfully treated 12 male patients who presented with RUF from 1990 to 1997 using the perineal subcutaneous dartos flap procedure. The RUF resulted from crush pelvic injury in 6 cases, gunshot wounds in 2, and post prostatectomy in 4. The fistula was associated with a urethral stricture in 4 cases. A perineal approach was used and combined with a transsymphyseal approach in the 4 patients with posterior urethral stricture. They interposed a subcutaneous dartos flap as a tissue flap between the repaired rectum and urethra. No leakage or perineal collection developed and there was no fistula recurrence. Follow-up ranged from 9 to 42 months. This technique of a perineal subcutaneous dartos flap may fulfill the principles for successful repair of RUF. Varma et al[866] also concluded that dartos muscle interposition is a straightforward technique that can result in successful fistula repair, but should not be used in immune-compromised patients or after radiation therapy.

Felipetto et al[810] used human fibrin sealant (Tissucol) to close a prostato-cutaneous fistula (as a complication of pseudomonas prostatitis). Venkatesh and Ramanujam[867] prospectively studied the efficacy of autologous fibrin glue for closure of recurrent anorectal fistulas. Overall success rate was 60% however patients with acquired immunodeficiency syndrome who had fistulas associated with the urinary tract failed to respond. Verriello et al[868] used fibrin sealant (Quixil) to inject it into the fistula tract and a rectal mucosal flap was used to close the internal opening. The fistula healed in few weeks, and the patient remained symptom free after 1 year of follow-up. Chirica et al[869] reported their experience with coloanal sleeve anastomosis (Soave procedure) as a salvage procedure for complex rectourinary fistulas after radical prostatectomy or following anterior resection for rectal cancer after radiochemotherapy. All eight patients had a temporary ileostomy, which was successfully reversed in 7. Lesser et al[870] reported a case of radiation and salvage cryoablation induced RUF after treatment of prostate cancer which was successfully repaired with a combined endorectal advancement flap with an Alloderm graft.

Muhlmann et al[871] compared techniques of rectal mucosal advancement flaps (RMAF) and fistula plugs (FP) used to manage complex anal fistulas. The results of treatment of complex anal fistulas are disappointing. The choice of operation of either a RMAF or a FP did not alter the poor healing rates of about one third of patients in each group.

Gonzales-Contreras et al[872] treated the RUF after radical prostatectomy with interposition of the gracilis muscle. Eight weeks after surgery and with colostomy closed, no evidence of recurrence was detected.

Chen et al[873] gained a high success rate in the treatment of complex rectovaginal fistulas and RUF by the technique of the gracilis muscle transposition and postoperative salvage wound irrigation-suction.

Yo et al[874] also treated the recurrent RUF in a man after anoplasty for anorectal malformation during early infancy.They used a gracilis muscle flap approximately 30 cm long which was harvested from the left thigh, brought into the deepest part between the separated rectum and urethra through a subcutaneous tunnel and afixed there.

Iwamoto et al[875] introduced a successful novel operative technique of a RUF with a pedicled vastus lateralis musculofascial flap. A first attempt failed to close the fistula utilizing the transanal rectal flap advancement technique.

Solomon et al[876] described a new perineal approach using the medial aspect of the puborectalis muscles

as a double-breasted rotational interposition flap to repair the RUF.

Ganio et al[877] achieved the closure of the RUF in all 11 patients by the repair of using a bulbocavernosus muscle graft.

Lee et al[878] presented a novel minimally invasive procedure: robotic-assisted laparoscopic segmental resection with rectoanal anastomosis for the management of difficult RUFs.

2.6. Summary

A review of recent literature shows an increasing number of papers describing UCF or RCF

treatment. The vast majority of available studies are retrospective cases and case series (level 3 evidence). There are many causes of these fistulas described in the literature but there is a lack of valid epidemiologic data about the incidence of UCF and RUF. The aim of the surgical approach is the closure of all types of fistulas. While spontaneous closure and success with a one-stage procedure has been reported, most cases to date involve 3 stages (double diversion, closure technique, and undiversion). An endoscopic approach using biological sealants is promising. Only a few urologists and general surgeons have gained wide experience in the management of UCF or RUF, and the management of these difficult conditions should remain in the hands of experts working in tertiary referral centres. No single procedure has yet proved to be best or universally applicable. Conservative treatment is generally ineffective in the management of large RUF. Surgical intervention offers symptomatic relief and improved quality of life in most patients. Regardless of complexity, rectourethral fistulas have an initial closure rate approaching 90% when the transperineal approach is used. Permanent fecal and/or urinary diversion should be a last resort in patients with devastated, nonfunctional fecal and urinary systems.

All reports are still only retrospective case series **(Level of evidence 3; grade of recommendation C).**

XII. THE ARTIFICIAL URINARY SPHINCTER (AUS)

Different devices designed to control urinary incontinence in the male began to be developed in the middle of the 18th century.[879] The gold standard today is the artificial urinary sphincter (AUS) designed by F.B. Scott, W.E. Bradley, and G.W. Timm in 1973.[880] The original model underwent a number of modifications, but the basic principle remains the same. It consists of a fluid filled hydraulic system with a cuff around the urethra, a pressure regulating balloon and an activating device, the pump, placed in the scrotum (AMS 800TM Urinary Control System, Boston Scientific, Marlborough, MA, USA). In recent years a competing model (ZSI 375, Zephyr Surgical Implants, Geneva, Switzerland) where the reservoir is incorporated into the pump in the scrotum has become available,[881] though a recent publication reports disappointing results.[882]

1. AVAILABILITY AND COST

The use of the AUS has increased dramatically since its introduction in 1975 when 90 AUS devices were implanted until 2008 when 4818 procedures were done, with 61% implanted for PPI.[883,884] In 2005, just over 10% of US urologists perform AUS surgery with the vast majority (92%) performing 5 or fewer surgeries a year and there were only 8 surgeons who implanted 21 or more AUS devices per year.[884] A recent study evaluating American Board of Urology case logs from 2003 to 2013 demonstrated that of those surgeons logging at least one AUS case the median number of AUS surgeries done over a 6 month period by those applying or recertifying for certification was 1.[885] The top 4% in that cohort logged a median of 8 cases over the 6 month period. This group performed 29% (652) of all AUS placements logged.

The results of an e-mail survey among urologists and gynecologists were previously published in the 3rd ICI, whereby members of the International Continence Society asking them if the AUS was available in their country; and if so, what was the price of the device (in US dollars). About 10% of the members responded by email from 31 countries. The high price in some countries at the time (Georgia, Hong-Kong, Romania and Saudi Arabia) precluded its use. Very few gynecologists implant the sphincter, probably since the majority of patients receiving the device are male.

2. INDICATIONS

The indication for AUS placement is for the *treatment of SUI that is persistently bothersome despite 6-12 months of active conservative management.* A recent ICS Consensus Conference recommended that patients with bothersome severe symptoms can be offered an AUS 6 months postoperatively while those with improving symptoms, even at 12 months, can at surgeon discretion still be observed.[886] As the most common cause of SUI in men is iatrogenic injury during prostate cancer surgery, it follows that the most common indication for AUS is post-prostatectomy incontinence (PPI). The use of the AUS for the treatment of PPI varies regionally. For example, within the United States, state-by-state use of the AUS ranges from 1% to 10% of all RRP patients, with an average of 6% of RRP patients ultimately undergoing AUS implantation.[887]

Previous radiotherapy to the pelvis is not a contraindication for AUS placement in males,[888] as the ultimate outcome seems to be similar in men whether or not they have received radiation therapy,[889] although a higher incidence of urethral atrophy, erosion and infection requiring surgical revision has been reported

in irradiated patients compared to those not irradiated (41% vs 11%). These patients should be counselled about this higher need for revision.[886] Despite this observation, long term continence and patient satisfaction appear not to be adversely affected in the irradiated male patient.[889]

The compressive effect of the AUS is temporarily relieved when the patient squeezes the scrotal pump, transferring fluid from the urethral cuff to the pressure-regulating balloon. Subsequently, the bladder can then empty either by bladder contraction and/or by abdominal straining. Accordingly, patients voiding with the Valsalva maneuver because of an underactive or neurologically acontractile bladder, do not seem to be at an increased risk of complications.[890] It should also be noted that patients with previous anti-incontinence procedures show a significantly higher explantation rate.[891]

Clinical experience suggests that enterocystoplasty or gastrocystoplasty can be done simultaneously with the implantation of the AUS.[892,893] However, AUS placement at the time of cystoplasty is associated with earlier infections, especially during the first 3 years postoperatively.[894] In the long-term (> 3 years) the infection rate is the same whether the AUS is implanted after or at the time of cystoplasty. AUS can also be successfully implanted in patients after bladder substitution,[471] and in those with locally recurrent prostate cancer with a relatively good prognosis,[895] or those with severe post-radical prostatectomy anastomotic stricture in whom a stent has been placed previously.[483]

Finally, advanced age is not a contraindication to AUS placement. A retrospective analysis by O'Connor and colleagues[896] of a cohort of men over age 75, revealed excellent success rates, with 21 of 29 men (72%) achieving successful continence. Revision rate was 14% at an average of 5 years follow-up, with 14% requiring explantation, and 21% requiring device deactivation due to deterioration in overall health precluding proper use of the AUS at an average of 47 months after placement. A recent analysis by Ziegelmann et al[897] demonstrated that patients over 80 years of age were more likely to experience device erosion or infection compared to a reference group of patients under 60. Nevertheless the overall device failure rate was noted to be low and the AUS was recommended for the appropriately selected and counselled octogenarian. A study by Raup et al[898] evaluating a similar population noted that those with intact cognition and manual dexterity did very well with an AUS, but cautioned that those with impaired cognition or manual dexterity showed a statistically significant increased rate of overall failure.

3. SURGICAL TECHNIQUES

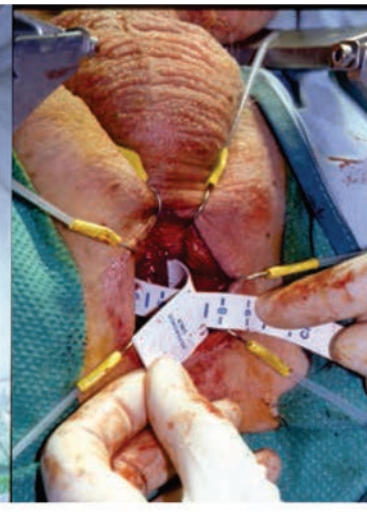
Preoperative prophylactic antibiotics should be administered within 60 minutes of skin incision and UTIs should be treated preoperatively. Patients can be positioned in either lithotomy or supine – lithotomy is preferred for perineal approach while supine is preferred if a trans-scrotal approach is to be performed. An appropriate scrub should be performed -chlorhexidine-alcohol has been shown to be superior to povidine-iodine.[886]

The original technique of implantation is illustrated in Figure 13**.** The cuff of the sphincter is placed around the bulbar urethra via a midline perineal incision, while the pressure regulating balloon and the scrotal pump are inserted via a separate inguinal incision. The inguinal incision is carried through the fascia, above the level of the ligament and an area in the prevesical space is bluntly cleared. The pressure-regulating balloon is placed there and filled with 23 cc of saline or contrast after which the fascia is closed. A tunnel is made under Scarpas fascia into the scrotum deep to the dartos fascia where a pocket for the pump is developed. The cuff tubing is transferred from the perineum to the inguinal incision after which the excess tubing is cut off and the appropriate connections are made with the quick connect system.

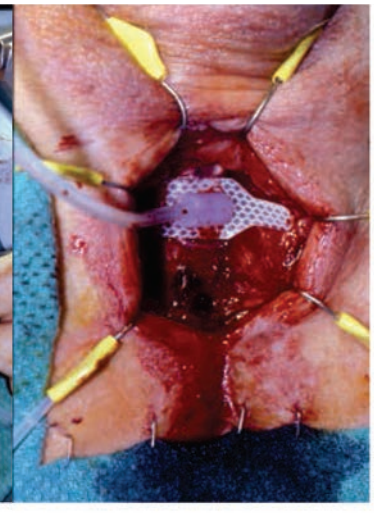
Another surgical approach has been described using a single, upper transverse scrotal incision which allows the placement of all 3 components of the system, the cuff, the pump in a scrotal pouch, and the reservoir behind the fascia transversalis.[363] Alternatively, the pressure-regulating balloon may be placed through a separate inguinal incision, with the cuff and control pump placed via a single trans-scrotal incision, with the connections among scrotal pump, balloon reservoir, and urethral cuff tubing made in the usual inguinal incision. While the trans-scrotal approach potentially minimizes the invasiveness of the AUS surgery, by limiting the surgical approach to a single incision,[363] a few reports have revealed that surgical success might be diminished compared with perineal cuff placement and abdominal balloon reservoir placement.[899,900] A multicenter retrospective study by Henry et al[900] of 158 patients operated on at 4 centers noted that in patients treated with a perineal vs trans-scrotal AUS the perineal group had a completely dry rate of 44%, vs 28% in the scrotal group (P<0.03) and had much higher rates of "social continence" as well. Thus, the perineal approach for initial artificial urinary sphincter implantation appears to control male stress incontinence better than the trans-scrotal approach.

Figure 13. Artificial Sphincter Technique

A. With the patient in lithotomy position, a perineal incision is made behind the scrotum to exposure the bulbar urethra.

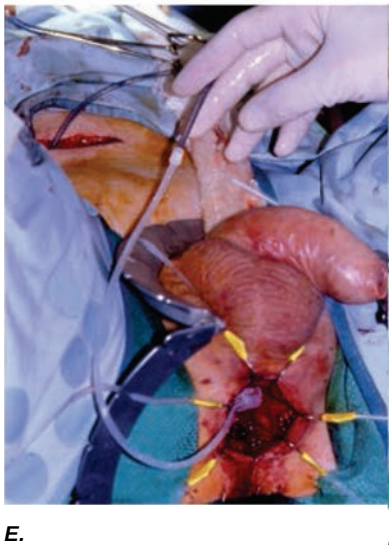


B. The urethra is mobilized circumferentially within the bulbospongiosus muscle and the measuring tape is used to obtain the cuff size.

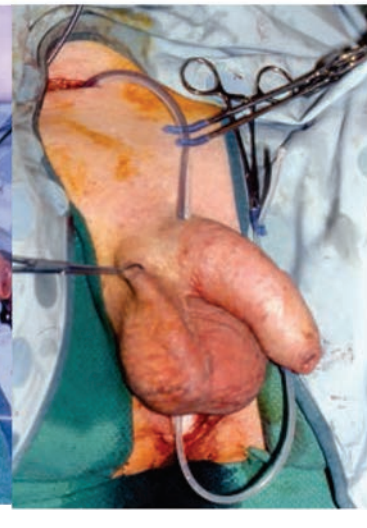


C. The belt-like cuff is positioned around the urethra.

D. A right lower quadrant (RLQ) abdominal incision is made and the extraperitoneal space is entered lateral to the rectus muscle for insertion of the reservoir.



E.



F.

G.

Figure 13. Artificial Sphincter Technique

H. Connectors are placed to join the tubes from the cuff and reservoir to the corresponding tubes from the pump in the RLQ incision.

The trans-scrotal approach appears particularly useful for simultaneous placement of an AUS and inflatable penile prosthesis through a single incision, with Kendirci and colleagues[901] reporting a urethral erosion rate of 9%, an overall revision rate of 14%, and a social continence rate of 100% in 22 patients at 17 months average follow-up. Sellers et al[902] recommend the simultaneous surgery for cost-efficacy. They demonstrated a $7,000 cost savings when both devices were implanted simultaneously through a scrotal approach, compared to staged implantation with 2 separate surgeries.

Recent experience with the relatively new 3.5 cm cuff has demonstrated significant efficacy, however men who with a history of radiation experienced a significantly increased risk of erosion (21%).[903]

A very well done concise review of pertinent surgical details (as well as indications and trouble-shooting) has recently been published by the 2015 ICS AUS Consensus Group[886] and is worth reviewing.

4. COMPLICATIONS

Complications following implantation of the AUS can be divided into the categories of incontinence, erosion and/or infection, and unusual complications. While the number of AUS procedures performed varies geographically throughout the world. Certain "centers of excellence" perform substantially more procedures than do community hospitals.[887] However, the total number of procedures done in a given center does not seem to be a determining risk factor for complications. Comparable erosion/infection rates have been reported from centers with fewer than 50 or more than 100 cases.[326] This suggests that erosion and infection may be more closely related to the physiologic state of the host rather than the experience of the surgical team, provided standard precautions are strictly applied. Nevertheless, as experience with the AUS has grown the overall revision rate has reportedly decreased.[884]

4.1. Incontinence

Incontinence following implantation of an AUS can result from (1) alteration in bladder function, (2) atrophy of the urethra, or (3) mechanical failure of the device. These causes may co-exist.

4.1.1 Alteration in Bladder Function

Lai and Boone[307] noted that based on postoperative patient symptoms and the need for anticholinergic medication up to 23% of men undergoing AUS for PPI can develop denovo OAB. UDS were not repeated postoperatively to define the bladder changes associated with this.

Alteration in bladder function has been reported principally in patients with neurogenic bladder dysfunction, especially in children.[904,905,906,907,908,909] These changes include de novo involuntary detrusor contractions, decrease in bladder compliance, and the development of a high-pressure system, causing incontinence, hydronephrosis and ultimately renal failure. Modifications in detrusor behavior (including its consequences on the upper urinary tract) occur in up to 57% of cases.[904,905,906,907,908,910,911,912,913,914,915] It should be pointed out, however, that there has never been a published report of hydronephrosis following implantation of an AUS for incontinence after prostatectomy.[916] While the ideal candidates for sphincter implantation are those with a low pressure, relaxed, and compliant bladder but an incompetent urethral sphincter[913] data described earlier demonstrated that even those with "unfavourable" urodynamic factors may have a good outcome after AUS placement.[62]

4.1.2 Atrophy of the Urethra

Urethral atrophy may occur at the cuff site secondary to long-term mechanical compression of the periurethral and urethral tissues. However, some authors do not mention it as a possible cause of AUS failure.[404,916,917] About 4 months following implantation, cuff efficiency diminishes, presumably because pressure atrophy occurs in every patient to some extent.[918] The incidence of urethral atrophy leading to revision varies from 3% to

9.3%.[292,298,301,914,919,920,921,922] Atrophy can be lessened with nocturnal deactivation of the cuff.[923]

However, a recent study from a very experienced center argues that urethral atrophy does not occur.[924] They reviewed 50 consecutive patients with recurrent incontinence after AUS placement who had the device explanted. In 31 a specific cause for malfunction of the AUS device was noted. In the other 19 where no specific cause was found 14 had the device replaced with a new, but same size cuff and pressure regulating balloon. Of those 14, 12 were successful without any cuff downsizing. They hypothesize that material failure of the cuff or balloon, likely because of age and the resulting inability to generate the appropriate pressure is the cause of failure and that urethral atrophy does not exist. In fact in 6 patients in whom the restrictive fibrous sheath around the cuff was excised, the urethral circumference was noted to immediately return to normal.

4.2. Mechanical Failure

This includes perforation of one of the components with loss of fluid from the system, air bubbles or organic debris within the system causing inadequate function of the pump, disconnection of the tubes, or kinking of the tubes. Introduction of "kink-free" tubing has virtually eliminated this last complication. The incidence of these complications varies widely and ranges from 0%[920] to 52.5%[308] with the longest follow-up. In this latter study, the cuff seemed to be the most vulnerable part of the system (22 cuff failures in 18 patients, most of them occurring during the first 2 to 3 years following implantation), followed by pump failure (6 times in 4 patients). Blockage is an exceptional event, occurring only once in 61 patients followed from 10 to 15 years.[308] In a publication from Baylor,[301] chronicling a 13-year experience with the AUS, mechanical failure occurred at an average of 68.1 months postoperatively. An unusual mechanical complication has been reported. The locking tab became

Figure 15. AUS Infection

displaced distally into the cycling portion of the cuff preventing the fluid from flowing into the cuff surrounding the urethra.[925]

4.3. EROSION AND/OR INFECTION

Erosion and infection are two major complications that almost invariably necessitate removal of the prosthesis (Figure 14 and Figure 15). Their incidence may be reported separately, or more commonly as a single complication. The incidence of these complications varies from 0% to 24.6%.[292,404,907,913,914,919,920,921,922,926,927] Most recent large series report an incidence of infection and erosion generally less than 8%.[60,300,301,313,916,917,928,929] As would be expected, the highest incidence has been reported with the longest follow-up (10-15 years).[292] Lai and colleagues[301] from Baylor reported that erosion occurred at an average of 19.8 months postoperatively rather than in the perioperative period. Previous surgery[930] at the site of cuff placement increases the risk of erosion. This, however, may be decreased by delayed cuff activation.[931] A study by Lai et al[932] noted that patients undergoing a "secondary" implant (after a prior explant for erosion or infection) had a four-fold higher erosion rate compared to "virgin" cases. Some authors, however, did not find an increased incidence of complications when a new cuff was implanted at the site where several months before a cuff has been removed for infection or erosion.[933] Other risk factors include urethral catheterization and urethral endoscopic manipulations with an activated sphincter in place.[934] This point is important and it is crucial that patients with an AUS understand that if they are to have a catheter placed they should ask their physician to have a urologist deactivate the AUS first.

A likely etiology of early erosion is intra-operative laceration of the urethra when dissecting it from the corpora cavernosa, where a difficult anatomical plane exists. Intraoperative recognition of urethral injury can be facilitated by retrograde perfusion sphincterometry

using a flexible cystoscope.[39] While recognition of a urethral injury may alert the surgeon to the necessary termination of the procedure, urethral erosion may still occur without a known urethral laceration.[935]

As mentioned above, while the majority of authors consider previous radiotherapy a risk factor for increased infection and erosion, it is not a contraindication to implantation of an AUS in the male patient with PPI.[291,293,315,397,889,917,936] Overall patient satisfaction is similar in those who have been irradiated, compared to those who have not been.[291,302,889] Furthermore, the degree of satisfaction does not diminish with an increased number of surgical revisions.[306,937]

4.4. Rare Complications

Several unusual and rare complications have been reported in the literature, such as the intravesical migration of the reservoir with secondary stone formation in the bladder,[938] or a giant urethral diverticulum at the site of a previously removed cuff because of erosion and urinary extravasation.[939]

5. DURABILITY OF AUS COMPONENTS

When defining durability of one of the components or the AUS as a whole, one should distinguish between explantation of the device due to device malfunction (e.g. leak in one of the components) or complications caused by an otherwise properly functioning sphincter unit (e.g. cuff erosion, infection at the site of implantation, etc.). This distinction is rarely made in the literature. Durability of a device is defined as time elapsed during which no mechanical problem alters the normal function of the device. This should exclude the second group from further analysis.

There are very few references in the literature pertaining to the length of time a device functioned normally before its removal due to mechanical failure. In a multicenter trial, for neurogenic bladders, conducted in France,[914] the authors mention that the "mean operational life" of the sphincter was 56 months (range 3-118 months). Haab et al[298] analyzed 68 patients and noted that the mechanical failure rate dropped from 44.4% to 12.4% since modifications were made to the device, mainly the cuff component. Survival time of these components was not provided. Similar conclusions can be drawn from a series from the Mayo Clinic[304] where the modification of the cuff design (narrower back) resulted in a substantial drop of the reoperation rate at 5 years. In the "narrow back" group 17% (31/184) required reoperation. In that cohort, non-mechanical failure decreased from 17% to 9% and mechanical failure decreased from 21% to 8% following introduction of the narrow back cuff.[304] Mean time to reoperation was 26.2 months (mean 2-68 months). Using Kaplan-Meier statistical analysis for this group of patients, the overall 5-year expected product survival was 75%. Another recent report from the Mayo Clinic noted that of 1082 patients with a primary AUS implantation, with a median follow-up of 4.1 years, 32.1% required secondary surgery.[940] Of 338 revision surgeries, 89 were for device infection and/or erosion, 131 for device malfunction, 89 for urethral atrophy and 29 for pump malposition or tubing complications. Of interest, while infection and/or erosion occurred at a median of 2 years from implantation, device malfunctions and urethral atrophy occurred at 4.5 and 4.7 years respectively. Overall device survival was 74% at 5 years, 57% at 10 years and 41% at 15 years. In Lai's report regarding Baylor's 13-year experience with the AUS, only 6% of devices failed mechanically, at an average of 68.1 months, with 75% of patients requiring no revisions at 5 years.[301] In a review, Venn et al[404] analyzed the outcome of 100 patients in whom an artificial urinary sphincter was implanted for more than 10 years. Thirty-six percent of them still had the original sphincter and were continent at a median follow-up of 11 years. The bulbar cuff, as compared to the bladder neck cuff provided a slightly better continence rate at 10 years, 92% and 84%, respectively. The lowest erosion rate occurred with the bulbar cuff. Device survival rate at 10 years was 66% in this series.

In a series of 30 boys with spina bifida, Spiess et al[941] found that the mean lifetime of all AUS was 4.7 years, with no statistically significant difference in sphincter survival of those inserted at the bladder neck or the bulbous urethra (4.6 and 4.9 years, respectively). A sharp drop was observed at 100 months with only 8.3% of the original sphincters still functioning beyond this point. In a series of 35 adolescents with neurogenic voiding dysfunction implanted with a bladder neck cuff over an 11-year period, with an average follow-up of 5.5 years, Lopez Pereira and colleagues[942] reported a 20% mechanical failure rate, with an additional 8.6% erosion rate. Adverse bladder storage changes developed in 31.8% of patients, who thereby required augmentation cystoplasty. However, continence was achieved in 91.4% of individuals.

In other series, the global long-term (2-7.7 years) revision rate, for any of the above mentioned reasons varies between 16% and 50%.[300,301,305,306,530,937,942,943,944] In Webster's report[937] of 554 implantations over a 10 year period, (i.e. performed since the 1987 device modification), he noted a mechanical failure rate of only 31/554 (5.5%). Non-mechanical failure was 88/554 (15.9%), with 63/554 (11.3%) due to urethral atrophy and 21/554 (3.8%) due to cuff erosion. Of the total cohort, 21.4% required at least one revision surgery, while 78.6% did not. Of those 119 patients who required re-operation, 76.5% required no further treatment (similar to the non-reoperation rate of the initial cohort), while 23.5% required reoperation for either mechanical or non-mechanical failure. Five-year durability of the AUS following primary or secondary implantation was comparable, with 80% for the initial placement, and 88% following revision surgery. Similarly, continence status was comparable, with 90% of primary and 82% of revision patients achieving 0-1 pad per day urinary

control. Patients with neurological deficits seem to have a higher risk of non-mechanical failure and the overall continence rate may be lower compared to non-neurologic patients.[36]

6. DIAGNOSTIC PROCEDURES RELATED TO ARTIFICIAL SPHINCTER FAILURE

The diagnostic evaluation of urinary incontinence after the placement of the AUS is critical for the management of these patients and represents a challenging problem for the urologist. Several diagnostic and management algorithms have been proposed, some relatively simple, others more complex.[36,37,315,326,915,945,946,947] Figure 16 shows an algorithm to investigate and treat the male patient with a previously functioning AUS who becomes incontinent.

Physical examination should exclude infection at the site of the cuff or the scrotal/labial pump (Figure 12). Difficulty compressing the pump suggests tube kinking, fluid loss or an obstructed system. Loss of fluid from the system may be suggested by the inability of the pump to appropriately refill after just one or two pumps.

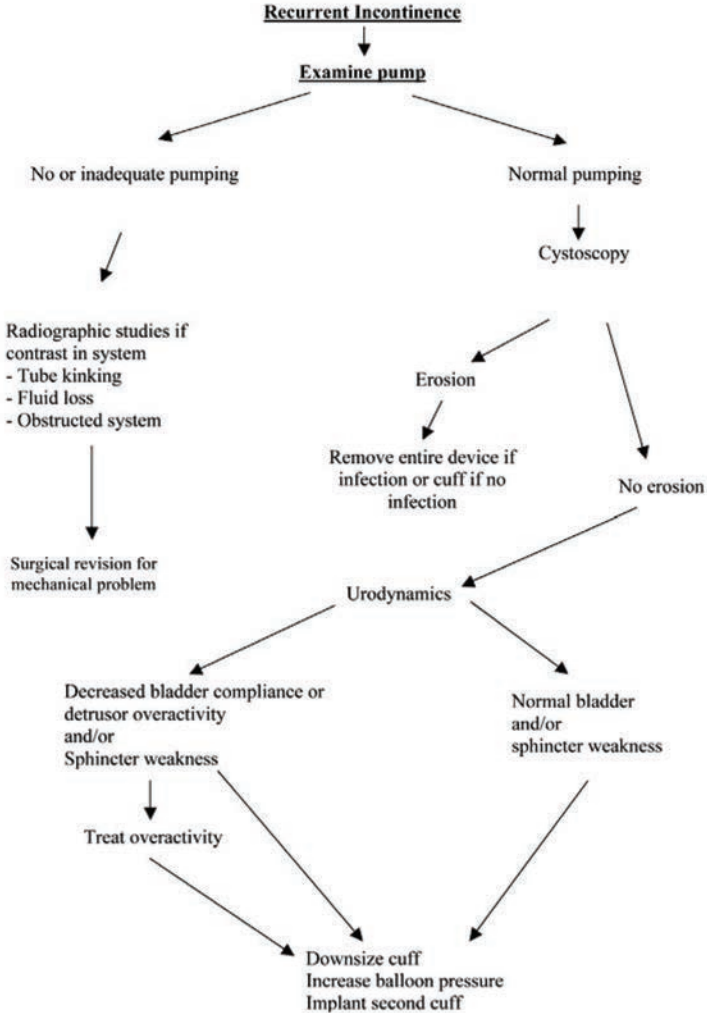

Figure 16. Algorithm for managing incontinence after AUS placement.

Figure 17. Endoscopic view of AUS cuff erosion into the bulbar urethra. The patient had undergone radiation after radical prostatectomy.

Plain x-rays of the abdomen or pelvis may show fluid loss, if the system is filled with radio-opaque solution (Figure 1).[948,949] Alternatively, sonography of the pressure-regulating balloon may show volume loss.

One should obtain a baseline plain film after the primary implantation when the reservoir is filled with contrast for subsequent comparison as radiographic imaging of the balloon does not detect changes until at least 50% of its volume has been lost.[19] Cystometrogram or complete urodynamic study will demonstrate changes in bladder behavior following insertion of the AUS as described above. Cystourethrography could eventually demonstrate a urethral diverticulum at the site of previous cuff erosion. Endoscopy will disclose any urethral erosion by the cuff (Figure 17).

Retrograde perfusion sphincterometry has been reported to diagnose the loss of compressive pressure in the urethral cuff.[36] It is done by infusing fluid from the meatus in a retrograde fashion. If the AUS cuff is functional and the urethral is intact there should be no flow when the pressure equals the AUS balloon pressure. This technique can also be used intraoperatively to detect urethral perforation or to adjust the pressure in the cuff.[39] This seems to be more useful than urethral pressure profile (UPP).[911]

Intraoperative electrical testing, using an ohmmeter[927,946] has been described to determine the site of fluid leakage from the system. This test can be helpful to avoid the need to change the whole system, and allow replacement of the leaking part only.

7. TREATMENT OF COMPLICATIONS

As outlined above, complications directly related to the presence of an artificial sphincter can be divided into categories: de novo OAB (which is typically treated as OAB), urethral atrophy, and/or mechanical failure, and infection/erosion. The treatment of these complications deserves comment, as no detailed reference can be found in the literature dealing exclusively with the treatment of these complications.

7.1. Atrophy of the Urethra

Several therapeutic options exist to increase cuff pressure around the atrophied urethral wall: changing the balloon reservoir for one generating a higher pressure, downsizing the cuff diameter,[19,293,950] or increasing the amount of fluid in the system. The most common approach is downsizing of the cuff. Another approach consists of placing the cuff inside the corporal tunica albuginea on the dorsal aspect of the urethra (transcorporal). This allows a safer mobilization of the urethra and adds some supplementary bulk of tissue to the circumference of the urethra, possibly decreasing the risk of erosion.[311] It should be mentioned, however, that there is a risk of reduced erectile function with this technique. The vast majority of such patients, however, already suffer from erectile dysfunction secondary to the prostate cancer surgery. As noted earlier however, some have recently suggested that “urethral atrophy” does not exist and that mechanical or material failure is typically responsible and that the cuff and balloon can simply be replaced with same size new components.[924]

The implantation of a double-cuff AMS 800 had a recent period of increased popularity, as a primary procedure in the totally or severely incontinent patient,[312,951] or as a salvage procedure, by adding a second cuff, following a failed previous single cuff.[309,310,951] Dimarco’s group[310] and others showed excellent results with the addition of a second urethral cuff, placed 1.5–2.0 cm distal to the primary cuff. Alternatively, a circumurethral wrap of an organic bulking agent can be fitted, with subsequent placement of the AUS cuff over the biologic external urethral bulking agent.[952] Early reports of primary double cuff placement did not demonstrate any significant increase in morbidity with the double-cuff as compared with the single cuff system,[312] and patient satisfaction also seemed to be higher[313] at an average of 21-41 months follow-up. However, O’Connor et al[314] recently described their experience with 28 men who underwent double cuff placement and in contrast to an earlier report of theirs found that with longer follow-up there was no difference in continence between those men and 28 who underwent single cuff placement. In addition, those who had the double cuff placement had a higher rate of additional surgery due to complications.

7.2. Mechanical Failure

As with any device, mechanical failure can be expected with the AMS 800 AUS. The treatment involves surgical replacement of the failed component and reconnecting the system. A recent study from the Mayo Clinic that retrospectively reviewed outcomes after repair of mechanical failures noted a trend toward better outcomes if all components were replaced instead of just one component.[953]

7.3. Infection

With overt infection the accepted treatment option is removal of the entire device and appropriate antibiotics. A second system can be subsequently implanted with equally good results.[931] It has been demonstrated, however, that immediate reimplantation of a new AUS after the removal of an infected, but not eroded, prosthesis can be a valid option with an overall success rate of 87%.[954] In 2007, AMS introduced the InhibiZone-coated AUS (rifampin and minocycline hydrochloride coating).[955]

7.4. Erosion

In cases of urethral cuff erosion, the “offending” cuff must be removed. No clear guidelines exist whether removal of the whole system is superior to removal of the cuff alone but it must be assessed for infection and if present the whole device should be removed. However, the recent AUS consensus panel noted that the decision to remove the cuff exclusively or the entire device mainly depends on time since AUS implantation[886]. In the immediate perioperative period (less than 6 weeks) erosion is likely the result of an unrecognized urethral injury and should be treated with cuff removal and preservation of the remaining AUS por-

tions (in the absence of evidence of infection). Erosions occurring years after surgery may require removal of the entire device. When in doubt remove the entire system. Reservoir erosion into the bladder has been described following the removal of an eroded cuff.[938] Furthermore, it is not known whether it is necessary to allow the urethra to heal over a catheter vs surgical repair. Most though would leave a catheter to allow for spontaneous healing, with the expectation that the urethra will re-epithelialize and permit reimplantation in the future[956] (after 4-6 months).

Some have advocated for the placement of sutures to re-approximate the urethral defect, known as abbreviated urethroplasty (AU), to facilitate healing and expedite time-to-reimplantation. Another option, especially for erosions accounting for >50% of the urethral circumference, would be to excise the cuff capsule, circumferentially dissect and debride the urethral margins, and mobilize the urethra sufficiently to allow a more formal primary urethral anastomosis.

Rozanski et al[957] compared stricture outcomes in patients with artificial urinary sphincter cuff erosion managed with and without synchronous urethral repair. In this retrospective case-series two cohorts of patients were evaluated (in situ urethroplasty vs Foley catheter only). Of the 26 artificial urinary sphincter cuff erosion cases identified 13 underwent in situ urethroplasty while 13 did not. Mean patient age was 73 years (range 61 to 83) with a mean follow-up of 24 months (range 8 to 69). The rate of urethral stricture formation after AUS explantation was significantly reduced among patients treated with in situ urethroplasty (5 of 13, 38%) compared to those treated with Foley catheter only (11 of 13, 85%; *P*=0.047). Performing the ISU did not add significant time to the operative procedure, averaging an additional 8 minutes. Those treated with in situ urethroplasty underwent significantly fewer procedures per patient before AUS replacement (0.4 vs 1.1, *P*=0.004) and had a much higher rate of eventually undergoing secondary AUS implantation (7 of 13, 54% vs 2 of 13, 15%, *P*=0.04) compared to those with cuff erosion treated with Foley catheter only.

Chertack et al[956] retrospectively reviewed medical records of patients treated for AUS cuff erosion from 2005 to 2015, in order to examine cuff erosion intraoperative management methods: Foley catheter placement, AU, or mobilization with primary urethral anastomosis (PA). Seventy-five patients with a median age of 77 years (72-83) were treated for AUS cuff erosion. Fifty-two underwent Foley placement, 8 AU, and 15 PA. Mean follow-up was 13 months (0-106). Severe erosions were more common in the PA group than Foley or AU (100% vs 37%, 100% vs 38%, *P* <0.001, *P* <0.001, respectively). Severe erosions treated with Foley were more likely to develop strictures than mild erosions (38% vs 5%, *P* =0.009). Tandem cuff patients treated with Foley were more likely to develop diverticuli than single cuff patients (33% vs 4%, *P* =0.016). There was no difference in probability of reimplantation between PA and Foley or AU (63% vs 69%, 63% vs 33%, *P* =0.748, *P* =0.438, respectively). The authors concluded that Foley catheter placement alone may represent suboptimal management for severe or tandem cuff erosions due to increased risk of urethral complications.

When a new cuff is placed it should be positioned away from the erosion site. In case of the erosion of one of the cuffs of a double system, removal of the eroded cuff can successfully convert a double-cuff system into a single cuff system.[958] It is logical that intraoperative urethral injury may precipitate cuff erosion if unrecognized.

8. CONSENSUS PROTOCOL FOR FOLLOW-UP OF PATIENTS WITH AUS

As complications continue to be seen for years after implantation,[959] it is helpful to have a structured follow-up plan. However, no standardized recommendations are available in the literature.

The consensus upon which the members of this subcommittee agreed and which is based on expert opinion are as follows:

1. Perioperative antibiotics are required. Gram-negative enteric bacteria and Staphylococcus epidermidis are the most frequently encountered microorganisms in infected prostheses.[934]
2. Hospital stay should be kept to a minimum.
3. Urethral catheters, if inserted, should be withdrawn within 24-48 hours of surgery and the preoperative continence management continued.
4. The sphincter device should not be activated immediately postoperatively. In the initial period scrotal edema and pain prevent patients from manipulating the pump adequately. When this subsides after 6 to 8 weeks the device can be activated. Earlier activation may also be acceptable. Irradiated patients may benefit from a longer initial period of deactivation, up to 12 weeks.[293] Nocturnal deactivation should be considered in high-risk patients.[292]
5. Patients are reviewed at 3 months after activation to ensure the device is working adequately, and to assess the continence status.
6. Long-term follow-up is different in the neurogenic and non-neurogenic patient. With time, alteration in bladder function may jeopardize renal function in the neurogenic patients. Periodic ultrasound evaluation of the upper urinary tract and monitoring of renal function is essential. If changes occur, urodynamic studies should be done to rule out detrusor overactivity. In non-neurogenic patients, periodic ultrasound may not be necessary.

7. When changes in the continence status occur diagnostic procedures depicted in the algorithm above should be considered.

(Level of evidence 3; Grade of recommendation B-C)

XIII. NEW TECHNOLOGIES UNDER EVALUATION

1. INTRODUCTION

Despite the advances in the surgical treatment of post-prostatectomy urinary incontinence (PPUI), both slings and AUSs present limitations in terms of continence rates and complications. With greater than 100,000 prostatectomies performed per year with a 9%-20% risk of incontinence, treatment of PPUI is a common clinical issue treated by urologists.[154] This context makes room for the development of new technologies and minimally invasive treatments.

2. FLOWSECURE ARTIFICIAL URINARY SPHINCTER (RBM-MED)

The FlowSecure sphincter is a one-piece device consisting of two reservoirs placed in the paravesical space, a cuff that surrounds the urethra and a control pump with a self-sealant port that is placed in patient's scrotum.[960] The first reservoir regulates resting urethral pressure and the other relieves stress pressure during intra-abdominal pressure increases. During bladder filling the cuff connected to the pressure regulating reservoir compresses and keeps the bulbar urethra closed at low pressure. When intra-abdominal pressure rises, the stress relief balloon provides additional pressure to the cuff to maintain continence. The fluid pressure of the prosthesis may be regulated by injecting or removing saline through the self-sealing port in the control pump located in patient's scrotum.[961] When the patient wishes to void he presses the control pump until good urine flow is achieved. In this way the cuff is emptied by moving the fluid from it to the pressure-regulating reservoir. Redirection of fluid flow and filling of the cuff is recovered when compression of the pump stops.[962]

The main potential advantage of the FlowSecure device over the AUS 800 is that while the latter exerts a high constant pressure over the urethra, the former causes an immediate increase in urethral pressure only when there is a sudden increase of intra-abdominal pressure. During the deactivated portion the cuff returns to the initial low pressure below 40 cm H_2O, thus minimizing the danger of urethral erosion.[962]

Knight et al[963] presented 9 male patients (mean age 66 years) with urodynamically proven stress incontinence due to radical prostatectomy treated with implantation of a FlowSecure sphincter. All 9 patients tolerated the surgery well and were followed for a minimum of 12 months. Two devices had to be removed for technical reasons. The mean leakage for the remaining 7 patients prior to implantation was 771 ± 658mL. Twelve months later the leakage was statistically significantly reduced to 52 ± 36 mL (P<0.05). Four patients required additional pressurization to achieve optimal continence and this was carried out without complication. Despite the promising initial results, no further series on PPUI are available in PUBMED. Further studies will be needed to define the role of this sphincter in the management of PPUI.

3. PERIURETHRAL CONSTRICTOR (SILIMED)

The Periurethral Constrictor (PUC) is a one-piece, two-part device. It is comprised of a constrictor cuff linked by a 20 cm silicone tube to a valve, which is elliptical in shape and rounded at the edges. The device was initially designed for implantation in pediatric patients to treat deficient bladder sphincter function.[964] The adjustable cuff is implanted around the bladder neck through a suprapubic approach or around the bulbous urethra through a perineal incision.[965] The injection port is designed to accommodate a fine Huber needle and is usually placed in the scrotum or in the subcutaneous space between the umbilicus and the iliac crest.[966]

A limited number of studies with controversial results have been published for using PUC in PPUI.[962] Schiavini et al[967] retrospectively studied 30 patients with PPUI and PUC implantation for a mean period of 42.1 months. In 22 patients (73.3%) the devices were functional leading to a good continence result. In 7 patients the device was removed due to cuff erosion (4 patients, 13.3%) and infection (3 patients, 10%).[967] In contrast, Lima et al. presented a study with 82.2-month mean follow-up, reporting higher device removal rates (41.07%).[965] The average time between surgery and the removal of the device was 22.6 months. The most frequent complication was urethral erosion in 15 patients (26.78%). Other complications were mechanical malfunction in 5 (8.9%), urethral stenosis in 3 (5.3%), urinary fistula in 2 (3.5%), infection in 2 (3.5%), and persistent urinary tract infection in 1 case (1.7%). In patients in whom the device was not removed (33), only 17 from them were continent, representing an overall success rate of 30.35%.

While the simplicity and the low cost of the PUC are attractive the high removal rates and mechanical malfunctions are concerning.

4. ZSI 375 (ZEPHYR SURGICAL IMPLANTS)

The ZSI 375 device is a one-piece device consisting of an adjustable cuff, which is connected by a tube to a pump and a pressure-regulating tank. It has no abdominal reservoir. In comparison to the AUS 800, potential advantages of the ZSI 375 include reduced cost, and the possibility to re-adjust the cuff in case of postoperative urethral atrophy.[962] However, there are only a limited number of publications in the literature, showing conflicting results.

Staerman et al[968] evaluated 36 patients who underwent a ZSI 375 device placement. The median (range) follow-up was 15.4 (6-28) months. No patient experienced bladder overactivity, chronic urinary retention, or any other adverse effect after device activation. Complications leading to device removal arose in four patients (one case of erosion, three cases of infection). Social continence (0 or 1 pad/day) was achieved in 28/36 patients (78%) at 3 months and 26/36 patients (73%) at 6 months after device activation.

Kretschmer et al[969] conducted a multicentric study to assess ZSI 375 efficacy and safety in men with stress urinary incontinence. Thirteen patients underwent implantation of a ZSI375 artificial urinary sphincter device between 2010 and 2012 in three international continence referral centers. There were no intraoperative complications. Median follow-up was 13.5 months. In this period, four device defects (30.8 %) were observed, being the main cause for device explantation, followed by device infection (15.4 %), nonresolvable pain (7.7 %), and urethral erosion (7.7 %). Overall explantation rate was 61.5 %. Mean time-to-explantation was 279 ± 308 days. There was no significant influence of previous irradiation or previous invasive incontinence therapy (P=0.587 and P=0.685, respectively). Mean daily pad usage decreased from 5.8 ± 1.5 to 2.4 ± 2.1 (P=0.066). One patient (7.7 %) did not use any pads. Social continence (0-1 pads) was achieved in only 15.4 % of the patients.

5. AROYO (GT UROLOGICAL)

The Aroyo device is a one-piece pre-connected system consisting of a reservoir, one-push pump and urethral cuff. The purported advantage of this device is the ability of the patient to push on the reservoir located in the lower quadrant to briefly increase the cuff pressure during periods of increased abdominal pressure (a cough for instance) and the fact that the pump only requires one push to open the cuff. A single study reporting positive 12 month outcomes was presented at the ICS in 2015 but further published data is lacking.[970]

6. STEM CELLS

The use of stem cells has been studied and reported on in females with SUI. Currently two studies looking at stem cells for male stress urinary incontinence are listed on clinical trials.org as enrolling patients.[971] One evaluating the use of autologous adipose derived regenerative cells is run through Nagoya University and the other utilizing autologous muscle derived stem cells is run through Cook Myosite. While the use of stem cells to treat male SUI is very attractive data collection and evaluation are still in the early stages and its use outside of a clinical trial cannot be recommended

XIV. SUMMARY AND RECOMMENDATIONS

1. EVALUATION AND RECOMMENDATIONS

Prior to surgery a basic patient evaluation should consist of history and physical examination, urinalysis and postvoid residual urine (Level of evidence 1-2: grade of recommendation A).

- A voiding diary is helpful to assess functional capacity and total urine output (Level of evidence 1-2: grade of recommendation B).
- Pad tests may be useful in certain circumstances, and pad use is a reasonable surrogate to a formal pad test (Level of evidence 1-2: grade of recommendation B).
- Blood testing (BUN, creatinine, glucose) is recommended if compromised renal function is suspected or if polyuria or poor urinary concentrating ability (in the absence of diuretics) is documented.
- Additional testing with cystoscopy and appropriate imaging of the urinary tract may be helpful in guiding therapy—this depends to a large degree on the type of incontinence and presumed etiology (Level of evidence 2-3: grade of recommendation B).
- The committee felt that multichannel urodynamics may be useful prior to invasive treatment for incontinence—this depends to a large degree on the type of incontinence and presumed etiology. (Level of evidence 3: grade of recommendation C).

2. INCONTINENCE POST-PROSTATECTOMY FOR BPO AND

POST-RADICAL PROSTATECTOMY FOR PROSTATE CANCER

After a period of conservative management, which may also be from 6 to 12 months (Level of evidence 3-4; grade of recommendation C):

- The artificial sphincter is the preferred treatment for properly selected men who have moderate to severe stress incontinence after radical prostatectomy as the AUS has the longest record of safety and efficacy. The AUS has been reported extensively for men with moderate to severe incontinence. This recommendation relates exclusively to the AMS 800 as newer devices do not have a similar evidence base or experience (Level of evidence 2-3; grade of recommendation A)
- Male slings are an acceptable surgical approach with several-year follow-up data supporting their safety and efficacy in men with mild to moderate degrees of PPI. They are associated with a low rate of urinary retention, infection, urethral erosion, and urethral atrophy. Adjustable slings do not appear to have a higher efficacy rate compared to nonadjustable slings, but have a higher reoperation rate, typically for readjustment. (Level of evidence 3; grade of recommendation C)
- Injectable agents, even with repeated application, have a low success rate and should only be used when more effective treatments are contraindicated. (Level of evidence 3-4; grade of recommendation C)
- Adjustable balloons have also been reported, but have a higher complication rate than do the AUS and male sling. (Level of evidence 3; grade of recommendation D [no recommendation possible])

3. INCONTINENCE FOLLOWING EXTERNAL BEAM RADIATION FOR PROSTATE CANCER

- The artificial sphincter is most widely used but radiation may be a risk factor for an increase in complications. (Level of evidence 3; grade of recommendation B).
- Slings generally have a lower success rate in radiated patients that in those who have not had radiation. (Level of evidence 3; grade of recommendation C).
- Injectable agents have a low level of efficacy in radiated patients. (Level of evidence 3-4; grade of recommendation C).
- Adjustable balloons have not been successful in the setting of radiation. (Level of evidence 3; grade of recommendation D [not recommended]).

4. INCONTINENCE FOLLOWING PELVIC TRAUMA

(Level of evidence 3; grade of recommendation C)

- The artificial sphincter is the most widely reported treatment for stress incontinence.
- Lower urinary tract reconstruction has also been reported on a limited basis.

5. INCONTINENCE IN ADULT EPISPADIAS EXSTROPHY COMPLEX

(Level of evidence 3; grade of recommendation C)

- Patients should be treated in centers of excellence.
- A patient-directed approach should be taken.
- The choices include further bladder neck reconstructive surgery, bladder neck closure, bladder reconstruction or diversion with bowel.
- The data are insufficient for a specific recommendation.
- Arrangements for transition between the pediatric and adult urologist are standard.
- Life-long follow-up is mandatory in terms of continence, voiding efficiency, upper tract status and other urological complications

6. REFRACTORY URGENCY INCONTINENCE AND DETRUSOR OVERACTIVITY

- BTx-A bladder injection is a minimally invasive treatment with efficacy (Level of evidence 1-2; grade of recommendation B). This is valid for onabotulinumtoxin—other types of BTx do not have the same recommendation grade.
- Neurostimulation is a treatment option with success reported in a limited number of male patients. (Level of evidence 3; grade of recommendation C).
- Detrusor myectomy has also been reported to be successful in a small number of male patients. (Level of evidence 3; grade of recommendation C).

- Augmentation cystoplasty is potentially successful in controlling symptoms but may be associated with unacceptable side effects. (Level of evidence 3; grade of recommendation C).
- Urinary diversion is a final option. (Level of evidence 3; grade of recommendation C).

7. REDUCED CAPACITY BLADDER

- Augmentation cystoplasty has been successful in most etiologies. Efficacy post-radiation therapy is diminished. (Level of evidence 3; grade of recommendation B).

8. URETHROCUTANEOUS FISTULA AND RECTOURETHRAL FISTULA

(Level of evidence 3; grade of recommendation C)

- Etiologic factors causing acquired urethrocutaneous or rectourethral fistulae are demonstrated by clinical, endoscopic and imaging studies.
- Similar diagnostic maneuvers are applied to rectourethral fistulae.
- In those that do not close with or without temporary urinary and fecal diversion, surgical reconstruction may be carried out.
- Surgical reconstruction is applied in the majority of cases.
- Most repairs are now carried out after prior urinary and fecal diversion.
- Various techniques are available for closure and can be done in collaboration with colorectal surgeons.

9. MANAGEMENT OF AUS COMPLICATIONS

(Level of evidence 3; grade of recommendation C).

- Incontinence may result from alteration in bladder function, urethral atrophy, or mechanical malfunction.
- Reported therapeutic options for recurrent urinary incontinence due to urethral atrophy include: change of the balloon reservoir for one generating a higher pressure; downsizing the cuff diameter (most common approach); increasing the amount of fluid in the system; transcorporal cuff and double-cuff implantation.
- Infection and/or erosion of components demand surgical removal of all or part of the prosthesis.
- Compared to primary urethral repair techniques, a Foley catheter placement alone may represent suboptimal management for severe cuff erosions due to increased risk of urethral complications. (Level of evidence 3, grade of recommendation C)
- A treatment algorithm is presented to aid in management and in follow-up of patients.

10. NEW TECHNOLOGIES

(Level of evidence C; grade of recommendation D)

- Tissue engineering has not been widely reported in males apart from isolated reports of preliminary studies.[972,973]
- A number of new artificial sphincter devices and slings are being evaluated. Currently, the number of patients implanted and studies with reported outcomes are relatively limited.

11. FUTURE RESEARCH DIRECTIONS

- New technologies, bulking agents, sling materials, prosthetic devices, neuromodulation devices and stem cell based treatments should continue to be evaluated.
- Accuracy in reporting of early research results is mandatory.
- Mechanisms of post-prostatectomy incontinence and device effects need further research.

12. CLINICAL TRIAL RECOMMENDATIONS

- Randomized trials (AUS and slings).
- Standardized workup and outcome measures including QoL.
- Evaluation of the role of urodynamics in the workup.
- Complete reporting of complications and outcomes especially those of slings.
- Standardized definitions of cure/improved/unchanged/worse.
- Reporting of procedures to salvage failures.
- Long-term results (>2 years).
- Standardized reporting of durability.

INTRODUCTION

This chapter aims to update the current status of surgical interventions for non-neurogenic female urinary incontinence. The structure is built upon prior versions, most notably that of the ICI-5 published in 2013 with the intent of building upon these previously presented data. However, given the vast amount of literature produced since the prior version, it was necessary to re-organise and expand several sections. This includes most notably considerable new data on MUSs including PVS, TO and single-incision mini-slings. In addition, new portions of the chapter include a section on the biology of implanted mesh as well as a section on evolving stem cell technology for urinary incontinence. Finally, as compared to prior editions of this book, there are several áreas which are not covered in this chapter including urinary incontinence in association with vaginal prolapse, and chemodenervation, which will be covered by the other committees elsewhere.

Within the reorganisation of the chapter, we have tried to minimise overlap between comparative studies as much as possible. For example, studies comparing a particular MUS vs. colposuspension will be covered in only one of the two relevant sections.

SEARCH STRATEGY

As in prior editions, material collected for this chapter was based on electronic searches of Medline, EMBASE, Cinhai, Cochrane Database of Systematic Reviews and the NICE website (www.nice.org.uk). Review papers were separately searched for additional references not identified by initial database search. Individual papers were then selected from these searches for inclusion where appropriate. Search terms included; Urinary incontinence: stress, mixed, urge. Surgical procedures: minimally invasive, urogenital, gynaecologic, urologic, urinary tract, urethra, vagina, bladder, colposuspension, vesicosuspension, urethrosuspension, vesicourethral or urethrovesical, colpourethrosuspension, Burch, Marshall-Marchetti-Krantz, paravaginal, obturator, surgical mesh, sling, bladder, surgical or synthetic, or biological or autologous; tape; urethra, suburethra, midurethra, transurethral, pubovesical; PVS, suprapubic; pubovaginal, implant; Prostheses: injections; bulking agents, Contigen; collagen; Macroplastique, silicones; microparticulate; hyaluronic acid; carbon particles; polytetrafluoroethylene; biocompatible materials; urinary sphincter, artificial.

Finally, we would like to acknowledge the overwhelming and tremendous contributions to this chapter made by the previous authors and committee members from prior Consultations. This includes the prior Chairs, Dr. ARB Smith and Dr. Roger Dmochowski. Our chapter is built on the framework set up by these individuals and truly represents an update to their prior work. Furthermore, we would like to acknowledge the considerable contribution from Dr. Sandy Hanssens in this version with her assistance to Dr. Cosson. And finally we are extremely grateful to Edna Johnson from Vanderbilt University for her editorial support.

I. SURGERY FOR STRESS URINARY INCONTINENCE (SUI)

1. TRADITIONAL BN PVS

The term 'traditional' sling procedure is used here, in line with the terminology used in the latest Cochrane review. (1). This is done mainly to distinguish open sling procedures typically placed at the region of the BN from the newer, minimally-invasive mid-urethral sling (MUS) procedures.

Sling procedures came into prominence in the beginning of the twentieth century. In 1907, Giordano transplanted gracilis muscle and wrapped it around the urethra. (2) Soon thereafter, other autologous tissues were transplanted under the urethra to provide additional support: pyramidalis (3), levator ani (4) rectus fascia (5), gracili (6), and bulbocavernosus muscle and fat (7). While it was hypothesised that the transplanted muscle would retain its contractility and act as a neo-sphincter to prevent SUI, these procedures compressed the urethra and created a partial obstruction. Complications such as recurrent cystitis, urethral sloughing, and fistula formation were common.

The modern autologous BN sling exists mainly due to the work of Aldridge in the 1940's and McGuire and Blaivas in the latter part of the twentieth century. (8-10). The majority of sling procedures have involved a combined abdominovaginal approach, although procedures performed entirely through an abdominal approach have been described. Suspended, or 'sling on a string,' methods have been developed in order to reduce the invasiveness of the procedure and to shorten the length of sling material. These shorter slings can also vary in length, from a "mid-length" sling (7-10 cm) to a "patch" sling (2-4 cm).

Sling materials may vary widely and individual materials may have only a modest effect on initial sling efficacy. However, these materials may considerably affect the long-term outcomes of sling procedures and the associated morbidity. Materials may be synthetic or biological. The latter include autografts (rectus fascia, fascia lata, round ligament, dermis, vaginal skin, and gracilis, levator, and rectus muscles), cadaveric allografts (fascia, dermis, and dura mater) and xenografts (porcine dermis and small intestinal submucosa, bovine dermis and pericardium).

Case series of autologous rectus fascial (ARF) sling were reviewed within the systematic review underlying the NICE guidance on urinary incontinence (11). Ten series including a total of 1280 women were considered. Studies had a mean or median duration of follow-up between 2 and 6 years, while in three studies, maximum follow-up of 15–18 years was reported. Subjective cure rates ranged from 26% to 97% (median 81%); and cure rates that included subjective and objective elements ranged from 73% to 95%. Satisfaction rates of 86% and 92% were reported in two studies.

Synthetic sling materials have included nylon, polyethylene, polytetrafluoroethylene (PTFE), and polypropylene. On occasion, these polymers have been 'enhanced' with synthetic or biologic coatings in an attempt to improve their biocompatibility profiles. Many additional variations in the technique have been described, although it is unclear which of these materially influence the outcome. Several case series have published outcomes for polyethylene and PTFE slings with short-term cure rates typically in the 80-90% range, depending on the definition [EL=3]. Vaginal extrusion, erosion, and sinus formation have been common with these materials. Since the last ICI review, there have been no additional studies published and the number of these procedures performed appears to have waned significantly in favour of polypropylene MUSs.

Both biological and synthetic sling materials are analysed together in the Cochrane review (1) although these were considered separately in the systematic review underlying the NICE guidance on urinary incontinence (1, 11). NICE has also published a non-systematic review of biological sling procedures under its Interventional Procedures Programme. The most recent Cochrane review included 26 RCTs (or quasi-randomised trials) describing a total of 2284 women of whom 1287 were treated with suburethral traditional slings. Sample sizes ranged from 20 to 655 participants. Several of these trials are available only in abstract form and remain unpublished as full peer-reviewed papers. Owing to the significant number of recent meeting abstracts about surgical procedures for SUI, only full publications have been included in this section. Additional studies have been included, but the majority of these are case-control studies and have a relatively low level of evidence.

There have been no new trials identified that compared traditional suburethral sling operation vs. no treatment, sham operation, conservative management (e.g. pelvic floor muscle training, electrical stimulation, cones, biofeedback), anterior repair, laparoscopic PVS suspension, or artificial urinary sphincter (1). One trial studied patients with MUI treated with oxybutynin or surgery (12). The type of surgery was selected according to Valsalva leak point pressure (VLPP): those women withVLPP <90 cm H2O underwent an ARF sling and those with VLPP ≥ 90cm H2O underwent Burch colposuspension. The results for the surgically managed group were similar to that in the subgroup having slings. The study suggested that slings are significantly better for treating MUI than oxybutynin.

Table 1: Traditional sling vs Bulking Agent

Author	RCT	Sling	Comparator	N/N (n1/n2)	F/U	Cure; effect size	EL	Comments
Corcos, 2005	Yes	ARF/Colpo	Bovine Collagen	133 (67:66)	12m	55% vs. 52 % ; p=ns 72% vs. 53 % ; p=sig	2	ITT analysis Per protocol with verbal update No differenceces in SF-36, IIQ
Maher, 2005	Yes	ARF	Macro-plastique	45/45 (22:23)	6m	81% vs. 9%; p=sig	2	Silicone injected tr ansurethrally

Results were analysed in terms of patient reported incontinence within one year (RR 0.18; 95% CI 0.08 to 0.43). Fewer women had persistent UUI after the sling surgery (RR 0.29; 95% CI 0.09 to 0.94).

1.1. Traditional sling vs. bulking agent (Table 1)

One RCT compared ARF sling with a single periurethral silicone injection in women with SUI secondary to ISD (MUCP ≤20 cm H2O) in whom conservative treatment had failed (13). At 6 months, no significant differences were seen between groups in subjective cure (1-hour pad test) or satisfaction, QOL (UDI-6, IIQ). Significantly more women undergoing sling surgery were objectively cured on the basis of urodynamic assessment (81% vs. 9%; p=0.0001), but duration of the procedure, catheterisation, inpatient stay, and time to return to normal activities were significantly longer in the sling group. A telephone survey of two thirds of the women at 5 years found no statistically significant differences between groups in urinary symptoms or in satisfaction with surgery, although fewer women in the silicone bulking group were satisfied (29% vs. 69%) (n=45). The average cost per patient for the Macroplastique (including reoperations) was significantly greater (AU$4410) than for the sling (AU$3500) (P < 0.0001). [EL=2].

Open continence surgery (a suspension procedure in 46% and ARF sling in 54%) was compared with periurethral collagen in women with SUI or MUI in an additional RCT (14). Notably, collagen is no longer commercially available as a bulking agent. The collagen group received an average of 9.7 mL of collagen in 2.9 injections per patient. As in the previous study, there were no significant differences in patient satisfaction or QOL (SF-36, IIQ) between groups at 1 year. Using ITT analysis, there was no significant difference in continence rates at 1 year (52% collagen, 55% surgery). If only the 89% of women who underwent the randomised intervention were considered, the continence rate with surgery was significantly higher (72% vs. 53%; p=0.01). The incidence of adverse effects was significantly higher in the surgery group: urinary retention 13% vs. 2%, transient voiding difficulty 36% vs. 17%, UTI 6% vs. 0% (n = 133). [EL=2]

A recent metanalysis (15) combined the results for the previous studies and suggested that the objective recurrence rate of periurethral bulking agents is significantly higher in comparison with the traditional slings (OR: 6.35, 95% CI: 0.18, 222.85). Furthermore, lower subjective recurrence rate was observed among patients undergoing traditional sling procedures in comparison with those undergoing bulking agents, although this trend was not statistically significant (OR: 2.02, 95% CI: 0.99, 4.12). Moreover, patients undergoing injection of bulking agents experienced a lower rate of voiding dysfunctions in comparison to the sling group (OR: 0.23, 95% CI: 0.11, 0.48). Urinary tract infections were less common in the bulking agent group although the difference did not reach statistical significance (OR: 0.30, 95% CI: 0.07, 1.33) [EL=1/2]

1.2. Traditional sling vs. colposuspension (Table 2)

Nine randomised or quasi-randomised trials were identified from the literature. Six of the trials compared suburethral slings with open abdominal PVS suspension (16-21) while two trials reported the long-term outcomes (22, 23) and another reported the complications of the aforementioned trial (24) One additional trial compared sub urethral slings with the Stamey transvaginal needle suspension (25). The Cochrane review systematically evaluated the six trials comparing suburethral slings with open PVS suspension and an additional trial that was only published in abstract form (1)

One RCT compared duramater sling with open colposuspension in 72 women with recurrent SUI after vaginal hysterectomy and at least one previous anterior repair (17). At a minimum follow-up of 32 months, the combined objective and subjective cure rates were 92% after duramater sling compared with 86% after colposuspension. While both were common, significantly more women in the sling group developed postoperative voiding difficulty or urinary retention (29% vs 11%).

More women in the colposuspension group developed a postoperative rectocele (13%). Bladder perforation and de novo urgency were common in both groups. The time to spontaneous voiding was significantly longer in the sling group (12.4 days vs 6.4 days) (n = 72). [EL=1/2].

Table 2: Traditional Sling vs Colposuspension

Author	RCT	Sling	Comparator	N/N (n1/n2)	F/U	Cure; effect size	EL	Comments
Henriksson, 1978	Quasi	Zoedler, Vaginal	MMK	30/30 (15:15)	3m	100% vs. 100% (o)	2	Quasi- RCT: by alternation; No ss calculation; analysis not clear if ITT
Hilton, 1989	Yes	Porcine Dermis	Stamey	20/20 (10/10)	3m 24m	90% vs. 80% (o) 92% vs. 86% (s)	2	Included only SUI w/vaginal narrowing unsuitable for colposuspension
Enzelsberger, 1996	Yes	Dura Mater	Colpo	72/72 (36:36)	32-48m	92% vs. 86% (s)	2	All patients had recurrent SUI after failed incontinence surgery; no ss calculation; analysis not clear if ITT
Sand, 2000	Yes	Gore-Tex	Colpo	36/37 (17:19)	3m	100% vs. 90% (o); p-ns	2	No ITT analysis 2 (12%) slings partial resection due to erosion
Culligan, 2003				28 (13:15)	33-116 m (Mean 72.6m)	100% vs. 85% (o); p-ns 84% vs. 93% (s); p=ns		
Demirci, 2001	Quasi	ARF	Colpo	34/46 (17:17)	12m	94% vs. 88% (0); RR 2.0; 95% CI 0.20, 20.04	2	Quasi RCT by alternation; no ss calculation; analysis not clear if ITT
Bai, 2005	Yes	ARF	Burch	61/61 (28:33)	6m 12m	92.8% vs. 90.9% (s+o); p-ns 92.8% vs. 87.8% (s+o); p-sig	2	No ss calculation; minimal details about randomization; some disparities between text and tables
Albo, 2007 Chai, 2009	Yes	ARF	Colpo	520/655 (326:329)	24m	SUI cure: 47% vs. 38% (s+o); p-sig Overall cure: 66% vs. 49% (s+o); p-sig	1	50% concomitant surgery for POP; 79% outcome assessment at 24m (265:255); postoperative UTIs, voiding and storage symptoms higher in ARF group
Brubaker, 2012	Yes	ARF	Colpo	357/482 (183:174)	60m	Overall cure: 30.8% vs 24.1% (s+o) p-sig		Paricipants enrolled more likely to be incontinent (85.5%) compared with those who were continent (52.2%), irrespective of assigned surgical group (p <0.0001).

Three trials compared ARF sling with open colposuspension. In a small trial alternating 17 women with primary USI (typeI/II) each to ARF and colposuspension, ARF had similar effectiveness to colposuspension at 12 months follow up by objective measures (94% vs. 88%) (19). In a second trial randomising women to ARF, colposuspension, and TVT, ARF was significantly superior to colposuspension at 12 months (92.8% vs. 87.8%) using a subjective and objective definition of cure (20). The significant difference in the two procedures was not evident at 6 months follow-up (92.8% vs. 90.9%). Finally, the Urinary Incontinence Treatment Network conducted the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr),(21) a randomised trial comparing outcomes from Burch colposuspension versus autologous fascial sling. Overall 655 women were randomized and 79% of participants (265:255) were available for the 24-month outcome assessment. ARF was significantly superior to colposuspension both in its cure of SUI (47% vs. 38%) and overall incontinence cure (66% vs. 49%) at 24 months. Fifty percent of the women underwent concomitant surgery for pelvic organ prolapse (POP). The low success rates reported can be explained by the stringent criteria applied to define success, including no self-reported symptoms of SUI, less than 15g pad weight in 24 hours, no incontinence documented in a 3-day voiding diary, a negative urinary stress test on physical examination, and no retreatment for urinary incontinence. The findings on efficacy were not modified by performance of concomitant surgery for POP. Although highly effective for SUI, the PVS was accompanied by higher rates of urinary tract infection, urgency incontinence (27% vs 20%, P = 0.04), voiding dysfunction (14% vs. 2%, p<0.001), and need for surgical revision to improve voiding when compared with traditional colposuspension. [EL=1]

A further study by the same group was undertaken to assess in more detail the complications data in SISTEr trial (24). Subjects undergoing concomitant surgeries had a significantly higher serious adverse events (SAE) rate (14.2% vs 7.3%, p=0.01) and AE rate (60.5% vs. 48%, p<0.01) compared to subjects undergoing continence surgery alone. Women undergoing ARF sling had a higher percentage of postoperative UTIs within the first six weeks of follow –up (p<0.01), voiding and storage urinary symptoms. Intermittent self-catheterization (ISC) increased the rate of cystitis by 17% and 23% in the Burch and sling groups, respectively. [EL=1]

The same group of researchers presented the long term results (more than 5 years postoperatively) (22). Women who completed the SISTEr trial were asked to participate in a long term prospective observational study with the aim to characterise continence, satisfaction, and AEs at least 5 years after a Burch urethropexy or fascial sling. Urinary continence status was assessed yearly for a minimum of five years postoperatively. Continence was defined as no urinary leakage on a three-day voiding diary and no self-reported stress incontinence symptoms (telephone or mail contact) AND no stress incontinence surgical retreatment. Incontinent participants were more likely to enroll in the follow-up study than continent patients (85.5% vs. 52.2%), regardless of surgical group (p <0.0001). Overall the continence rates were lower in the Burch urethropexy group than in the fascial sling group (p=0.002). The continence rates at five years were 24.1% (95% CI 18.5% to 29.7%) compared to 30.8% (24.7% to 36.9%), respectively. Satisfaction at 5 years was related to continence status and higher in women undergoing a sling (83% vs. 73%, p=0.04). Satisfaction declined over time (P=0.001) and remained higher in the sling group (p=0.03). The two groups had similar AE rates (10% Burch vs.9 % sling) and similar numbers of participants with AEs (23 Burch vs. 22 sling). [EL=1]

Two small RCTs evaluated an expanded polytetrafluoroethylene patch sling (PTFE; GoreTex®) and open colposuspension in women with USI with low pressure urethra (MUCP<20cm H2O) and urethral hypermobility. The second trial provided the long-term subjective and objective outcomes of the same group of patients

(18, 23). Although the groups were different at baseline in terms of the proportion with DO (DO) (95% colposuspension vs. 41% sling), cure rates with PTFE were not significantly different from open colposuspension at 3 months (objective 100% vs. 90%) and at 2.5 years (objective 100% vs. 85%; subjective 84% vs. 93%) (n = 36). No significant differences were found between groups in hospita stay or time to catheter removal. [EL=2]

In the Cochrane review, trials comparing rectus fascia with other materials heavily weighted the comparison of different types of sling (1). Furthermore, the results of the most recent, and by far the largest and most rigorous RCT of colposuspension and ARF sling heavily weighted the results of the analysis (21). This trial randomised 655 women of whom 520 were assessed at 24 months, while the next largest trial randomised 72 women (17). The summary statistic, combining urodynamic and symptom only diagnosis, showed a lower incontinence rate with sling procedures (RR 0.75; 95% CI 0.62 to 0.90) for a follow-up from 1-5 years. The data from the trials where women all had urodynamic SUI showed no significant difference in urinary incontinence after one year (RR 0.72, 95% CI 0.31 to 1.67). Data beyond five years were provided by only one trial (23), and there was no statistically significant difference between the groups, but with very wide confidence intervals (RR 2.31; 95% CI 0.24 to 22.62). There was an inadequate number of studies to support a metaanalysis of objective cure. AEs in general (47% vs.63% (p<0.001) and voiding difficulty in particular (14% vs. 2%, p<0.001, RR 6.08; 95% CI 3.10 to 11.95,) were more common in sling group (24). Women in the colposuspension group had their catheters removed earlier (Mean difference :8 days; 95% CI 6.8 to 9.2). However, it is unclear if this was due to the procedures themselves or differences in hospital policies. There was no statistical

significant difference of de novo urge symptoms or DO between the two procedures[EL=1].

Only one small trial (10 women in each group) is available to allow comparison between sling (porcine dermis) and needle suspension (Stamey) in a group of women unsuitable for abdominal colposuspension because of vaginal narrowing secondary to either previous interventions or atrophic change (25). Although there were no differences in objective cure rates at 3 or 24 months, perioperative complications (RR 4.50; 95% CI 1.28 to 15.81) and length of hospital stay (RR 13.00; 95% CI 5.00 to 21.00) favored the needle suspension procedure (n=20). [EL=2]

A recent Cochrane review (26) assessed the results of the open Burch Colposuspension. In a subgroup analysis of studies comparing traditional slings and open colposuspension showed better effectiveness with traditional slings in the medium and long term (RR 1.35; 95% CI 1.11 to 1.64 from one to five years follow up, RR 1.19; 95% CI 1.03 to 1.37).

1.3. ARF vs. other traditional slings (Table 3)

Our review identified 3 RCTs and 2 quasi-RCT comparing one type of traditional sling with another (27-31), with an additional RCT providing long-term outcomes of one of the aforementioned studies (32). The remainder were cohort and case control studies.

ARF and vaginal wall slings were compared in one RCT and two non-randomised retrospective studies (29, 33, 34). All of these trials were considered to be of poor quality. The RCT reported high subjective cure, and satisfaction rates (80–100%) for both procedures, with median follow-up of 7 months and minimum follow-up of only 3 months (n = 26) (29) [EL=2]. The non-randomised studies reported similar 'success rates' with both interventions, ranging from 80% to 97% with follow-up of 21 months and 70 months versus 45 months (n=232, n=79) (33, 34) [EL=2/3]. Other than the proportions of patients requiring intermittent catheterisation after surgery (2% in the ARF group and 0% in the vaginal wall group), no additional differences were noted in rates of other postoperative complications (e.g. voiding and storage dysfunction, wound infection and seroma formation, and bladder or urethral injury).

One RCT compared two techniques of fascial sling in 168 women with urodynamic stress incontinence (USI), 89% of whom had had prior continence surgery (28). Women underwent a standard fascial sling procedure or a 'sling on a string' (a shorter sling mounted on each end with a nylon thread) (28). At 1 year, subjective cure rates were 84% using both techniques. Satisfaction and changes in IIQ scores were also similar in both groups, whereas improvements in UDI scores were greater with the standard approach (adjusted for differences in baseline UDI data). A further evaluation of women in this study was reported at 5 to 7 years of follow-up(32). There were no significant differences in symptoms of SUI or UUI between groups, with 40%-53% vs. 36%-51% reporting SUI in a sensitivity analysis. [EL=1]

Eight non-randomised studies compared the outcomes of autologous and allograft slings in a total of 859 women with SUI (35-37) (38-42) while one additional study also compared both interventions with a xenograft material (porcine dermis) (43). All were retrospective reviews, each with differences in duration of follow-up for the interventions evaluated (between 1 month and 3 years), with dropout rates of 4% to 34%. Additionally, between 16% and 82% in different studies underwent other concomitant surgeries, and all of these studies were considered to be of poor quality. [EL=3]. Four of these studies compared autologous with allograft (cadaveric) fascia lata. Three reported similar results for all outcomes (subjective cure, satisfaction, and UDI-6, IIQ-7 and SEAPI scores) (35, 36, 41), while the fourth study reported significantly higher cure rates in the autologous group (40) [EL=3]

In three studies that compared autologous rectus fascia or fascia lata with allograft fascia lata, two found a significantly higher cure rate in the autologous group (37, 43) the other found no significant differences in cure rate, although satisfaction rates were higher in the autologous group after 2 years follow-up (38). In the study with a xenograft arm, cure rates were significantly higher with autograft material (43). The study comparing ARF to cadaveric dermis found no significant difference in subjective cure rates at a mean follow-up of 18 months and 13 months, respectively (42)[EL=3].

One RCT compared the porcine dermis sling vs. ARF (sling on a string technique) and tension-free vaginal tape (TVT), a RP MUS (44). Women recruited had primary SUI. It should be noted that the ARF and porcine dermis slings were placed at the midurethra rather than the BN, but suspended above the rectus fascia like traditional slings. The primary outcome was patient-reported improvement rates at 6 months and 1 year. At 6 months, the porcine dermis arm had significantly poorer improvement rates (73%) than TVT (92%) and ARF (95%), and, at 1 year, only 61% of the porcine dermis slings remained as improved, vs. 93% and 90% of the TVT and ARF arms, respectively. At 1 year, women undergoing porcine dermis slings had significantly lower dry rates (22%) as compared to TVT (55%) and ARF slings (48%), respectively. Subsequently, the porcine dermis arm was suspended following interim analysis.

There was no difference in success rates between the TVT and ARF arms.

1750

Table 3: Traditional Sling vs Traditional Sling

Author	RCT	Sling	Comparator	N/N (n1/n2)	F/U	Cure; effect size	EL	Comments
Kaplan, 1996	No	ARF	Vaginal Wall	79 (43:39)	6-51 m (Mean 21.4m)	84% vs. 89% (s+o)	3	9%o vs. 94% satisfied or very satisfied

One in five women in the porcine dermis arm had surgery for SUI by 1 year, but none had undergone additional surgery in the other arms. [EL=1/2].

One non-randomised trial compared porcine dermis sling vs. ARF (45), a second compared porcine dermis sling vs. both ARF and TVT(46), and a third trial mentioned earlier compared porcine dermis vs. both ARF and allograft slings (43). At a follow-up of 36 months, the subjective success rate (cure and improved) after ARF sling was significantly higher than porcine dermis sling (80.4% vs. 54%) (45). Women undergoing porcine dermis slings were found to have significantly higher postoperative symptom severity than women undergoing either ARF sling or TVT (46). Objective cure rates after ARF were significantly higher (87%) than either porcine dermis sling (54%) or cadaveric fascia lata (64%) (43) [EL=2/3]

A quasi-RCT compared an ARF sling with a self fashioned polypropylene mesh sling placed at the BN (31). At a median follow-up of approximately 24 months, cure and satisfaction rates were similar but operating time and hospital stay were significantly shorter in the polypropylene sling group. Delayed voiding and wound pain occurred in more women in the ARF sling group. No other significant differences were seen between groups in complications (e.g. haematoma, dysuria, de novo urgency or UUI) (n=50). [EL=2] A second, retrospective,non-randomised trial found no significant difference in subjective cure rate (81% vs. 88.9%) in women undergoing ARF and polypropylene mesh (Marlex) slings (47). It should be noted that both slings in this study were placed at the midurethra but tied without tension above the rectus fascia as in the traditional BN sling. Interestingly, vaginal extrusion rates and rates of surgical intervention for extrusion were not significantly different between ARF and Marlex slings. [EL=3]

One RCT compared ARF and PTFE slings in women with type III SUI, 92% of whom had had previous continence surgery (27). Combined objective and subjective cure rates at 6 months follow-up were 81% and 88%, respectively. No complications were reported in the ARF sling group; however, , recurrent UTI and de novo DO were very common with PTFE (n= 48). In 2 patients there was an erosion of the urethra and the Goretex sling had to be removed 3.5 years later. [EL = 1] A quasi-randomised comparison of a MycroMesh patch sling (PTFE mesh impregnated with silver diacetate and chlorhexidine) with vaginal wall sling gave no statistical analysis, but found combined subjective and objective cure in 95% vs. 75% at mean follow-up of 22 months. Complications reported were wound infection, UTI, bleeding, vaginitis and transient de novo UUI (30) [EL=2] Again, the need for sling removal was common, reported in up to 31% (median 8%) in a review of case series within the systematic review underlying the NICE guidance on UI (11)[EL=3].

A retrospective cohort study compared an ARF sling with one reinforced with polyglactin mesh in women with USI, one-third of whom also had UUI (n=51) (48). Follow-up differed between groups and, overall, no clear difference was seen between groups in success rates. As with most studies, results depended on the definition of success used. No significant differences were noted between groups in terms of complications (e.g. wound infection, incisional hernia, voiding dysfunction, and de novo DO). [EL=3]

A small, non randomised trial compared ARF to bovine dermis sling (n=85) (49). Patients were allocated to material by institution and all had ISD (VLPP≤60 cm H2O)., advanced age, and/or recurrent SUI after previous anti-incontinence surgery. At 12 months follow-up, the SUI-specific cure rates (consisting of subjective stress SEAPI domain and negative cough stress test) and global cure rates (consisting of SEAPI composite score and visual analog score) were not significantly different between the two slings. QOL indices (UDI-6, IIQ-7) were significantly improved in both groups. There were significant differences in several preoperative demographic variables between the groups.

In the Cochrane review of traditional BN slings, there were six studies comparing one type of sling to another (1) including four published trials in their statistical comparison (27-29, 32) as well as two trials in abstract form. A total of 379 women studied after 12 months showed no statistically significant difference in incontinence rates (RR 0.89; 95% CI 0.72 to 1.10). However, results reported improvement after one year in favour of the traditional ARF sling (RR 0.33; 95% CI 0.17 to 0.64). The incontinence rate after five years was reported in only one trial (28) and showed no statistically significant difference between different lengths of the autologous material used (RR 1.17; 95% CI 0.86 to 1.59). There was significant heterogeneity in the incidence of perioperative complications between groups in two trials, which was attributed more to complications with the use of Gore-Tex in one trial (RR 0.05; 95% CI 0.00 to 0.80, (27). In the other trial, there was no statistically significant difference between two biological slings (RR1.14, 95% CI 0.78 to 1.66, (28). No statistically significant difference was found in assessment of the following AEs, reported in only one trial : bladder perforation (RR 0.69; 95% CI 0.12 to 4.03), UTI (RR 1.73; 95% CI 0.66 to 4.54), de novo DO or urge symptoms (RR 3.11; 95% CI 0.65 to 14.97), and voiding dysfunction (RR 1.16; 95% CI 0.65 to 2.07).

1.4. Traditional sling vs. MUS (Tables 4 and 5)

Our review identified 17 trials that addressed the comparison between traditional sling operations and MUS operations. Eight RCTs compared traditional slings placed at the BN with the RP MUS (Table 4) (20, 50-56) and 3 additional RCTs provided long-term outcomes of aforementioned studies (44, 57, 58).

Table 4: Traditional Sling vs RP MUS

Author	RCT	Sling	Comparator	N/N (n1/n2)	F/U	Cure; effect size	EL	Comments
Arunkalaivanan, 2003	Yes	Porcine Dermis	TVT	128/142 (74:68)	Median 12m	89% vs. 85% (s); p=ns	2	No ss calculation
Abdel-Fattah, 2004				(68:60)	Median 36m	82.4% vs. 88.3% (s); p=ns	2	90.1% response rate to questionnaire at 36m
Hung, 2004	No	Prolene	TVT	80 (57:23)	Mean 20m:23m	93% vs. 91.3% (o); p=ns 68.8% vs. 77.4% (s); p=ns	3	TVT better than prolene at BMK27.3 kg/m'
Bai, 2005	Yes	ARF	TVT	59/59 (28:31)	6m 12m	92.8% vs. 90.3% (s+o); p=ns 92.8% vs. 87.0% (s+o); p=sig	2	No ss calculation; minimal details about randomization; some disparities between text and tables

One of the trials (51) was only available as an abstract and 3 studies were non-randomised case-control or cohort studies (46, 59, 60). Two RCTs compared a traditional ARF sling to a TO MUS (Safyre-t) (Table 5) (61, 62). Finally, a non-randomised trial compared PVSs (material not stated) with TVT and TO MUS (63). Six RCTs compared ARF sling with TVT and reported on a total of 463 patients (20, 51, 56); (52, 54, 55). Three of the studies were recently updated at a longer-term follow-up (44, 58, 64). Cure rates at 12-36 months (subjective +/- objective) varied widely depending on definition and were 47%-95% for both ARF and TVT.

Although a statistical difference was not observed at 6 months, one trial (20) showed a significant difference in subjective + objective cure rate at 12 months favoring TVT (92.8% vs. 87%). This trial also had a colposuspension arm, which had a 12 month cure rate of 88%. [EL=2]. The remainder five RCTs did not reveal a statistical difference in cure rates (subjective or objective) between ARF and TVT. [EL=1/2].

Another trial randomised 201 women with clinically and urodynamically confirmed SUI to TVT, ARF (sling on a string) or Pelvicol™ sling (44, 51). At 6 months the Pelvicol™ arm had poorer improvement rates (73%) than TVT (92%)/ARF (95%); P = 0.003. At 1 year only 61% of the Pelvicol slings remained as improved, versus 93% of TVTs and 90% of ARFs (P < 0.001). Following interim analysis the Pelvicol™ arm was suspended due to the significant poorer results. There was no difference in the success rates between TVT and ARF. ARF took longer to do (54 minutes versus 35 minutes for TVT/ 36 minutes for Pelvicol) and had higher intermittent self catheterisation rates (9.9 versus 0% Pelvicol /TVT 1.5%). Hospital stay was shortest for TVT (2 days). [EL=2]

In order to assess long term efficacy, participants were assessed by postal questionnaires or via a telephone interview (64) In all, 162 (80.6%) women were available for follow-up with a median (range) duration of 10 (6.6–12.6) years. 'Success' rates for TVT, AFS and Pelvicol™ were 73%, 75.4% and 58%, respectively. Comparing the 1- and 10-year 'success' rates, there was deterioration from 93% to 73% (P < 0.05) in the TVT arm and 90% to 75.4% (P < 0.05) in the AFS arm; 'dry'rates were 31.7%, 50.8% and 15.7%, respectively. Overall, the 'dry' rates favoured AFS when compared with Pelvicol (P < 0.001) and TVT (P = 0.036). The re-operation rate for persistent SUI was 3.2% (two patients) in the TVT arm, 13.1% (five) in the Pelvicol arm, while none of the patients in the AFS arm required further intervention. [EL=2]

A non randomised prospective comparative study examined the efficacy and complications of ARF and MUS in surgically naïve women with SUI. A total of 201 women were given the option between a PVS and an MUS (top-down). Ninety-one women (45%) underwent ARF and 110 underwent MUS (55%). The two groups were comparable on the baseline characteristics. At a median follow-up of 13.8 months the cure rate in the ARF group (75.8%) was not statistical significant different from that in the MUS group (80.9%) De novo urinary urgency incontinence appeared in 16.7% of the PVS group and 33.3% of the MUS group (non significant). Complications and voiding difficulty were similar between the groups (4.4% in ARF vs 2.7% in MUS)(65) [EL=2]

One RCT found no statistical difference in objective and subjective cure rates at 12 months after cadaveric fascia lata slings and the intravaginal slingplasty (IVS), a multifilament, polypropylene MUS (53) [EL=2]

One non-randomised trial that also included a porcine dermis arm found no statistical difference between ARF slings and TVT (46). Symptom severity, as assessed by validated questionnaire, was not significantly different between the ARF sling and TVT groups. [EL=2/3].

Two randomized studies compared the porcine dermis sling with PVS tape (TVT) (50, 51) The first RCT comparing porcine dermis sling with TVT found no significant differences in operating time, hospital stay, complication rates, or subjective cure at 1 year (85% vs. 89%) (50), nor in cure (88% vs. 82%) or satisfaction at 3 years, assessed by mailed questionnaire (77% vs. 80%) (57) [EL=1]. The other study (44, 51) compared 3 treatment arms (ARF, porcine dermis sling-Pelvicol™, and TVT). At 1 year only 61% of the Pelvicol™ slings remained as improved, versus 93% of TVTs and 90% of AFSs (P < 0.001). It is not clear why the first study (50) found comparable results between porcine dermis and TVT, whereas the 3-arm trial found such significantly poorer results after porcine dermis to require the premature curtailment of recruitment (44, 51).

The non-randomised trial mentioned in the previous section (46) that included a porcine dermis arm, found that symptom severity was significantly higher in the porcine dermis group than in the other 2 groups of ARF and TVT. [EL=2/3]

A retrospective study compared traditional ARF sling, TVT, and the TO MUS (63). Overall complication rates were not significantly different between the sling groups. At 2 years postoperatively, the cumulative cure rates of the traditional sling, TVT, and TO MUS groups were significantly different (87.3% vs. 86.7% vs. 34.9%, respectively; p<0.0001).

The risk of treatment failure in women who received TO MUS was 4.6 times higher than in women who underwent traditional sling. The 7-year cumulative cure rates of traditional sling and TVT groups were 59.1% and 55.1%, respectively. [EL=2/3]. Another retrospective cohort study of 242 women who underwent ARF (n = 79) or midurethral (n = 163) sling found that women with rectus fascia slings were more likely to report any leakage of urine (P = .04) and were

Table 5: Traditional Sling vs TO MUS

Author	RCT	Sling	Comparator	N/N (n1/n2)	F/U	Cure; effect size	EL	Comments
Silva-Filho, 2006	Yes	ARF	Safyre-t	20 (10:10)	6m	39g vs. 8.4g (o; pad weight); p=sig	2	Mean operating time & hospital stay significantly shorter in Safyre group
Jeon, 2008	No	PVS	TO MUS TVT	159 (87:72)	24m	87.3% vs. 34.9% (s+o); p=sig	3	Retrospective; complication rates similar at 24m; RR treatment failure of TO MUS=4.6x higher than ARF
Tcherniakovsky, 2009	Yes	ARF	Safyre-t	41/41 (20:21)	12m	95% vs. 90.5% (s+o); p=ns	2	Randomization technique not stated; no ss calculation

13 times more likely to require urethrolysis (P < .001) than patients with MUSs. Patient satisfaction was lower in the rectus fascia sling group compared with the MUS group (P = .01). (60) [EL=3]

Two small RCTs compared ARF sling to Safyre-t TO MUS (61, 62). At a follow-up of 12 months, subjective + objective cure rates were not statistically different (95% vs. 90.5%) in one trial (62), while higher pad weight at 6 months was observed for the ARF group in another trial (39g vs. 8.4g) (61) [EL=2]

The Cochrane database identified 12 trials that addressed the comparison between traditional sling procedures and minimally invasive, MUS operations. (1).Ten of these studies have been summarized in our assessment and 2 studies were only in abstract form. (8, 20, 44, 50, 53-55, 58, 62, 63). Data on incontinence after the first year were available from four RCTs (20, 44, 50, 54). Incontinence was reported by 31.6% of those women in the traditional sling and 25.3% of those in the MUS groups. This was not statistically significant (RR 1.23; 95% CI 0.91 to 1.66). This translates to 311 per 1000 women being incontinent after a traditional sling compared with 253 per 1000 after a MUS. Improvement after a year was addressed by two trials (44, 50) and there was no statistically significant difference between the two types of sling (RR 1.30; 95% CI 0.57 to 2.94).

Pooled data from 3 trials (50, 54, 62) showed a statistically significant higher risk of perioperative complications after traditional sling operations (RR 1.59; 95% CI 1.03 to 2.44). Seven RCTs(20, 50, 54, 55);(66) (abstract only); (58, 62) reported bladder perforation. There were more perforations after MUS procedures, but this did not reach statistical significance (RR 0.62; 95% CI 0.34 to 1.11) and the confidence interval was wide. The combined results from 3 trials showed less de novo urgency symptoms after MUS (RR 3.13; 95% CI 0.96 to 10.24) but this did not reach statistical significance and the confidence interval was wide. However, 3 trials showed that development of de novo DO was significantly less after MUS operations (RR 3.21; 95% CI 1.29 to 8.03). This was principally due to the higher weighting given to the largest trial (53). The combined results from 5 trials showed that more women had postoperative voiding dysfunction after traditional slings than after MUS (RR 1.60; 95% CI 0.94 to 2.71) but this did not quite reach statistical significance and the confidence interval was wide. More women in the traditional sling group required release of sling (9% versus 2%), reported in two trials (RR 3.67; 95% CI 0.95 to 14.22) but again this was not statistically significant. There was no statistically significant difference in urinary retention up to 6 weeks (RR 5.51; 95% CI 0.68 to 44.63) from one trial and vaginal erosion (RR 0.35; 95% CI 0.02 to 8.10) based on one trial.

Summary

Only a few new studies have emerged on traditional slings since the 5th edition.

AFS (autologous fascial sling) is the most widely evaluated biological sling and is an effective and durable treatment for SUI. [EL=1].

There is little short term difference in efficacy between biological slings using autograft or allograft (EL=2/3) and synthetic slings and biological slings placed at the BN. However, those studies that find a difference between biological materials for sling all favor autologous materials [EL=2].

As compared to AFS, AEs may be more common following the use of synthetic materials as 'traditional' (BN) sling procedures (exposure, erosion, etc.) [EL=3].

In comparison to other procedures:

AFS is more durable than injectable bulking agents as a treatment for SUI (EL=2/3)

AFS (BN slings) are as effective as MUS in the short term [EL=1] however OR time and LOS are significantly shorter with MUS

AFS is modestly more effective than colposuspension at mid-long term (EL= 1/2) albeit with a higher rate of early postoperative voiding dysfunction. The limited data available suggest that the overall rates of late surgical complications are similar after sling and colposuspension; however, the pattern of complications may vary.

Due to the variability and somewhat unique array of complications associated with each procedure, as well as the relatively low incidence of short term and long term complications overall, and the relatively

small number of comparative trials with a complete accounting of all complications between AFS, biological materials, MUS, and colposuspension, there is an insufficient database on which to recommend or differentiate these procedures on the basis of AEs/complications alone.

Recommendations

Autologous fascial sling (AFS) is recommended as an effective treatment for female stress urinary incontinence, which has longevity for both primary and redo surgery. [Grade A]

2. COLPOSUSPENSION

2.1. Open Colposuspension

Open PVS colposuspension is a surgical treatment which involves lifting the tissues near the BN and proximal urethra in the area behind the anterior pubic bones to correct deficient urethral closure. Since its introduction by Goebell, Stroekl, and Frangenheim in 1910, various alternative techniques have been described. The Marshall-Marchetti- (67)and the Burch procedures (68, 69) are two traditional approaches that have had long-term success rates in restoring continence.

2.1.1 Marshall-Marchetti-Krantz (MMK) Procedure

There were no new RCTs involving the MMK procedure and therefore no new recommendations since the 2009 edition of the ICI-3 book.

Although short-term results indicate comparable cure rates to colposuspension, there is limited evidence that longer-term outcome is poorer following MMK [EL=1], and declines further over time [EL=3]. The previous edition of this consultation found no reason to support the continued use of MMK over colposuspension; there is no new evidence to indicate a change in this view.

Recommendation

The MMK Procedure is not recommended for the treatment of SUI. [Grade A]

2.1.2 Burch Colposuspension

There have been only two newly published randomised trials since the 2009 edition of the ICI-3 book, which are one comparing open colposuspension with TVT procedure(70) and one with TO MUS procedure. (71)

In common with previous systematic review supported by meta-analysis, (26)the combined results from the various studies show open colposuspension to have comparable subjective and objective outcomes to both traditional sling procedures and to the newer minimally invasive midurethral PVS sling procedures; it has better outcomes than anterior colporrhaphy, BN needle suspension and MMK procedure [EL=1].

Open colposuspension has been shown to be an effective surgical treatment for stress urinary incontinence. In common with other procedures there is some loss of efficacy with time.

Recommendations

Open Burch PVS colposuspension can be recommended as an effective treatment for primary and recurrent stress urinary incontinence, which has longevity. [Grade A]

Open Burch colposuspension can be considered for those women in whom an open abdominal procedure is required concurrently with surgery for SUI. [Grade D]

2.2. Laparoscopic/Robotic Colposuspension

Laparoscopic minimally invasive approaches to PVS was introduced by Vancaillie and Schuessler in 1991, as an alternative technique of open colposuspension that features the advantages of reduced pain, a shorter length of hospitalisation, and a more expedient return to activity while avoiding the morbidity associated with the open PVS colposuspension.

2.2.1 Laparoscopic versus Open Colposuspension (Table 6)

The Cochrane review of laparoscopic colposuspension includes details of 22 RCTs that include laparoscopic colposuspension (72), 14 more than their initial review (34). Of these 22 trials, ten compared laparoscopic colposuspension with open colposuspension (18, 61, 73-80).

Eight of the ten studies comparing laparoscopic colposuspension with open colposuspension were included along with eight retrospective cohort studies in a recently published meta-analysis (43).

One RCT compared laparoscopic colposuspension (81) with open colposuspension and one RCT compared different techniques of laparoscopic colposuspension. In addition, two publications with longer-term follow-up (37) or cost-effectiveness data (82) were added.

We identified two RCTs (83, 84), which were included in the Cochrane review of open colposuspension.

Table 6: Published level 1 & 2 evidence relating to laparoscopic colposuspension

One is only an abstract (83). They reported shorter operative times with open colposuspension, by 15-30 minutes and a longer hospital stay after open compared to laparoscopic colposuspension. Tuygun also reported that the time to catheter removal or the time to return to normal activities was longer in the open colposuspension group.

Studies included in the Cochrane review had different lengths of follow-up, although eight studies had follow-up in the region 6 to 18 months. In comparison with open colposuspension they found subjective cure rates to range from 58% to 96% in the open and 62% to 100% in the laparoscopic group within the 18 months follow up, with a non-significant 5% lower relative subjective cure rate for laparoscopic colposuspension (RR 0.95, 95% CI 0.90 to 1.00)(72) [EL=1]. The two studies with follow-up at five years or beyond unfortunately remain unpublished and available in abstract form only. Both these studies were relatively small, and their results are inconsistent, one finding better subjective outcome from the laparoscopic procedure (80), and one favouring the open procedure (79); the methodology of this latter study in particular has been questioned [EL=2].

Overall, the objective cure rate as judged by cough stress testing or pad test within 18 months was statistically significantly lower following laparoscopic colposuspension (RR 0.91, 95%CI 0.86 to 0.96) [EL=1]. Between 18 months and five years there was no significant difference (RR 1.01, 95%CI 0.88 to 1.16); again however, there was heterogeneity with one small trial greatly favouring open procedure (79) and the other favouring laparoscopic(80) [EL=2]. When objective cure was judged by urodynamic investigations there was a significantly higher success rate following open colposuspension (RR 0.91, 95%CI 0.85 to 0.99).

2.2.2 Laparoscopic Colposuspension vs. Other Techniques

Eight trials have compared laparoscopic colposuspension with minimally invasive mid-urethral slings(4, 106-110).

In comparison with minimally invasive mid-urethral slings there was no statistically significant difference in subjective cure rates within 18 months (RR 0.91, 95% CI 0.80 to 1.02) [EL=1]. The definition of objective cure varied widely between studies, although overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92, 95% CI 0.85 to 0.99) [EL=1]. (for addition information on laparoscoptic colposuspension vs. MUS, please see section on RP MUS)

Although laparoscopic colposuspension is regarded as a less invasive operation than the open colposuspension, the mid-urethra tape procedures had significantly shorter operating time (<0.001), hospital stay (<0.001) and time for resuming normal activity (<0.01 -0.001) as compared to the laparoscopic colposuspension.

2.2.3 Different Techniques of Laparoscopic Colposuspension

Different aspects of the laparoscopic technique have been compared including one vs. two sutures (111), sutures vs. mesh (86, 112, 113) and transperitoneal vs. extraperitoneal approach to laparoscopy(114).

Two sutures on either side of the BN resulted in higher subjective (RR 1.37, 95% CI 1.14 to 1.64) and objective (RR 1.42, 95% CI 1.14 to 1.77) cure rates as compared to one [285] [EL=2].

When comparing sutures and mesh to secure paraurethral support, sutures resulted in a higher subjective (RR 1.28, 95% CI 1.11 to 1.47) and objective (RR 1.20, 95%CI 1.07 to 1.35) cure rate than mesh (74, 86, 112, 113) [EL=1].

The transperitoneal versus extraperitoneal study reported above employed different techniques (sutures vs mesh) and therefore gives little insight into the value of either approach given the superior results obtained with sutures.

The use of glue or fibrin sealants has not been reported outside small case series.

2.2.4 Complications of Laparoscopic Colposuspension

Bladder, ureteric and vascular injuries are recognised complications of colposuspension. The Cochrane review reported 21 bladder injuries among 521 laparoscopic procedures (compared with 10 among 507 open procedures) and two studies reported obturator vein lacerations. However, when compared with the traditional open colposuspension, the laparoscopic group was found to have significantly fewer postoperative complications (RR 0.74, 95% CI 0.58–0.96) with lower estimated blood losses and shorter duration of catheterisation.

Longer operating times are a significant disadvantage of the laparoscopic approach (73, 76, 83, 84); however, women have reported significantly less pain, (79, 115-117) shorter hospital admissions, faster recoveries and quicker return to normal activities. (91, 93), (102),(86),(62, 70, 118, 119) (83),(84).

2.2.5 Longevity of Laparoscopic Colposuspension

A long-term review of women who had undergone laparoscopic colposuspension more than 10 years previously(60, 120) compared the results with a group of women who had open colposuspension. Subjective cure rates deteriorated over time from 71% and 67% at 6 months to 52% and 36% at 10 years for the laparoscopic and open procedures, respectively. Vaipas updated their previous study comparing TVT with laparoscopic colposuspension (109), and showed that both objective and subjective cure rates were significantly higher in the TVT group (94%,

64%) than in the laparoscopic mesh colposuspension group (78%, 51%) (105).

The conclusion from the Cochrane review was that the available evidence suggests that laparoscopic colposuspension may be as effective as open colposuspension two years postoperatively (72). The systematic review specific to laparoscopic colposuspension and TVT™ concluded that the evidence so far appears to favour the latter as the minimal access technique of choice for USI (121). In both cases however the authors indicated that the place of laparoscopic colposuspension in clinical practice could not be clearly defined without further long term results.

It should also be noted that much of the published research in this area is from individuals with enthusiasm and skill in laparoscopic surgery; their results should not necessarily be seen as being generalizable to the urogynecological/urological community at large. The NICE guidance includes amongst its recommendations that laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women, but that the procedure should be performed only by an experienced laparoscopic surgeon working in a multidisciplinary team with expertise in the assessment and treatment of UI (122, 123); this same point is emphasised in the meta analysis from Tan and colleagues [275] [EL=4].

Summary

Laparoscopic colposuspension shows comparable subjective and objective outcome to open colposuspension in the short to medium term; longer term outcomes are unknown [EL=2].

Limited evidence suggests that the subjective outcome from laparoscopic colposuspension is similar to the TVT™ , however the objective outcome is poorer. (EL=2)

Recommendations

Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise. (Grade C)

Women should be advised about the limited evidence available about the long term durability of laparoscopic colposuspension. (Grade C)

3. MIDURETHRAL SLING

3.1. Retropubic MUS

The tension-free vaginal tape (TVT) procedure for treatment of female PVS was first introduced by Ulmsten, et al. in 1996(124). The development of the TVT operation was an attempt to support the middle portion of the urethra, instead of restoring anatomy and correcting urethral hyper-mobility at the BN. The idea of supporting the “mid-urethra” has been derived from the results of several research projects conducted during the last thirty years. The work of Zacharin in 1968 and DeLancey in 1994 had already shown that the pubourethral ligaments inserted at the mid-urethra and that the urogenital diaphragm also was closer to the middle portion of the urethra than the BN(125, 126). In 1978, Owman et al. found that the most densely innervated portion of the urethra was the middle part and Huisman in 1983 showed in histological studies that the mid-urethra had the most abundant vascularisation(127). Additionally, Westby et al. in 1982 showed in radiographic studies how the urine stream was interrupted at the mid-urethra on holding in continent women and Asmussen et al. in 1983 showed that the maximal urethral closure pressure was situated at the midurethra(128, 129). It quickly became apparent that focusing on the mid-urethra might bring improvement in the performance of incontinence surgery.

Prospective observational cohort studies revealed that placing a macroporous, monofilament polypropylene tape at the mid urethra resulted in cure rates between 80-90 % in primary cases of SUI (123, 124, 130-132), in recurrent cases (133, 134), in mixed incontinence cases (133), and in an unselected group of women including primary, recurrent and mixed incontinence as well as women with ISD(132). Since those initial reports of success, several groups have reported long-term outcomes exceeding 5 years (107, 135-138) and 10 years after the TVT procedure (139, 140). A variety of follow-up regimens and definitions of success reveal that the effects of the TVT on resolution of SUI are durable over the long-term.

Since the last ICI review was conducted, the literature regarding the TVT and other RP MUS procedures has expanded at an almost exponential pace. As an example, 16 RCTs comparing MUS to other procedures were available for review. The number of RCTs and large cohort studies now available significantly exceeds the previous review, and, unless otherwise mentioned, only fully-published studies have been included herein.

3.1.1 RP MUS vs. No Treatment (Table 7a)

No recent trial has compared RP MUS and no treatment. A multicentre, prospective RCT performed by Campeau et al. enrolled 69 elderly females who initially consented to be randomised to either undergo immediate TVT surgery or to wait for 6 months before submitting to the same surgery (control group). (141) The main outcomes measured at every visit (pre-randomisation, 8-12 weeks and 6 months) consisted of the Incontinence-Quality of Life (I-QOL) Questionnaire, the Patient Satisfaction Questionnaire and the Urinary Problems Self-assessment Questionnaire. The analysis included 31 patients in the immediate surgery group and 27 subjects in the control group. Perioperative complications in the immediate surgery group were bladder perforation (22.6%), urinary retention (12.9%), urinary tract infection (3.2%) and de novourgency (3.2%). At 6 months, the mean scores

on each questionnaire were significantly in favour of the TVT group. [EL=1/2]

3.1.2 RP MUS vs. Pelvic Floor Muscle Training (PFMT)

Pelvic floor muscle training (PFMT) with or without biofeedback is a recognised and effective treatment for various pelvic floor conditions, including SUI, UUI, and pelvic pain.

Since ICI-5, Labrie et al. published a multicentre RCT which included 215 women in the surgery group and 202 women in the physiotherapy group. At 1 year, a total of 49.0% of women in the physiotherapy group and 11.2% of women in the surgery group crossed over to the alternative treatment. In an intention-to-treat analysis, at 1 year, there was higher rates of subjective improvement (90.8% versus 64.4% (absolute difference, 26.4 percentage points; 95% [CI], 18.1 to 34.5), subjective cure (85.2% vs 53.4% (AD, 31.8 pp; 95% CI, 22.6 to 40.3) and objective cure (76.5% vs 58.8% (AD, 17.8 pp; 95% CI, 7.9 to 27.3) in women in the surgery group compared with women in the physiotherapy group (Lot 1). A post hoc per-protocol analysis showed that women who crossed over to the surgery group had outcomes similar to those of women initially assigned to surgery and that both these groups had outcomes superior to those of women who did not cross over to surgery.

3.1.3 RP MUS vs. Bulking Agents

No trial comparing bulking agents to MUS slings was found.

3.1.4 RP MUS vs. Open Colposuspension (Table 7b)

Since the ICI-5 review, only two additional studies have been published comparing TVT and open colposuspension. (142, 143) While El-Din Shawki 2012 reported outcomes, we were not able to include the data in the review because they did not specify how the participants were allocated across the three treatment groups. For Trabuco 2014, only the abstract was available and the trial has not been included in this review.

Three of the studies from ICI-5 compared TVT with open colposuspension (70, 144, 145). In a nonrandomised trial with significant failed-to-complete-follow-up, McCracken et al. found no difference in subjective success rates via questionnaire between colposuspension and TVT at 5 to 10 years. [30] In an RCT randomising 49 women to TVT or colposuspension, Tellez Martinez-Fornes found no significant difference in subjective success rates (cured/improved) between the 2 procedures at follow-up periods of 6, 12, and 36 months.(70) In a retrospective, nonrandomised trial comparing 105 women who underwent TVT with 81 women who underwent MMK, the authors found that while the short-term success rate of the MMK was 89%, the rate fell to 68.2% at 5 years and 32% at 10 years. (145) In comparison, the short-term success rate of the TVT was statistically similar to the MMK (90%) but decreased only to 84.3% at 5 years. Women who underwent TVT also experienced shorter operative time, less blood loss, and shorter hospital stay. [EL=3]

A systematic review and meta-analysis comparing open colposuspension and sling procedures was published in the Cochrane Database(146). Twenty-two trials compared suburethral slings (traditional slings or trans-vaginal tape or TO tape) and open colposuspension, involving a total of 2343 women (slings procedures n=1254, vs. open colposuspension n=1089). The authors of this review acknowledged the discrepancy of the data which was attributed to the different types of sling operations performed. There were non-significant differences in long-term patient reported cure rate (RR 1.11; 95% CI 0.97 to 1.27) and in objective cure rate (RR 0.70; 95% CI 0.30 to 1.64). Six trials involved traditional (BN) suburethral sling procedures, 12 trials used RPMUS, 3 trials TO MUS and one trial did not specify whether the TVT or TO MUS procedure was the approach taken.

The operative time (18.06 ; 95%CI 14.67 to 21.46) and the hospitalisation stay (MD (Mean difference) 3.99; 95%CI 3.71 to 4.28) were shorter with TVT as compared to open colposuspension. The time for catheter removal was shorter in the TVT group compared with the open colposuspension (RR 4.51; 95%CI 3.05 to 5.97).

There was no significant difference in the perioperative complication rates between colposuspension and TVT (RR 1.11; 95% CI 0.66 to 1.87). There was no significant difference between these two groups in the number of de novo urgency symptoms or urgency incontinence (RR1.28 ; 95%CI 0.65 to 2.50) or for de novo DO (RR 1.28 ; 95%CI 0.71 to 2.32). However, there was a nearly 40% lesser risk of developing voiding difficulties after open colposuspension as compared to sling procedures (RR 0.41; 95% CI 0.26 to 0.67). Trials which focused on TVT however, showed no significant difference in the risk of voiding dysfunction between the two groups (RR 0.66 ; 95%CI 0.06 to 7.09). Women had a higher risk of developing new or recurrent prolapse when undergoing open PVS colposuspension compared to those undergoing sling procedures (RR 1.85; 95% CI 1.25 to 2.75).

There was a lower risk of bladder perforation (RR 0.20; 95% CI 0.08 to 0.49) and vascular injury in open colposuspension compared to TVT.

3.1.5 RP MUS vs. Laparoscopic Colposuspension (Table 7c)

Since ICI-5, there are no additional trials published comparing RP MUS and laparoscopic colposuspension. Four of the 12 RCTs in ICI-4 comparing RP MUS with traditional incontinence procedures compared TVT with laparoscopic colposuspension. (87, 94, 96, 98) Two additional trials were added for ICI-5(119, 153) as well as an update of the Paraiso et al. study(99). The Cochrane review included 5 fully-published manuscripts (87, 94, 96, 98, 153) along with 2 abstracts. (154).

In the studies comparing TVT or Supra Pubic Arc Sling (SPARC; a monofilament polypropylene MUS placed through a top-down approach) with laparoscopic colposuspension objective cure was assessed by a pad test in 2 of the 6 studies (87, 96), and by a cough-stress test in 3 of the studies (94, 96, 98). The criteria for cure or improvement were unclear in the study by Foote et al. (153). The trial by Valpas et al. with the greatest number of patients enrolled showed a significantly higher objective and subjective cure rate in the TVT group than in the laparoscopic colposuspension group ($p<0.0001$), (96) while the other studies showed similar cure rates for both procedures ranging between 72.9% and 96.8% in the TVT groups and between 58.8% and 87% in the laparoscopic colposuspension groups. It was thought that the Valpas et al. trial may have shown a significant difference in outcomes in favour of TVT due to a difference in laparoscopic technique (using mesh rather than sutures to perform colposuspension). (154) In their trial, Paraiso et al. performed postoperative multichannel urodynamic studies in 32 laparoscopic Burch colposuspension and 31 TVT patients. This showed a higher rate of urodynamic stress incontinence at 1 year in the laparoscopic Burch colposuspension group, 18.8% versus 3.2% ($p=0.056$). (98) There was a significant improvement in the number of incontinent episodes per week and in UDI and IIQ scores in both groups at 1 and 2 years after surgery ($p<0.001$). However, postoperative subjective symptoms of incontinence (stress, urge, and any urinary incontinence) were reported significantly more often in the laparoscopic Burch colposuspension group than in the TVT group ($p<0.04$ for each category). At long-term follow-up of the previous study, Jelovsek et al. confirmed that the TVT has similar efficacy to the laparoscopic Burch for the treatment of SUI. (99) While not always bothersome, the authors cited a substantial number of women in either group who had some degree of incontinence 4 to 8 years after surgery. Although laparoscopically-performed colposuspension is regarded as a less-invasive operation than the open colposuspension the MUS procedures had significantly shorter operating time, hospital stay, and time for resuming normal activity as compared to laparoscopic colposuspension. [EL=2]

As with the studies comparing open colposuspension with MUS, the conclusions of studies comparing MUS with laparoscopic colposuspension may be limited due to underpowering. Dean et al. performed a systematic review of laparoscopic colposuspension (n=264) and TVT (n=290) which included 7 trials. (155) There was no statistically significant difference in the reported subjective cure rate between laparoscopic colposuspension and TVT within 18 months (RR 1.12, 95% CI 0.98 to 1.29). However, within the same time period, the overall objective cure rate was statistically significantly higher for TVT (RR 1.16, 95% CI 1.07 to 1.25). There were no significant differences between the two procedures with regards to perioperative complications, de novo DO, voiding dysfunction, procedural costs and QoL scores. The authors confirmed that the TVT procedure was quicker to perform and was associated with a shorter hospital stay. [EL=1/2]

A systematic review by Novara et al. evaluated open and laparoscopic colposuspensions together with RP MUS. (156) Women receiving MUS had significantly higher overall (OR 0.61; 95% CI 0.46 to 0.82, $p=0.00009$) and objective (OR 0.38; 95% CI 0.25 to 0.57, $p<0.0001$) cure rates than those receiving colposuspension. A clinical and economic subanalysis of the Valpas et al. study suggested that over a follow-up period of 1 year the TVT is more cost-effective than laparoscopic mesh colposuspension as a primary treatment for female SUI. [103] ??[49][EL=1/2]

3.1.6 RP MUS vs. Traditional Sling

This comparison is addressed in the section on traditional PVSs.

3.1.7 RP MUS vs. Other RP MUS (Table 7d)

The favourable results obtained with the TVT operation have resulted in several modifications of the procedure and the use of different tape materials. These PVS modifications have not been evaluated satisfactorily clinically and only 6 randomised studies comparing these with the TVT have been published.

The meta-analysis by Novara et al. did not differentiate between different types of RP MUS procedures. (156) In ICI-5, 4 non-randomised studies compared TVT with SPARC. (157-160) In the Dietz et al., study (TVT vs. SPARC), there were no significant differences for subjective cure/improvement, patient satisfaction, or symptoms of incontinence. (157) The cough-stress test was positive in 8 of 37 women who underwent SPARC compared to 4 of 69 TVT patients ($p=0.019$). The TVT had a more negative effect ($p=0.001$) on postoperative voiding. In the Gandhi et al. study, 107 of 122 women returned for objective postoperative evaluation after surgery. (158)

The TVT procedure was associated with higher subjective (86% vs. 60%, $p=0.001$) and objective (95% vs. 70%, $p<0.001$) SUI cure rates, while there was no difference between the TVT and SPARC groups in the resolution of subjective and objective UUI.

Kim et al. found no difference in objective cure rates at 1 year of follow-up and complication rates were similarly low. (159) Paick et al. found no significant difference in cure of SUI or cure of all incontinence between TVT and SPARC at 6 months. (160) [EL=3/4]. Notably, SPARC is no longer commercially available as of 2016.

In ICI-5, two studies compared TVT against other PVS midurethral MUS procedures. Agarwala found no difference in subjective (94% vs. 92%) and objective (96% vs. 94%) cure rates in 96 women consecutively assigned to TVT or to Lynx mid-urethral sling (Boston Scientific; monofilament polypropylene), respectively. (161) Yoon et al. compared TVT to the IRIS (Innovative Replacement of Incontinence Surgery) with a follow-up of 3 years. (162) The instrument of the IRIS system is comprised of a nondisposable metal handle to which two metal needles can be attached. The needles have an outer diameter of 5-6 mm and the non-absorbable polypropylene tape, which is 11 mm wide and 450 mm long with a plastic sheath cover, is fixed to the needles. The tape of the IRIS system is polypropylene monofilament mesh (Trelex; Meadox Medicals, Oakland, NJ/Boston Scientific, NJ, U.S.A.), and the diameter of the pore size is greater than 75 μm such as the tape of TVT. Success rate encompassing both objective and subjective criteria were not statistically different between the 2 procedures at 12 and 36 months. Likewise, the incidence of perioperative complications and postoperative voiding dysfunction was not statistically different. [EL=3]

A recent Cochrane systematic review and meta-analysis of mid-urethral sling operations compared the PVS bottom-to-top approach to the PVS top-to-bottom approach(163) . Five trials were included, including a total of 636 women.

The subjective cure rate within 12 months was significantly higher with the bottom-to-top approach (TVT) compared with the top-to-bottom approach (SPARC) (RR 1.10, 95%CI 1.01 to 1.19), while the objective cure rate was similar (RR 1.06, 95%CI 0.97 to 1.17). At one year follow-up, there was no statistically significant difference in the mean IIQ scores for quality of life (-4.6; 95% CI: -7.5 to16.7).

There were no significant differences between the 2 groups for the duration of operation (RR -2.15, 95% CI -4.68 to 0.38), length of hospital stay (RR -0.03, 95% CI -0.37 to 0.30), or postoperative de novo urgency symptoms (RR 0.84, 95% CI 0.52 to 1.34). With the bottom-to-top approach, there were fewer bladder or urethral perforations (RR 0.55, 95% CI 0.31 to 0.98), less voiding dysfunction (RR 0.40, 95% CI 0.18 to 0.90), and fewer vaginal tape erosions (RR 0.27, 95% CI 0.08 to 0.95). There were no data reported on the need for further treatment.

3.1.8 RP MUS vs. Single-Incision Mini-Slings (SIMS) (Table 7e)

Single-incision mini-slings (SIMS) have emerged as an additional option for the woman with SUI. These procedures theoretically require minimal anesthesia and may be performed, in some instances, under local anesthestic. A recent systematic review and meta-analysis of SIMS and RP MUS procedures was published in the Cochrane Database. (171) Five studies were included, comparing TVT-Secur (n=X) to bottom-to-top RP MUS. No trials compared single-incision slings to top-to-bottom RP MUS. Four trials involved one type of mini-sling : TVT-Secur. One of the trials (Andrada Hamer 2012) was stopped at interim analysis (2 months) because of poor efficacy and high complication rates associated with the TVT-Secur. A total of 573 women were included (RPMUS n=281, vs. SIMS n=292). The meta-analysis reported no significant difference in patient reported cure rate when comparing SIMS with RPMUS (RR 1.38, 95% CI 0.55 to 3.46). RPMUS were associated with significantly higher objective cure rates when compared to SIMS (RR 4.44, 95% CI 2.06 to 9.56). Quality of life was statistically better in the PVS group. A shorter operation time was associated with SIMS (RR -17.33 95% CI -32.09 to -2.57) but there was no significant difference in the length of inpatient stay between the two procedures (RR -0.10 95% CI -0.69 to 0.49). SIMS had a higher risk of de novo urgency compared with RPMUS (RR 2.39, 95% CI 1.25 to 4.56).

There were no significant differences between the two groups for the other complications : operative blood loss (-16.60 95% CI -34.41 to -1.21), major vascular or visceral injury (RR 3.23 95% CI 0.13 to 77.90), vaginal wall perforation (RR 1.02 95% CI 0.07 to 15.89, not estimable), bladder or urethral perforation (RR 0.45 95% CI 0.15 to 1.38), urinary retention or need for catheterisation (RR 0.87 95% CI 0.38 to 1.99), infection related to use of synthetic mesh (RR 2.00 95% CI 0.22 to 17.89), vaginal mesh exposure (RR 1.37 95% CI 0.23 to 8.16), mesh extrusion into bladder or urethra (RR 0.76 95% CI 0.19 to 3.01), long-term pain (not estimable), dyspareunia (RR 2.90 95% CI 0.32 to 26.30), new-onset DO (RR 0.89 95% CI 0.13 to 5.98), repeat stress incontinence surgery (RR 2.34 95% CI 0.79 to 6.92) or need for any other additional or new surgical procedure to treat exposure (RR 1.18 95% CI 0.29 to 4.74). The authors concluded that the overall results demonstrated that TVT-Secur was considerably inferior to PVS slings for the treatment of women with stress incontinence. This product has already been withdrawn from clinical use. Six additional studies comparing TVT and SIMS were published since the last Cochrane review. (171) Five of them are randomised trials(172) (LE (Level of evidence) 3/4); (173) (LE 2) ; (174-176) (LE 2) ; and one was a retrospective trial (172).

Excepting the Ross et al. trial, which was small, all of these studies are in demonstrate inferiority of the SIMS procedures (Table 7e).

3.1.9 RP MUS vs. TO MUS (Table 7f)

A unique complication of the RP MUS procedures has been inadvertent puncture of PVS and, on occasion, intra-abdominal viscera or neurovascular structures. The most common organ punctured is the bladder and the rates of puncture have varied between 0.8% and 21 % in different studies (179). Two systematic registries on the rates of complications associated with the TVT operation have been published, one from Finland including the first 1455 operations performed nation-wide and one from Austria including 2795 operations (106, 180). The rates of bladder perforation were 3.8% and 2.7%, respectively. In an effort to minimise the incidence and morbidity of bladder injuries, Delorme in 2001 introduced a modified tape procedure in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramina on both sides ('outside-in')(181). De Leval further modified the outside-in TO MUS procedure to be an 'inside-out' procedure, now called the tension-free vaginal tape-obturator (TVT-O)(182).

The comparison between the PVS and TO MUS procedures has been the subject of numerous publications over the last few years. ICI-5 reported the results of 2 Cochrane systematic reviews(154, 156) . The two reviews did not show any difference for the subjective cure rate between the two procedures. However, the objective cure rate was significantly higher when using the PVS route(154). Moreover, in one of these reviews [48], a statistically significant difference in favour of TVT was shown when comparing objective continence rates between TVT and inside-out TO MUS (OR: 0.71; 95% CI OR: 0.52 to 0.96; p= 0.03), whereas no difference was found comparing TVT to outside-in TO MUS (OR: 0.90; 95% CI OR: 0.66to 1.22; p= 0.51). Sensitivity analyses limited to studies of higher methodological quality showed only a nonstatistically significant trend in favour of TVT with regard to objective cure rate (OR: 0.74; 95% CI OR: 0.54 to 1.01; p= 0.05).

With regard to complications, bladder or vaginal perforations, and postoperative haematoma were significantly more common following RP MUS (156). The rates of vaginal extrusion were slightly higher following TO MUS in one of these reviews(156), possibly due to the use of ObTape, a device removed from the market due to a high risk of erosion and extrusion,however, there were no statistically significant differences in the second review (154).

There was no significant difference between the 2 groups in the need for repeat incontinence surgery, postoperative DO, de novo urgency and urgency incontinence(154, 156). There was a significantly higher occurrence of groin pain (12%) in women with a TO approach compared with a higher incidence of suprapubic pain in women with a PVS sling. However, postoperative voiding dysfunction occurred significantly less frequently in the TO route group (4% versus 7%, RR 0.63, 95% CI 0.44 to 0.89) in one of these reviews(156) but with no difference noted in the second one(156).

In ICI-5, one other RCT trial compared PVS and TO MUS(149). This was a multicentre, randomised equivalence trial with the primary outcome being objective and subjective success at 12 months. A total of 597 women were randomly assigned to a study group and 565 (94.6%) completed the 12-month assessment. The objective and the subjective cure rates were significantly higher in the RP group. The rates of voiding dysfunction requiring surgery was higher in the RP group (2.7% versus 0% ,p = 0.004) and the rate of neurological symptoms were higher in the TO group (4.0% versus 9.4%, p = 0.01). There were no significant differences between groups in postoperative urgency incontinence, satisfaction with the results of the procedure, or quality of life. Thus, the success rates met the predetermined criteria for equivalence of the 2 procedures. [EL=1]

In ICI-5, numerous additional, non-randomised trials published in peer-reviewed literature. [100-118] The majority of these concluded that there is no statistically significant difference in subjective or objective outcome measures between PVS and TO MUS procedures. As concluded in the RCTs, postoperative complications are more common in the RP MUS group. [EL=3/4]

A recent Cochrane systematic review and meta-analysis of mid-urethral sling operations compared TO MUS and RP MUS(163). Fifty-five trials with a total of 8652 women were included, with a sample size ranging from 20 to 597. The meta-analysis reported non-significant differences in subjective cure rate at 12 months (RR 0.98, 95%CI 0.96 to 1.00) ranging from 62% to 98% in the TO MUS group, and from 71% to 97% in the RP MUS group. Short-term objective cure was similar in the 2 groups (RR 0.98, 95% CI 0.96 to 1.00). Long-term subjective cure was also similar between the groups (RR 0.95, 95% CI 0.80 to 1.12).The rate of bladder perforation was lower after TO MUS compared with RP MUS (RR 0.13, 95% CI 0.08 to 0.20). Major vascular/visceral injury (RR 0.33 95% CI 0.19 to 0.55), mean operating time (RR -7.54 95% CI -9.31 to -5.77), operative blood loss (RR -6.49 95% CI -12.33 to -0.65) and length of hospital stay (RR -0.25 95% CI -0.59 to -0.09) were lower with the TO approach. Postoperative voiding dysfunction was less frequent following TO MUS (RR 0.53, 95% CI 0.43 to 0.65). There were no significant difference in de novo urgency and urgency urinary incontinance between the 2 groups (RR 0.98, 95% CI 0.82 to 1.17). Groin pain was higher in the TO MUS group (RR 4.12, 95% CI 2.71 to 6.27) whereas suprapubic pain was lower (RR 0.29, 95% CI 0.11 to 0.78); both being of short duration. There was no significant difference in vaginal tape erosion/exposure/extrusion (RR 1.13, 95% CI 0.78 to 1.65) or bladder or urethral erosion (RR 0.34, 95% CI 0.01 to 8.13) between the 2 groups.

Repeat incontinence surgery in the long term was more likely with the TO approach as compared to PVS. (RR 8.79, 95% CI 3.36 to 23.00). At 24-month follow-up, there were no significant differences in sexual function or in dyspareunia between the two groups.

Ten additionnal RCTs compared PVS and trans-obturator approaches(183) (LoE (Level of evidence) 1), (184) (LE 1), (185) (LE 1), (186) (LE 3), (187) (LE 3), (188)(LE 3), (189)(LE 1), (190) (LE 3), (191) (LE 1) and (192) (LE 2)). There was no significant difference between the objective and the subjective cure rates in these studies. In Albo 2012, 253 women underwent TVT and 263 TO. At 24 months, the subjective (55.7% versus 48.3%, 95% CI for difference of 7.4% : -0.7, 15.5%) and the objective cure rates (77.3 versus 72.3%, 95% CI for difference of 5.1% : -2.0, 12.1%) were similar. In another study, Bellaster included 24 women in the TVT group and 37 in the TO group. There was no difference for the subjective cure rates between these groups.

In Costantini 2016, there were no differences for the objective cure rate. The Kaplan–Meier survival curve showed that the continence rate decreased for up to 25 months after surgery, with stabilisation thereafter for the TVT group while continuing to drop in the TO MUS group, with no inter-group difference. The patients in both groups were highly satisfied at long-term follow-up. The Brennand 2015 study is subset of original RCT by Ross 2009. TO and RP MUS were grouped together in this analysis. The probability of objective cure remained significantly higher for non-obese women than obese women (p=0.018, RR 1.26, 95% CI 1.04–1.52), after controlling for MUS type. Surgery type was not significantly associated with cure (p=0.492, RR 0.95, 95% CI 0.83–1.10). In Kenton 2015, the authors made a per protocol analysis; RP MUS treatment success rate was 7.9% greater than TO MUS (95% CI -1.4 to 17.2), and did not meet the prespecified criteria for equivalence of 12% in the original trial or 15% in the current study. However, the CI included 0%, indicating that success rates also cannot be considered different from one another. Treatment failures were primarily due to SUI symptoms only, while others were due to SUI symptoms and surgical retreatment, as well as surgical retreatment only.

Cavkaytar 2015 is a non-randomised, prospective observational study; in both groups, postoperative Q-tip values were significantly reduced, but postoperative urethral mobility was more frequent in the TO MUS group. In Bohlin 2015, authors conducted an observational study; pre-, peri- and postoperative (8 weeks and 1 year) data were retrieved from the Swedish National Register for Gynecological Surgery of MUS procedures (PVS procedures, n=4.539; TO procedures, n =1.769) performed between January 2006 and December 2011; multiple logistic regression analyses were performed between the outcome variables and BMI and smoking, presented as adjusted odds ratios (adjOR) with 95 % CI; subjective 1-year cure rate was 87.4 % for all MUS procedures (88.3 % with the PVS technique and 85.2 % with the TO technique (p=0.002); preoperative daily urinary leakage and urgency were more common with increasing BMI, but surgery reduced symptoms in all BMI groups; lower cure rate was seen in women with a BMI >30 (0.49; CI 0.33–0.73), in diabetics (0.50; CI 0.35–0.74) and women aged>80 years (0.18; CI 0.06–0.51); perioperative complications were more common in the PVS group (4.7 % vs 2.3 % in the TO group, p=0.001) and in women with BMI<25. Smoking did not influence any of the outcome variables.

Jeong 2014 was a retrospective study; when dividing women by the route of approach, the success rates in the TO approach became worse with increasing BMI (P=0.037, linear by linear association), while those in the RP approach were not different according to the BMI groups (P=0.06, linear by linear association); the satisfaction rates were not different among the BMI groups in either approach; in the multivariate logistic regression models, only the presence of preoperative MUI (clinically-defined) was identified as a risk factor for treatment failure in all patients.

Laurikainen 2014 is a 60-month update of Palva K, Rinne K, Aukee P, et al. There were no differences between the groups (TVT and TVT-O). In the Zyczynski 2014 study, there were no statistical differences in the objective and the subjective cure rate. The total incidence of complications was 13.4% for the TVT, 9.3% for the TO MUS and 8.6% for the modified TO MUS (sig higher for TVT)(190)

Summary

RP MUS has demonstrated equal or superior efficacy compared to other procedures for female SUI (LE=1/2).

RP vs. colposuspension:

RP MUS is at least as effective as open colposuspension in the short and medium term, and may be superior to laparoscopic colposuspension although most studies are small and underpowered (EL=1/2). Overall the rate of complications of RP MUS and colposuspension are similar between procedures. However, the rates of specific complications (e.g. bladder perforation, need for subsequent POP surgery, etc.) differ between the procedures. RP MUS is associated with a shorter operative time and hospital stay. (EL=1/2)

RP MUS vs. TO MUS:

Overall, PVS and TO MUS procedures perform equally at a short term follow-up of 6 to 12 months. (EL= 1/2). There are insufficient data to make conclusions regarding the long term comparable efficacy of these procedures.

Key:

MUS: midurethral sling; **N**: number; **F/U**: follow-up; **AEs**: AEs; **TO MUS**: transobturator midurethral sling; **m**: months; **y**=years; **med**: median; **VLPP**: valsalva leak point pressure; **UTI**: urinary tract infection; **PVR**: post-void residual; **MUI**: mixed urinary incontinence; **SUI**: stress urinary incontinence; **KHQ**: King's Health Questionnaire; **BMI**: body-mass index.

1. Two types of outside-in TO MUS used: Heine Medizin® urethral support system, Germany, and I-STOP® CL Medical, France.
2. Safyre T®, Promedon, Argentina.

The rate of complications, including bladder puncture postoperative voiding dysfunction, and haematoma formation are higher for the RP MUS as compared to the TO approach whereas thigh discomfort is more common with the TO approach. [EL=1/2]. The overall rate of vaginal MUS erosion is no different between these techniques. (EL=1/2)

Surgical approach for RP MUS (top-down vs. bottom-up):

RP MUS appears to be somewhat more efficacious when being placed from 'bottom-up' as compared to an 'top-down' approach (LE=2). But only limited long term "up-down" data exists (LE=2) Intraoperative and postoperative AEs are less common with the 'bottom-up' approach. (EL=1/2)

Recommendations

RP MUS is recommended as an effective and durable treatment for stress urinary incontinence. [Grade A]

3.2. TO MUS

Owing to trocar passage through the PVS space, inadvertent puncture of PVS and, infrequently, intra-abdominal viscera or neurovascular structures comprises a unique complication of the PVS slings, and RP MUS in particular. (106, 219-221)

In an effort to minimise the incidence and morbidity of bladder injuries, a novel modified MUS procedure was introduced in which the tape was brought to support the mid-urethra from inside the thighs through the obturator foramina bilaterally (181). De Leval further modified the outside-in TO MUS procedure to be an inside-out procedure, now called the tension-free vaginal tape-obturator (TVT-O™; Gynecare, Ethicon, Somerville, NJ, USA)(182).

The materials used for TO MUS have continued to be modified to decrease risk of erosion, extrusion and infection. Today, nearly all of the commercially-available synthetic TO MUS products are made of Amid type I polypropylene mesh and have an extrusion and erosion rate well below 5%.

The TO technique has since gained immense popularity, owing to its reproducible results and low rates of complications. The "outside-in" and "inside-out" methods of insertion continue to be the major division in the classification of surgical outcomes and complications.

3.2.1 Long-Term Outcomes of TO MUS

Long-term outcomes are rapidly emerging for the TO MUS and several case series have reached mean or median follow-up periods ≥48 months (Table 8a).

Despite wide variations in objective and subjective definitions of success, both the outside-in and inside-out TO MUS are associated with good long-term outcomes (Level 3b/4). The conclusions should be interpreted with caution since all of the available data are from single-institution, retrospective cohort studies.

3.2.2 Trials Comparing TO MUS and Other Slings

A Cochrane systematic review recently compiled randomised controlled trials (RCT) comparing TO MUS vs. other procedures. (163) The review assessed 81 trials that included 12,113 women. The outcome analysis between the PVS and TO MUS is the most studied comparison of two procedures in the SUI literature. To minimise redundancy, the discussion of this comparison is covered in the section on RP MUS. Likewise, the comparison between TO MUS and single-incision mini slings (SIMS) will be covered in the section on SIMS. What follows is an evaluation of the existing literature comparing the TO MUS to other surgical procedures. Studies and analyses previously covered in ICI-5 will be summarized, while new literature will be covered in greater detail.

3.2.2.1 TO "Inside-Out" Approach vs. "Outside-In" Approach

Nine trials in the Cochrane review compared the inside-out approach with the outside-in approach. (209, 232-239) The study by Hassan et al. was reported only as an abstract, while the other eight trials were reported as full articles. An additional trial appeared in a trials registry, but, to date, there has been no additional information provided by the authors (240). Median sample sizes was 110 (range 74 to 341). Five studies included women with MUI [But and Faganelj, 2008; Lee et al., 2008; Abdel-Fattah et al., 2010; Park et al, 2012; Scheiner et al., 2012], and two trials included women who had undergone previous incontinence surgery [Abdel-Fattah et al., 2010; Scheiner et al., 2012]. The trial by Scheiner et al. included women with POP as well as women undergoing concomitant pelvic surgery. Median follow-up was 12 months (range 3-36 months). The outcomes of the initial trial by Abdel-Fattah et al. (235) have since been updated in several additional reports. (241-246) The most recent Cochrane review has added an additional five trials to the previous version, that included four trials of small size

3.2.2.1.1 Objective and Subjective Outcomes

There were no statistically significant differences in either short-term (≤12 months) subjective cure rates (6 studies, 759 women; RR 1.0, 95% CI 0.96 to 1.06) or subjective cured and improved rates (5 studies, 732 women; RR 1.02, 95% CI 0.97 to 1.08). Similarly, there were no statistically significant differences in either medium-term subjective cure rates (2 studies, 235 women; RR 1.06, 95% CI 0.91 to 1.23) or subjective cured and improved rates (2 studies, 399 women; RR 1.00, 95% CI 0.90 to 1.11). No trials have thus far published long-term data. There were no statistically significant differences in short-term objective cure (6 studies, 745 women; RR 0.99, 95% CI 0.95 to 1.04) or cured plus improved rate (RR 1.00, 95% CI 0.95 to 1.07) between the two groups.

In a recently-published, secondary analysis of a single-blind RCT, 83 of 341 women (24%) with MUI were randomised to outside-in (Aris®, Coloplast, Denmark, n=42) or inside-out (TVT-O, n=41) TO MUS (247). The primary outcome was patient-reported success rate, defined as very much improved/much improved on the Patient Global Impression of Improvement (PGI-I), while secondary outcomes included improvement in QoL, impact on preoperative urgency/UUI, and repeat surgery for SUI. A total of 66 women completed 3-year follow-up. The patient reported success rate was 73.8% with no significant differences between the groups (OR 1.035, 95% CI 0.342-3.134, p=0.951). Overall, 34 (50.1%) and 26 women (56.5%) reported cure of preoperative urgency/UUI, respectively, while 52 women (86.7%) had a clinically significant improvement in QoL (≥18 points in total Kings Health Questionnaire (KHQ) score) compared to baseline. In each group, two women underwent further continence surgery.

A recent systematic review and meta-analysis of inside-out vs. outside-in TO tapes summarised five RCTs and three cohort studies (248). As in the Cochrane Review, there was no significant difference in short-term subjective cure/improvement (OR 1.25, 95% CI 0.78 to 1.99, p=0.35) or in objective cure/improvement (OR 1.66, 95% CI 0.8 to 3.43, p=0.17) between the two groups. Meta-analysis of cohort studies confirmed similar results.

3.2.2.1.2 Perioperative and Postoperative Complications

There were no statistically significant differences between the two groups in terms of: duration of operation in minutes, (4 studies, 481 women; MD 0.52, 95% CI 1.09 to 2.13); operative blood loss in mL (3 studies, 255 women; MD 1.11, 95% CI -6.01 to 8.22); length of hospital stay in days (2 studies, 190 women; MD -0.77, 95% CI -2.54 to 0.99); and, time to return to normal activity in weeks (1 study, 100 women; MD -0.60, 95% CI -1.80 to 0.60). The following table summarizes the perioperative and postoperative complications from the Cochrane Review (Table 8)(163).

As in the Cochrane Review, Madhuvrata et al. concluded that vaginal angle injuries (vaginal perforation) were significantly higher with the outside-in route (OR 0.14, 95% CI 0.05 to 0.41, p=0.0003), while groin/thigh pain (OR 1.42, 95% CI 0.94 to 2.13, p=0.10) and de novo urgency (OR 1.46, 95% CI 0.63 to 3.36, p=0.38) were not significantly higher with the inside-out route. [35] Meta-analysis of cohort studies confirmed these findings.

3.2.2.1.3 Impact on QoL

Five of the ten trials in the Cochrane Review assessed QoL using validated questionnaires(163). In the trial by Houwert et al., there was significant postoperative improvement in IIQ-7 and UDI-6 scores compared to scores obtained preoperatively within each group, but no significant postoperative differences between the two groups (42 women; MD 16.54, 95% CI 4.84 to 28.24)(209). But and Faganelj assessed QoL with IIQ and UDI questionnaires and visual analog score (VAS), but reported no results(232). Lee et al. used a validated Korean version of the Incontinence QoL (I-QoL) and showed improvements within the groups, but with no significant postoperative differences between the groups(233). Scheiner et al. used the KHQ and found no significant difference between the groups at baseline and postoperatively, but noted improvement following surgery compared to baseline scores in all domains(238). Abdel-Fattah et al. used the KHQ, Birmingham Bowel and Urinary Symptoms Questionnaire, Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ-12), PGI-I and the short form of the ICIQ to assess QoL(235). Overall, there was statistically significant postoperative improvement in total scores, as well as in each of the nine domains of the KHQ. There was no significant postoperative difference in any of the QoL scores between the two routes.

Table 8b: Perioperative and postoperative complications (from Cochrane)

Category	Incidence	# Studies	N	RR	CI	Significant
Vaginal Perforation	7.39%	3	541	0.25	0.12-0.53	Yes: less w/inside-out
Voiding Dysfunction	5.53%	8	1121	1.74	1.06-2.88	Yes: less w/outside-in
Overall Perioperative Complications		2	214	1.30	0.23-7.51	No
Major Vascular/ Visceral Injury		4	622	0.71	0.23-2.19	No
Bladder Perforation		6	794	0.38	0.07-1.92	No
De Novo Urge/ UUI		3	357	1.01	0.46-2.20	No
Detrusor Overactivity (DO)		1	114	0.87	0.27-2.84	No
Vaginal Extrusion		7	1087	0.42	0.16-1.09	No
Groin/Thigh Pain	9.2% vs. 8%	6	837	1.15	0.75-1.76	No

Key: N: number of patients; RR: relative risk; CI: 95% confidence interval

3.2.2.1.4 Impact on Sexual Function

Three trials in the Cochrane Review evaluated postoperative sexual function following inside-out and outside-in TO MUS(163, 209, 235, 237). There was significant improvement in PISQ-12 scores following

surgery (improved sexual function compared to baseline), but no significant difference between the two groups at follow-up. Rates of de novo dyspareunia following surgery were extremely low, with evidence of symptom resolution by 24 months of follow-up.

Several recent retrospective cohort studies have added to the information available regarding postoperative sexual function in these women. Forty-eight of the 62 women returning a follow-up questionnaire following inside-out or outside-in TO MUS were sexually active before and after surgery(249). The frequency and appreciation of intercourse, extent of sexuality, and the frequency of leakage during intercourse were not significantly different after surgery. Fifteen women (31.2%) reported an improvement in intercourse satisfaction while five (10.4%) complained of sexual function deteriorating after the TO MUS. Of the 62 women, ten (16.1%) were dissatisfied with the surgical outcome because of persistent or recurrence of SUI (6) and a deterioration of intercourse satisfaction after surgery (4). Partner discomfort remained unchanged. Narin et al. administered the self-reported libido scoring system (LSS) in 59 sexually-active women preoperatively and six months after outside-in TO MUS(250). Two parameters of the LSS, orgasm and who starts the sexual activity, increased at a statistically significant rate following surgery. Kamalak et al. used the Female Sexual Function Index (FSFI) in 30 women before and three months after TO MUS(251). There was a statistically significant improvement in libido (desire), arousal, lubrication, orgasm and satisfaction. A reduction of urinary leakage during sexual activity was also seen.

Finally, the Nine Questions Regarding Sexual Functioning (NSF-9) questionnaire was administered before TO MUS to 34 sexually active women and repeated at the 3-month, 6-month, 12-month follow-up visits and annually thereafter (252). Scores in all domains of sexual function were significantly improved after surgery. The frequency improved in 24 women (70.5%), lubrication improved in 12 (57.1%), orgasm improved in 21 (67.1%), pain improved in 14 (70%), and, in leaking patients, sexual satisfaction improved in 85.7%, while in non-leaking patients improvement was seen in 40%. Sexual relations were not satisfactory in 26 women (76.4%) before surgery; however, of these, 21 (80%) had improved sexual satisfaction after surgery. De novo urgency and dyspareunia developed in one and two patients, respectively.

Summary

Ten RCTs in the Cochrane Review totaling 1199 women compared the TO inside-out approach with the outside-in approach (Level 1/2). Evidence from the ten trials, two of which reported medium-term data, showed no significant difference between the two approaches in regards to objective and subjective cure and cured/improved rates. Likewise, the rates of the majority of perioperative and postoperative variables and complications were not significantly different between approaches. The only exceptions were voiding dysfunction, where higher rates were reported in the inside-out group, and vaginal perforation, which had higher rates in the outside-in group. Despite this, there was no resultant increase in the rate of tape erosion. Postoperative improvement in QoL and sexual function was observed with each approach, regardless of the outcome measure employed. The addition of a contemporary update of one of the RCTs (247) and several cohort studies has not served to alter these conclusions.

Recommendations

Since both approaches (outside-in and inside-out) to TO sling are associated with similar outcomes and overall incidence of AEs, the choice of surgical technique in those individuals undergoing a TO MUS should be based on other factors such as professional judgement and experience.. Grade A/B

3.2.2.2 TO MUS vs. BN PVS

A Cochrane Review identified two trials in which a TO MUS was compared with a traditional BN sling (1). Silva-Filho et al. randomized 20 women to aPVS or Safyre outside-in TO MUS(61). The Safyre consists of a polypropylene suburethral portion held between polydimethylsiloxane self-anchoring columns. Pre- and postoperative quantification of the severity of incontinence and QoL was done by pad test and KHQ, respectively. While mean operating time (21.1 vs. 69.5 minutes; $p<0.001$) and hospital stay (28.8 vs. 44.4 hours; $p<0.001$) were shorter in the Safyre group, the postoperative pad test (39.4 vs. 8.4 g; $p=0.01$) was in favour of the autologous sling. Likewise, improvement in KHQ was significantly higher in the autologous sling group. Tcherniakovski et al. randomised 21 women to TO MUS and 20 patients to PVS sling(62). At 12 months of follow-up, the success rates were 90.5% (19/21) and 95% (19/20), respectively, with fewer overall complications observed in the TO MUS group.

In an additional retrospective cohort trial 203 women who underwent TO MUS were compared with 260 women who received autologous rectus fascia (ARF) slings (253). Both groups were statistically similar with regard to age, parity, BMI, number of previous gynaecological surgeries, and anti-incontinence therapies. After 12 months, women in the TO MUS group had a higher subjective efficacy rate compared to those in the ARF sling group (94% vs. 88%, $p<0.05$). However, this difference was no longer statistically significant at 24-month follow-up (88.7% vs. 84.6%, $p=0.20$). The TO MUS was associated with fewer overall postoperative complications (14.1% vs. 25.6%, $p<0.05$) and similar intraoperative complication rates (1.15% vs. 2.3%, $p=0.22$).

Summary

The available data from two small RCTs and a retrospective trial suggest that overall outcomes after autologous BN slings and TO MUS are similar (Level 2b/3) at short to medium terms. These conclusions should be interpreted with caution owing to the small numbers of women recruited in the RCTs.

Recommendation

The surgeon may offer either TO MUS or autologous fascial sling to the index patient. (Grade B/C)

3.2.2.3 One Method of TO MUS Insertion vs. Another (Via Same Route)

Five trials in the Cochrane Review compared different TO outside-in approaches (240): Monarc vs. TO MUS (254); TO MUS vs. adjustable TO MUS(255); TO MUS vs. TO MUS with two-point fixation sutures (256); and, synthetic TO MUS vs. biological TO MUS(257, 258). Four additional trials compared TO inside-out approaches: TVT-O vs. shorter TVT-O and less lateral dissection (259); TVT-O vs. TVT-O plus Ingleman-Sundberg (IS) bladder denervation procedure(260); TVT-O vs. TVT-O with less dissection (261); and, TVT-O vs. self-tailored TVT-O mesh (262).

Other than the synthetic vs. biological TO MUS comparison which was addressed in two small trials, the remaining comparison groups included only a single small trial. For all outcomes measured in each trial, there were no statistically significant differences reported, with the exception of the study by Juang et al. (260) In this study, 96 women with MUI were randomised to TVT-O plus IS (Ingleman Sundberg) (n=49) and to TVT-O alone (n=47). The primary outcome measure was objective assessment of surgical outcomes, and the secondary outcome measure was warning time. Objective cure rate was statistically in favor of TVT-O plus IS (84.8% vs. 62.8%; p=0.019). Furthermore, a significant increase in warning time was observed in the TVT-O plus IS group (from 3.9 to 9.4 min; p=0.006), but the increase in warning time within the TVT-O alone group was not statistically significant (from 4.3 to 4.5 min; p=0.695). The short-term objective cure rates between synthetic and biological TO MUS were not significantly different (RR 1.03, 95% CI 0.94 to 1.14). The trials by Paparella et al. and Tommaselli et al. revealed that the PISQ-12 scores decreased after the procedure in both groups, indicating improved sexual function after surgery. (257, 261) No significant differences were observed between groups after the procedures.

Two additional, retrospective cohort studies have addressed different TO MUS from the same approach. A hand-made outside-in MUS (polypropylene monofilament; n=41) was compared with a commercially-available, outside-in TO MUS (n=61) [Ciftci et al., 2015]. (263) Age, menopausal status, and BMI were similar for both groups. There was no significant difference in 1-year success rates between the groups (p=0.319); however, the rate of vaginal extrusion (p=0.016) was significantly lower in the commercially-available MUS group. Likewise, a self-created TO MUS (SCTOT; n=67) was compared with the standard, industrially-created TO MUS (ICTOT; n=47) (264). The IIQ-7, UDI-6, ICIQ-SF, and OAB symptom score (OABSS) were recorded. Cure was defined as a negative CST and no need for additional surgery. At 18-month follow-up, objective cure was achieved in 56 women (83.5%) in the SCTOT group and in 40 women (85.1%) in the ICTOT group (p>0.05). There was a significant improvement in IIQ-7, UDI-6, ICIQ5-SF, and OABSS in both groups. Improvement was better in the group with pure SUI than in patients with MUI, but this difference was not significant. The post-operative infection rates were 7-10% and not significantly different between groups. De novo OAB symptoms occurred in four women (5.9%) in the SCTOT group and three (6.3%) in the ICTOT group.

Summary

Despite several design or procedural modifications to TO MUS inserted via the same route, there was no difference in the efficacy, surgical outcomes or occurrence of AEs. These conclusions should be interpreted with caution owing to the small numbers of trials evaluating each comparison and short term follow-up. (Level 2b/3)

3.2.2.4 Other Materials Used for TO MUS

Linder and Elliott evaluated 33 consecutive women that underwent autologous rectus fascia TO MUS. (265) Patients were seen at three months postoperatively and mailed a questionnaire at least one year after surgery for further follow-up. Outcomes were measured by ICIQ-FLUTS. When isolated sling placement was performed, 88% (15/17) were outpatient procedures. Median follow-up was 14.9 months (IQR 3.6, 18.7), during which five patients underwent repeat anti-incontinence surgery. For those without retreatment, 25/28 (89%) completed ICIQ-FLUTS at last follow-up. Compared to preoperative scores, patients who completed ICIQ-FLUTS questionnaires at 1-year or greater (n=18) showed significant improvement in all domains: frequency (p=0.007), voiding (p=0.02) and incontinence (p=0.004), and in QoL related to frequency (p=0.008), voiding (p=0.002) and incontinence (p=0.01). Among those who completed questionnaires both at 3-month and at least 1 year after surgery (N=17), there was no significant deterioration in ICIQ-FLUTS scores. Overall retreatment-free survival rate was 92% at 1 year. No patients suffered severe (Clavien III-V) complications or required sling release.

Sabadell et al. compared the efficacy and safety of polyvinylidene fluoride (PVDF) TO MUS to polypropylene (PP) MUS. (266) A PVDF sling was used in 23 women and a comparison group was randomly selected among all women treated with a PP sling in a 1:4 ratio (n=92). The median follow-up was 24.6 months in the PP group and 21.3 months in the PVDF

group. The survival functions showed a higher incidence of failures in the PP group, primarily because of obstructive symptoms. However, the differences were not statistically significant (HR of failure 4.31; 95% CI 0.56 to 33.05). Complication rates did not differ between the two groups; however, more cases of voiding dysfunction were observed in the PP group.

Summary

Little can be concluded regarding alternative materials for TO MUS slings from two, short term retrospective cohort studies. (Level 4)

3.2.2.5 TO MUS in Special Populations

Several risk factors for failure of anti-incontinence surgery, in general, have been assessed in the literature. Several of these (obesity, ISD, presence of MUI, and previous MUS failure) are addressed below in the context of TO MUS procedures.

3.2.2.5.1 Obese Women

Obesity, defined as a BMI≥30 kg/m^2, and its relationship to TO MUS outcomes has been evaluated in several studies. The results, thus far, have been mixed. Pereira et al. found no difference in 48-month, objective cure rates between obese (n=72) and non-obese women (n=96) undergoing TO MUS (95% vs. 95.8%, respectively). (231) The cumulative incidence of complications was, likewise, not significantly different between BMI groups. On the other hand, Heinonen et al. noted that women with BMI>30 kg/m^2 had significantly higher scores on the IIQ-7 (p<0.01), UDI-6 (p<0.01), VAS (p<0.001), UISS (p<0.01), and DIS (p<0.001), than those with BMI<30 kg/m^2. (224) Likewise, in the study by Jeong et al., success rates were lower for women with higher BMI measurements. (188) This was a retrospective assessment of 243 women, of whom 69.5% underwent one of three TO MUS procedures: TVT-O, Monarc, and SMESH (WooRhi Medical, Namyangju, Korea). The mean follow-up was 58.4 months (range 36-101) and 30.5% were of normal weight, 51% were overweight, and 18.5% were obese. It must be noted that the BMI cutoffs for the Asian population were used (normal weight (18.5-23 kg/m^2), overweight (23.1-27.4 kg/m^2), and obese (≥27.5 kg/m^2). Cure was defined as absence of subjective complaint of leakage and negative CST, while improvement was defined as rare subjective leakage and satisfaction, regardless of the CST. The cured/improved rates after the transobturator MUS decreased as BMI increased: 94.3%, 88.6%, and 78.6%, for normal weight, overweight, and obese groups, respectively (p=0.037). Notably MONARC is no longer commercially available as of 2016.

3.2.2.5.2 Intrinsic Sphincter Deficiency (ISD; Low MUCP and/or Low VLPP)

As with evaluating obesity as a risk factor for TO MUS failure, the findings for lower leak point or closure pressures have been inconsistent. In the study by Costantini et al., the overall objective cure rates (dry) were 74.4% for patients with VLPP>60 cm H_2O and 65% in those ≤60 cm H_2O (p<0.654). (222) The overall objective cure rates were 75% for patients with MUCP>40 cm H_2O and 68.6% in those ≤40 cm H_2O. Finally, the overall objective cure rates were 82.4% for patients with MUCP>40 cm H_2O and VLPP>60 cm H_2O and 69.2% in those with MUCP≤40 cm H_2O and VLPP≤60 cm H_2O (p<0.956). No significant differences were recorded for women with MUI. In a RCT comparing PVS and TO MUS from the same group, 95/145 (65.5%) of the patients had a VLPP>60 cm H_2O and the remaining 50 (34.5%) had a VLPP≤60 cm H_2O. (267) The objective cure rates were 75.8% for patients with VLPP>60 cm H_2O and 72% for those with VLPP≤60 cm H_2O (p<0.619). No significant differences in objective cure rates emerged when patients were stratified for preoperative VLPP and matched for either TO or RP MUS. Thus, no difference was seen for those with lower VLPP/MUCP compared to higher VLPP/MUCP.

Ryu et al. reported on 204 women who underwent TVT-O, with cure defined as absence of objective and subjective SUI. (268)[59] The numbers of women with Stamey grades I, II, and III were 99 (48.5%), 84 (41.2%), and 21 (10.3%), respectively. A total of 30 (14.7%), 87 (42.6%), and 87 patients (42.6%) had VLPP≤60, 60<VLPP≤90, and VLPP>90 cm H_2O, respectively. Preoperative VLPP was not significantly different according to preoperative I-QoL or change in I-QoL after surgery; however, I-QoL after surgery improved in patients with a high preoperative Stamey grade (p=0.001). In this study, VLPP was not a factor related to surgical outcome from the MUS; however, Stamey grade was important for predicting subjective QoL and improved incontinence-related QoL after surgery.

On the other hand, at a mean follow-up of 8.1 (range 6-12) months after a Monarc MUS, 56/70 (80%) women with urodynamically diagnosed SUI and urethral hypermobility were continent based on a CST and subjective report (269). The median VLPP at 150 mL (VLPP150) in the failures and successes was not different (p=0.12). However, the median VLPP at cystometric capacity (VLPPcap) in the failures was 32 cm H_2O vs. 71 cm H_2O in the successes (p<0.001). Also, the median MUCP in the failures was 20 cm H_2O and 45 cm H_2O in the successes (p<0.001). No correlation existed between the degree of urethral hypermobility, as measured by the cotton swab test, and surgical success (p=0.17). Using a combined model, the cutoff values of VLPPcap >60 cm H_2O and MUCP >40 cm H_2O were the most predictive of surgical success, revealing a sensitivity of 83% (0.55, 0.95) and specificity of 79% (0.67, 0.88).

3.2.2.5.3 Recurrent SUI

From a multivariate analysis of potential preoperative risk factors for failure of TO MUS, Abdel-Fattah et al. found that a history of previous incontinence surgery was the only independent risk factor based both on

the patient-reported and objective outcome. (235) Van Baelen and Delaere reported retrospectively on 21 women who underwent repeat TO MUS procedure after failed MUS treatment (TVT in five, TO MUS in 16). (270) At a mean of 16 months, physician-determined cure and improvement were achieved in 55% and 15% of patients, respectively. Subjective cure and improvement based on the ICIQ was seen in 53% and 5%, respectively. Additionally, a Cochrane Review attempted to summarize the data regarding different types of MUS procedures for recurrent SUI after failure of primary surgical therapy. (271) Twelve studies were identified, but all were excluded from group analysis because they did not meet eligibility criteria. Thus, there were no data to recommend or refute any of the different management strategies for recurrent or persistent SUI after failed MUS surgery.

While there are sparse data to support or refute the use of TO MUS in recurrent SUI, recent surveys suggest that this approach may not be the reoperative procedure of choice for female pelvic medicine subspecialists. A pretested, web-based survey designed to explore assessment and surgical management was sent to IUGA members. (272) A total of 385 participants opened the survey and 331 eligible responses were obtained. The type of previous surgery, urodynamic findings, and surgeon's preference/experience were considered to be the most important factors in choosing the type of surgical management. RP MUS was the preferred surgical option in most of the clinical scenarios with urethral bulking agents being more popular in the absence of urethral hypermobility after a failed RP MUS.

Likewise, a recent update of two UITN trials suggests that any MUS, in general, may not be preferred in cases of recurrent SUI.(273) A secondary analysis of the SISTEr and ToMUS trials compared the retreatment-free survival rates by initial surgical procedure. Half of the women in the SISTEr trial met inclusion criteria for this analysis (329/655, 174 Burch and 155 fascial sling), as did 444/597 (74%) of subjects in ToMUS (221 TO MUS (TMUS), and 223 RP MUS (RMUS). Types of surgical retreatment included autologous fascial sling (19), bulking agent (18), and synthetic sling (1). Five-year retreatment free survival rates (and standard errors) were 87% (3%), 96% (2%), 97% (1%), and 99% (0.7%) for Burch, autologous fascial sling, TMUS, and RMUS groups respectively ($p<0.0001$). In these cohorts, 6% of women after standard anti-incontinence procedures were retreated within five years, mostly with injection therapy or autologous fascial sling. Not all women with recurrent SUI chose surgical retreatment.

3.2.2.5.4 Women with MUI

Although Jeong et al. found that cured/improved rates after the TO MUS decreased as BMI increased, in their multivariate model, only the presence of preoperative MUI was proven to be the risk factor for treatment failure after the TO approach (OR 6.39, $p=0.003$). (188) The percentage of women with MUI was higher in obese women than in non-obese women undergoing the TO MUS. However, it also appears that OAB symptoms improve after the TO MUS. Habibi et al. evaluated 87 women with stress-predominant MUI one year after undergoing TVT-O. (274) Prospective assessment included 3-day bladder diary, Urgency Perception Score (UPS), ICIQ-FLUTS, and IIQ-7. At 1-year follow-up, subjective cure of SUI was 78% and significant point improvements (vs. baseline) in mean daily pad use (2.5 to 0.9, $p<0.05$) and mean incontinence episodes (3.6 to 0.7, $p<0.05$) were seen. Mean questionnaire scores for UUI significantly improved from 2.0 to 1.0 ($p<0.001$), with 32% and 31% of patients reporting cure and improvement of UUI, respectively. Similarly, mean UPS score improved from 10.1 to 6.7 ($p<0.001$). Eighty-two percent of the women did not require anticholinergics over the 1-year follow-up period and urgency outcomes were associated with improvements in QoL.

Finally, Lee et al. evaluated OAB symptoms, especially nocturia, in 237 women with MUI after outside-in TO MUS. (275) Of these, 86 (36.4%) had preoperative nocturia. Women with neurogenic DO and those who were being treated with anticholinergics and antidiuretic hormones were excluded, leaving 70 subjects for analysis. TO MUS treatment resulted in an overall significant improvement in OAB symptoms including nocturia. Frequency-volume charts revealed that TO MUS treatment significantly decreased the actual number of nightly voids (ANV) and the nocturnal bladder capacity index (NBCi) in the entire cohort. However, in a subgroup of women with nocturnal polyuria, there was no significant change in ANV or NBCi after the sling operation. Correlation analysis of the whole cohort revealed that the postoperative changes in NBCi correlated positively with postoperative changes in ANV.

Summary (TO MUS in special populations)

Currently available data are insufficient to make conclusions regarding the utility of the TO MUS in the obese population, those women with ISD or MUI, or those undergoing reoperation for recurrent or persistent SUI after definitive MUS. (LE= 3/4) Likewise, no Level 1 data is available to recommend the TO MUS vs. other anti-incontinence procedures for these special populations.

Summary

TO MUS demonstrates similar efficacy vs. other procedures (aPVS, colposuspension, RP MUS, SIMS) at short to medium term (LE= 1/2) however long term RCT data are lacking vs. these procedures.

Both approaches (outside-in vs. inside-out) to TO MUS are associated with similar short/medium term efficacy outcomes. (LE=1) However, vaginal wall perforation is higher with the outside-in approach and voiding dysfunction is higher with inside-out approach.

Recommendation

TO MUS may be offered as an effective treatment for SUI with appropriate counseling regarding its current limitations including unique AEs, and limited long term RCT data regarding durability. (Grade B)

3.3. Single Incision Mini-Slings (SIMS)

The single incision mini slings (SIMS) have been developed in an attempt to further reduce the morbidity associated with continence surgery and to provide an outpatient or office procedure to treat PVS(276, 277). The blind passage of needles, during TVT and TO MUS procedures, through the PVS space or the obturator foramen respectively is associated with a small risk of vascular, nerve or visceral injury (278). The shorter SIMS is thought to minimise this risk while maintaining the efficacy of these predicate procedures. The concept of the single incision sling is not novel. Smith presented a small series of SIMS in 1987 using porcine dermis. However this was a xenograft sling procedure which demonstrated poor long term cure rates which could have been attributed to in-vivo degradation.

The first commercially available mid-urethral single incision sling, TVT-Secur (Gynaecare), was launched in 2006 with no published human trial data. However 5 of the 7 trials of TVT-Secur found it to be inferior to TVT or TVT-O. Several different outcome measures were reported in these 7 trials, making it difficult to compare the trials directly. Two of these trials were stopped prematurely following an interim analysis which demonstrated TVT-Secur results to be significantly less effective than the comparator MUS (Table 9). Hamer et al (279) also reported concerns about the morbidity associated with TVT-Secur. They reported three significant complications in 67 cases, one hemorrhage 1000ml, one urethral perforation and one perforation of the bladder. Based on these reports, TVT-Secur was withdrawn from the market by the manufacturer, having been shown to have poor clinical outcomes at the midterm follow-up (280). (Table 9)

In the meantime, additional SIMSs were launched with different anchoring mechanisms in the obturator foramen. All are made of type I polypropylene mesh however the length and anchoring mechanisms are variable. The method of insertion is either U shaped, inserted in the same manner as the TVT or the H "hammock" insertion of the TO MUS. Three trials compared MiniArc to MUS, two found no significant difference between MiniArc and obturator tapes however the third trial by Basu et al (281) reported a considerably worse outcome for MiniArc compared to TVT, 9 out of the 37 patients who underwent the MiniArc subsequently had a TVT (Table 2). Notably, MiniArc is no longer commercially available as of 2016.

After excluding RCTs evaluating TVT-Secur, updated meta-analysis of RCT comparing SIMS to standard MUS was reported by Mostafa et al. in 2014. A total 26 RCTs (n=3308) were included. There was no evidence of significant differences between SIMS and MUS in patient-reported cure rate (RR:0.94; 95% CI, 0.88-1.00) and objective cure rates (RR:0.98; 95% CI, 0.94-1.01) at a mean follow-up of 18.6 months (282).

Afterwards 8 more trials have been published including 1581 women (Table 10). Three RCTs compared MiniArc to MUS, 3 compared Ajust to MUS, 1 compared Fixation single incision sling to MUS and 1 compared to Contasure to MUS. Three RCTs of MiniArc found it to be not inferior to MUS and 3 RCTs of Ajust reported that there was no difference for subjective and objective outcome from MUS.

One of the reasons for the development of SIMS is to reduce the morbidity of continence surgery. Hence trial design should include an assessment of morbidity, including perforation, hemorrhage, chronic pain and voiding difficulty. The meta-analysis showed that SIMS had significantly lower postoperative pain (weighted means difference [WMD]: -2.94; 95% CI, -4.16 to -1.73) and earlier return to normal activities (WMD:-50.8; 95% CI, -9.59 to -0.56 and WMD: -7.20: 95% CI -12.43 to -1.98, respectively) (282). Recent RCTs (Table 2) also reported that there was no significant difference for postoperative complications and SIMS was superior with respect to postoperative pain.

Nambiar et al. (171) have published the Cochrane review of SIMS which will enable ongoing assessment of data. Due to the considerable variation in the anchoring mechanisms of each type of SIMS, data from one device cannot be extrapolated to another. Palomba et al. reported a 2014 update of their trial comparing three SIMS procedures at 24 months. Subjective cure rates were not statistically different between the Ajust, MiniArc and TVT-Secur and similar patients in each group received a second anti-incontinence procedure for SUI (174). There is a need for further RCT comparing with various SIMS.

Summary

Several trials report that SIMS (except TVT-Secur) are not inferior to standard MUS in the short to midterm (longest data 24-36 months). (LE=2) These procedures may be associated w/ less pain, but similar AEs compared to standard MUS. Rates of postoperative pain favor SIMS in the short-term, but appear to be similar with longer follow-up.

Recommendations

SIMS is an option for some individuals with SUI after appropriate counseling including the lack of long term RCT data (Grade B)

3.4. Other considerations with synthetic mesh: Host Response and the Risk of

Tumorigenesis with Polypropylene Mesh

While the United States Food and Drug Administration has stated in their 2013 report that the safety and efficacy of MUSs has been well established in clinical trials that followed patients for up to one year (299) some authors have questioned the potential for these materials to induce a harmful immunogenic, inflammatory and possibly malignant response in host tissues. (300, 301) Evaluation of the potential impact of implanted biografts is difficult to separate from the host's normal response to surgical wounding.

3.4.1 The Impact of Biografts on Wound Healing After Sling Placement

Any surgical incision or tissue trauma is associated with a normal cascade of events that is triggered in mammalian tissues as a response to the injury. Initially, a cascade of hemostasis, inflammation, proliferation, and remodeling will occur over time with the generation of scar tissue.(302) The quality of the scar tissue and its integration into the surrounding tissues will vary based on numerous host characteristics including the presence of pre-existing immunological disease, history of smoking, obesity, medications, age, and diabetes, among others. The presence of prolapse itself has been shown to potentially influence wound healing during vaginal reconstructive surgery. Jackson and colleagues(303) showed an association between prolapse and a reduction in total collagen and decreased collagen solubility with an increase in matrix metalloproteinase 9 activity leading to a fourfold increase in collagen turnover in those women with prolapse compared to controls.

With implantation of a polypropylene mesh sling, the normal healing cascade is impacted to some degree by the host's response to a foreign body with a separate cascade of seven overlapping phases including: injury, protein adsorption, acute inflammation, chronic inflammation, foreign body reaction, the formation of granulation tissue and encapsulation. It is now clear that the characteristics of implanted mesh may have a profound effect on the host's response to implanted materials, and more specifically, mesh used for vaginal reconstruction such as slings. Use of lightweight, loosely woven, monofilament, polypropylene sling mesh with large pores will be better incorporated into the vaginal and periurethral tissues than heavier weight multifilamentous mesh with small interstices. Pascual et al.(304) looked at the effect of pore size and mesh weight on collagen formation and the tensile strength of a healing abdominal wound. They compared four different types of polypropylene mesh and found that large pore, lighter weight mesh showed more rapid incorporation with Type III collagen and faster conversion to the stronger Type I collagen compared to heavier meshes. The most porous lightweight mesh achieved the greatest tensile strength in a short term model.

During the acute and chronic inflammation phase of the foreign body reaction, a matrix forms around the sling that is rich in cytokines, growth factors and chemoattractants. This leads to histamine-mediated phagocyte recruitment and mast cells coming into the wound along the graft. Their release of histamine and interleukin enhances neutrophil activity and then monocytes and lymphocytes become active in the chronic phase of inflammation and lead to the formation of foreign body giant cells.(305, 306) The cytokines and growth factors influence the activity of macrophages and fibroblast proliferation that leads to tissue ingrowth into the sling. Cytokine responses and leukocyte adherence from cells adhering to hydrophobic materials, like polypropylene, are more marked than when cells are in contact with hydrophilic materials.(307) Rechberger and colleagues(210) examined the affect of increased cytokines on the risk for sling exposure through the vagina. They found that women with mesh exposure had higher interferon levels preoperatively compared those women whose slings healed normally. These data suggest that pre-existing systemic inflammation may play an adverse role in wound healing after sling placement but that there is no evidence for an enhanced local inflammatory response leading to systemic immunological symptoms. Moalli and colleagues concluded that the foreign body reaction and inflammation surrounding polypropylene mesh implants is largely limited to the immediate area of the implant with no evidence for a systemic inflammatory response. Further knowledge of the influence of polypropylene on wound healing and the presence of risk factors for impaired wound healing will be important to further reduce the low risk of poor healing when polypropylene is used for anti-incontinence and prolapse surgery.

3.4.2 Tumorigenesis in Animals with Biografts

Tumorigenesis in laboratory animals after implant placement has been demonstrated. Ostergard and Azadi have questioned whether these animal data would extend to humans having polypropylene grafts implanted through the vagina. They present data on studies showing induction of sarcomas in mice with polypropylene coated transponder chips(308) and sarcomas induced in rats that had radiated polypropylene discs implants.(309) But Witherspoon et al. showed no tumor induction in mice over two years who had monofilament polypropylene hernia mesh implanted.(310) The absence of tumorigenesis following implantation of a loosely woven polypropylene mesh in a rodent model is likely due to the "Oppenheimer effect".

Oppenheimer showed that the surface characteristics of an implant are important in tumorigenesis. They showed that while inert materials (glass and inert metals) implanted as discs and sheets might induce sarcomas, the powder and porous forms of these materials woud not induce cancers in the same species. This would explain why smooth sheets and discs of polypropylene would induce sarcomas but polypropylene mesh would not. So while the WHO in 1999 listed smooth sheets of polypropylene as possibly carcinogenic (Category 2b), Williams stresses that at the Lyon meeting of the WHO many products were placed in the 2b category because there was no hard evidence that they were not carcinogenic and the WHO felt it was prudent to say that smooth sheets of polypropylene were possibly carcinogenic.(311) It has been suggested that a biofilm induced inflammatory response around an implanted polypropylene mesh sling might be an inductive factor in carcinogenesis. This might lead to genomic instability and mutagenesis. However, Weber et al. were unable to find any genomic instability in a rat model of animals with preneoplastic and neoplastic tumors.(312)

It is important to recognise that tumorigenesis in rodents is common and very rare in humans. Therefore,whether or not the processes that ultimately result in carcinogenesis in rodents are relevant in humans is unknown and suggesting that such a relationship exists is purely speculative. Moalli and colleagues bring up the potential absurdity of directly translating animal research data to human clinical care in referencing the article by Moore and Palmer in 1977, reported in the Journal of the American Medical Association entitled “Money causes cancer: ban it”.(313) They found that implanting metal coins into rats caused 60% to develop sarcomas within 16 months.

3.4.3 Tumorigenesis in Humans with Biografts

Peer reviewed scientific literature on the subject of mesh induced carcinogenesis in humans is lacking. Ostergard and Azadi stress that we may not be seeing associated malignancies in humans because the induction time for malignancy is quite long in humans and estimated to be 15 to 20 years- but may be as long as 40 years. This suggestion does warrant long term diligence but must be balanced against the clear advantages brought to the clinical arena in the last two decades by the MUS as compared to prior procedures for female SUI.

Williams, in his review, brings up data that shows that even when humans have been exposed to potential carcinogens, the risk for malignancy remains very low. For example, while product liability law suits in the later 20th century flourished asserting that silicone leaking into the breast tissue would be carcinogenic, careful scientific review has shown no greater incidence of cancer, death from cancer or negative impact on breast cancer survival in women who received these silicone implants.(314) Even Trilucent ™breast implants that had a filler of polyunsaturated fatty acids in a silicone elastomer shell did not induce cancers or any local or systemic markers of cancer. This was in spite of the fact that lipids had a tendency to degrade the silicone elastomer shell allowing some of the lipid filler to leak into the tissues. It is known that when these fatty acids undergo lipid peroxidation when exposed to body fluids that it leads to the formation of aldehydes, including malondialdehyde. The malondialdehyde is known to be mutagenic and carcinogenic in animals but no humans developed cancers in 4 years of study. This was in spite of peroxidation in the tissue.(315)

King et al(316) specifically examined the malignant potential of polypropylene MUSs in a single centre study of 2361 such slings performed at their institution between 2004 and 2013. With an average follow-up of 42 months and as long as 122 months they noted that 2 of the 2361 women had developed a single bladder and a vaginal cancer felt to be unrelated to the sling placement. The bladder cancer was a high grade urothelial cell carcinoma that occurred 4 years after a TO MUS with no bladder perforation. The vaginal cancer was anatomically separate from the sling at the apex and was associated with human papilloma virus. The overall incidence was 0%.

In 2014, Birolini et al.(317) reported on two cases of mesh-related squamous cell carcinomas of the abdominal wall associated with long term mesh infections for 6 and 24 years. The mesh was a polyester mesh and the authors concluded that it was the long term infection with poorly incorporated mesh that led to the evolution of these malignancies and that this was not related to the material. More recently, Lin et al(318) reported a case of clear cell carcinoma alongside an exposed midurethral polypropylene sling. She presented with retention 10 years after placement of an inside-out TO MUS. She had no history of intrauterine diethylstilbestrol. She initially had a tender and indurated anterior vaginal wall with a 1cm mesh exposure in the right vaginal sulcus and she had a mesh excision two weeks later. But two months after excision she was noted to have friable vaginal tissue under the distal 3 cm of the urethra. Biopsy revealed a poorly differentiated high-grade clear cell carcinoma. The authors considered that the inflammation caused by the sling exposure could have been related but recognise that there is nothing in the literature to support that mesh causes cancer in humans.

In an editorial comment on this case report, Dwyer reported another case of a squamous cell carcinoma proximate to a RP MUS discovered as a 3 cm paraurethral mass 14 months after placement of the sling.(319) These authors concluded that the exposed mesh was likely just an incidental finding in a patient with clear cell carcinoma. They remark that this is the first case in 20 years of MUSs where a malignancy has been found proximate to a MUS. Tens of millions of patients have undergone surgery with polypropylene mesh or sutures in the past 60 years without prior reports of, or an association with clear

cell cancer. Goldman and Dwyer also recognised that animal studies had only identified the potential for sarcomas. Williams suggests that with exposure in over 100 million humans to all types of implantable medical devices with more than a billion implant-years of observation one would expect that tumors would develop in proximity to the implant but the evidence to date does not support this(315).

Review of the literature shows that there is little evidence of an association between the implantation of polypropylene mesh MUSs and tumorigenesis in humans. The data also show that trying to extrapolate experimental data from rodents on inflammatory and oncologic induction in humans is misguided. While it is clear that we need to be vigilant in looking for cases of malignancy in subjects with implantable mesh we need to be careful not to frighten women who are considering having a MUS with excessive concern and anxiety about the neoplastic potential of these implants.

3.4.4 Degradation of Mesh in Vivo

Legal proceedings have suggested that polypropylene mesh may fracture in vivo and cause harm. This has been suggested because of the cracked appearance of explanted mesh. However, Ong and colleagues (320)have recently shown that this may be an artifact due to the formalin fixation process and inadequate mesh cleaning. Careful cleaning of the explanted mesh with distilled water, sodium hypoclorite and Proteinase K shows that cracked flaking material seen on explanted mesh was from inadequate cleaning and could be washed away leaving clean, smooth, unoxidized and non-degraded polypropylene fibers. Analysis of the flaking material shows it contains magnesium, phosphorous and calcium indicative of the adsorbed protein coating on the polypropylene and not disruption of the fibers themselves. The authors concluded that in vivo degradation of polypropylene mesh is a myth.

Summary

A causative relationship between the implantation of MUSs with loosely woven polypropylene MUSs and the development of systemic inflammation or aberrant host response has not been proven in humans. (EL=4)

A causative relationship between the implantation of MUSs with loosely woven polypropylene MUSs and the development malignancy (oncogenesis) has not been proven in humans.(EL=4)

Recommendation

The option of utilizing loosely woven polypropylene MUS for the treatment of SUI should NOT be limited or impacted by the risk of subsequent development of tumorigenesis or systemic inflammation (Grade D)

4. URETHRAL BULKING AGENTS

One of the mechanisms for stress continence is reliant on effective coaptation of the urethra during increases in intra-abdominal pressure. If the "watertight seal" is inadequate, SUI results. Urethral bulking agents are designed to address defective coaptation and may be injected either transurethrally or periurethrally in a retrograde fashion, using either direct cystoscopic, ultrasonographic, or implacer-guided device implantation. The procedure may be performed under local, regional, or general anesthesia. Device implantation optimally occurs in the mid- to-proximal urethra, and strategic planning for reinjection at some point after initial injection is warranted. Clinical trials have defined specific injection schedules (usually three injections) as part of trial therapeutic algorithms; however, the optimal injection technique has yet to be standardised.

4.1. Available Agents

Due to manufacturing cessation, bovine collagen (Contigen®) was already obsolete by the ICI-5 compilation. Its inclusion in this chapter is strictly as a comparison (control) group. Currently available agents include: calcium hydroxyl apatite (Coaptite®), carbon coated zirconium beads (Durasphere®), polydimethylsiloxane elastomer (PDMS; Macroplastique®), polyacrylamide hydrogel (PAHG; Bulkamid®), and Urolastic (Urogyn BV, Nijmegen, The Netherlands), a new bulking agent that consists of vinyldimethyl terminated PDMS, tetrapropoxysilane cross-linking agent, platinum vinyltetramethyl siloxane complex catalyst, and titanium dioxide radiopacifying agent. Additionally, limited data has been published regarding non-animal stabilised hyaluronic acid/dextranomer (NASHA-dx; Zuidex®). Polytetrafluoroethylene (Polytef paste) continues to be available in some International sites. In the Cochrane Review, women treated with NASHA-dx appeared to have significantly higher rates of injection site complications (16% with NASHA-dx vs. 0% with bovine collagen; RR 37.78, 95% CI 2.34 to 610) and this product has now been withdrawn from the U. S. market. (321) It remains available for injection therapy to address vesicoureteral reflux. Its inclusion in this chapter is for completeness only. Recent experience with adult stem cells for SUI treatment will be covered in the section "Stem cell technologies for SUI"

4.2. Outcomes

4.2.1 Cohort Studies

Mohr et al. reported a large series of 514 women treated with various forms of bulking therapy (bovine collagen, NASHA-dx, ethylene vinyl alcohol (no longer marketed,) and PAHG). (322) Outcomes were reported using standardized pad tests, visual analogue score (VAS) for severity of incontinence, and Kings Health Questionnaire (KHQ). Sixty-one

women were lost to follow-up. At one year post-implantation, pad testing was negative in 73.2% of women and there was statistical improvement in both pad weight and VAS for each of the agents used. Re-injection was permitted six weeks after initial injection.

4.2.2 Carbon-coated Zirconium Beads

No new studies of periurethral carbon-coated zirconium beads were located from ICI-5.

4.2.3 Calcium Hydroxyl Apatite

From 2011-2013, 60 women underwent one (30%), two (63%) or three (7%) periurethral calcium hydroxylapatite injections performed by a single surgeon. (323) Thirty-seven patients provided questionnaires and 38 provided pad counts, all with a mean age of 75 years. The overall American Urological Association Symptom Score (AUASS), AUASS QOL, and overall Michigan Incontinence Symptom Index (M-ISI) scores improved in 67.6%, 54.8%, and 61.3 % respectively (4.5 ± 7.9, 1.3 ± 1.7 and 5.5 ± 8.6 respectively). The M-ISI bother score improved in 44.8 % with a mean improvement of 0.5 ± 2.9, but did not reach significance. There was a 1.7 ± 3.7 decrease in the mean number of pads used daily after the procedure ($p = 0.006$) and 19 % experienced transient urinary retention.

4.2.4 Polydimethylsiloxane Elastomer (PDMS)

Ghoniem et al. evaluated the 24-month outcomes in women treated with PDMS in a multicenter study. (324) The participants were culled from a RCT comparing polydimethylsiloxane vs. bovine collagen (325), and included those women achieving initial treatment success (defined as ≥1 Stamey grade improvement 12 months from baseline). Outcome measures were Stamey grade, PGI-I, Physician Assessment of Improvement, 1-hour pad weight, Incontinence Quality of Life (I-QoL) scores, and safety assessment. At 24 months, 56 of 67 patients (84%) had sustained success from their 12-month visit, of whom 45 of 67 (67%) were dry (Stamey grade 0). Of the dry patients at 12 months, 33 of 38 (87%) maintained cure at 24 months. Also, 12 of 29 patients (41%) considered improved at 12 months were dry at 24 months. Overall I-QoL scores and all subscales showed statistically significant improvement from baseline ($p < 0.001$). Mean pad weight was 24 g at baseline and 4 g at 12- and 24-month follow-up. Patient and physician assessments rated 85% of patients dry or markedly improved 24 months after the last treatment.

Ghoniem and Miller performed a systematic review of the scientific literature from 1990 to 2010 to quantitatively summarise the safety and effectiveness of PDMS. (326) A total of 958 patients from 23 cohorts were eligible for inclusion and were analyzed. Random-effects models were used to estimate the improvement and cure rates following treatment at three time periods: short-term (<6 months), mid-term (6-18 months), and long-term (>18 months). Improvement rates were 75% [95% CI, 69 to 81] in the short-term, 73% (9 % CI, 62 to 83) in the mid-term, and 64% (95% CI, 57 to 71) in the long-term. Cure/dry rates were 43% (95% CI, 33 to 54), 37% (95% CI, 28 to 46), and 36% (95% CI, 27 to 46) over the same follow-up periods, respectively. Higher study reinjection rates were associated with improved long-term SUI outcomes. Safety events associated with injection included retention, irritative voiding symptoms, dysuria, and urinary tract infection.

4.2.5 Polyacrylamide Hydrogel (PAHG)

The use of PAHG in women with SUI or MUI has been reported in several recent cohort studies. At 12-month follow-up, 47 of 135 women (35%) underwent repeat injection (327). The overall subjective response rate was 66% and incontinence episodes per 24 hours decreased from a baseline of 3 to 0.7. Additionally, pad weight decreased from 29 g at baseline to 4 g at the end of the trial. ICIQ demonstrated overall improvement in QoL. At 24-month follow-up in this cohort, 64% maintained subjective improvement (vs. 67% at 12 months)(328). The overall decrease in incontinence episodes and pad weights, as well as improvement in QoL indices, remained stable from the 12-month evaluation.

From 2006 to 2011, 256 women underwent bulking with PAHG and were assessed at least annually with QoL and ICIQ questionnaires(329). Eighty-two percent reported cure/significant improvement at three months and the high satisfaction rate (via both VAS and ICIQ scores) was maintained at a median follow up of 38 months. There were no reported adverse reactions and no significant safety concerns.

In a single-centre, prospective study, 80 women with severe SUI had PAHG bulking between June 2010 and October 2011(330). Before and after treatment, QoL was assessed with the Patient Global Impression of Severity (PGI-S), ICIQ-SF, and PGI-I. At a mean follow-up of 18.6 ± 5.3 months, 60% of women had improvement and no patient had worsening of PGI-I after injection. The ICIQ -SF score improved from 17 ± 2.84 before injection to 13 ± 5.52 after surgery, with a significant 30% decrease ($P<0.00001$). The reinjection rate was 29%. The complication rate was 16% (17/108): 11 cases of transient postoperative retention, two cases of cystitis, and four episodes of dysuria. There were no abscesses or infection at the injection site.

Recently, 24 of 25 women who underwent PAHG injection eight years earlier were contacted (331). Fifteen had had no further treatment, seven underwent MUS placement, and two had been re-injected with PAHG. Eleven women attended for objective examination and all non-attenders were interviewed by telephone. In 44%, SUI was subjectively cured or much improved, with a positive outcome according to the KHQ. Objectively, all patients had visible PAHG deposits on vaginal ultrasonography. No local adverse

reactions were seen in the vaginal mucosa and the results of staged MUS were reportedly unaffected by previous bulking.

Finally, a systematic review of the MEDLINE (1966-2015), Scopus (2004-2015), POPLINE (1974-2015) and ClinicalTrials.gov (2008-2015) databases was performed to assess efficacy and AE profile of PAHG bulking (332). Observational studies, prospective, retrospective, and RCTs were included. Eight studies which enrolled a total of 767 women were included. In order to achieve adequate efficacy, 186/767 women (24.3%, range 12-35%) required reinjection. The most frequent adverse effects were pain at the site of injection (4-14%) and UTIs (3-7%). Both the number of incontinence episodes/24 h and the number of mL/24 h were significantly reduced one year following treatment. Likewise, QoL was significantly improved.

4.2.6 Vinyldimethyl-terminated Polydimethylsiloxane Polymer (VDM-PDMS)

A prospective, cohort study included 20 women who underwent VDM-PDMS periurethral injections under local anesthesia(333). The injection procedure was repeated after six weeks, when indicated. Patients were evaluated for efficacy and safety parameters at six weeks, three months, and 12 months after therapy. Thirteen patients (65%) received one injection each (overall average of 2.1 mL), while seven received a second injection. Nineteen women completed the 12-month follow-up. The mean Stamey grade significantly decreased from 1.9 at baseline to 0.4 at 12 months ($p<0.001$). While none of the patients were dry at baseline, 68% were dry at 12 months. The mean number of incontinence episodes significantly decreased from 6/day at baseline to 1.6/day at visit IV ($p<0.001$). Pad weight reduced from 20.2 g to 7.8 g at one year. The mean I-QoL score significantly increased from 51 at baseline to 76 at visit #4 ($p<0.001$). Six women (30%) developed minor complications related to the injection procedure.

The 19 women completing 12-month follow-up in the study above were invited for the 24-month follow-up study (334). Four of the 18 women who responded to the correspondence reported removal of the VDM-PDMS implant at another facility. The explanation for this removal was painful intercourse in one woman and less than optimal dryness in three. The overall objective improvement in continence status at 24-months was 66% compared to the 89% at the 12-month follow-up. The 1-hour pad weight test showed >50% reduction in pad weight in 66% of patients compared to 84% at the 12-month follow-up. AEs reported were UTI in one woman, local genital infection with erosion into the vagina in one, painful intercourse in two, and urgency in four.

4.2.7 Adjustable Continence Therapy (ACT®)

The ACT device consists of two balloons each attached to an injectable port placed in the labia majora. The port enables postoperative adjustment in balloon coaptation pressure.

A review of the PubMed database yielded eight studies that were published between 2007 and 2013. (335) The mean follow-up of these studies was 1-6 years. The mean age of the patients ranged between 62 and 73 years, and 40-100% of the patients had already been treated surgically for their SUI. A significant reduction in the number of pads used per day was observed after ACT(®) balloon placement, with improvement of short pad tests from 49.6 to 77.3 g preoperatively to 11.2-25.7 g after balloon placement. Fifteen to 44% of patients considered that their SUI had been cured, and 66-78.4% of the patients were satisfied with the result. No major complication was reported; however, the explantation rate was 18.7-30.8%. Quality of life was significantly improved.

More recently, a single-centre retrospective study reported on 52 women who underwent ACT balloon placement between 2000 and 2013, with 64.5% performed under local anesthesia. (336) Among these women, 35 (67.3%) had already undergone previous surgery for SUI. Clavien grade I-II early post-operative complications occurred in five (9.6 %) patients. Median follow-up was 10.5 months (IQR 3-24.25) with 11 women (21.1 %) lost to follow-up. At last follow-up, seven patients (13.5%) were subjectively continent after the first implantation and 13 (25%) had an >80% improvement rate (10 patients after first implantation, two after second implantation, and one after third implantation). Four patients (7.7%) found the procedure unsuccessful even after several consecutive implantations. Ten patients (19.2%) reported a partial result and were still having successive balloon inflations. Explantation occurred in 22 patients, caused by infection, erosion or balloon migration. In intention-to-treat analysis, the failure rate was 42.3%.

4.3. Method and Location of Injection

A Cochrane Review identified 14 trials (excluding one that was subsequently withdrawn from publication and not included in this analysis) including 2004 women; however, the Review has not been updated since ICI-5(321). The limited data available were not suitable for meta-analysis because they all came from separate trials. Trials were small and generally of moderate quality. The Cochrane Analysis concluded that there was no difference in periurethral vs. transurethral manner of delivery, although there was a non-significant trend towards higher early complications with periurethral injection. Additionally, weak evidence supports mid-urethral injection resulting in improved patient satisfaction compared to BN injection.

4.4. RCTs Comparing Bulking Agents

A RCT enrolling 247 women compared PDMS (n=122) and bovine collagen (control group; n=125) (325). Repeat injection was allowed at three months after initial delivery for persistent incontinence. Efficacy was determined at one year post last injection

using Stamey grade scoring, pad weight change, and Urinary Incontinence Quality of Life Scale. At one year post-treatment, 61.5% of women who received PDMS had improved by one Stamey grade vs. 48% of controls. The dry/cure rate at one year was 36.9% in the PDMS group vs. 24.8% in the control group ($p<0.05$). One hour pad weight change was 25.4 mL from baseline in the PDMS group vs. 28 mL in the control group ($p=0.64$). Both groups had improvement in QoL assessment (28.7% and 26.4%, respectively; $p=0.49$).

The Zuidex Study Group performed a prospective 2:1 randomised trial of NASHA-dx vs. bovine collagen in 344 women at 23 North American sites (337). Outcomes at 12 months from last treatment failed to demonstrate that NASHA-dx was equivalent to bovine collagen in the primary outcome, which was the proportion of women who achieved a 50% reduction in urinary leakage on CST (84% in the bovine collagen group vs. 65% of NASHA-dx).

A single-blind, randomised, prospective, 33-centre, 2-arm parallel study of PAHG vs. bovine collagen had follow-up to one year (338). At baseline, women underwent CST, pad weight, bladder diaries, and QoL questionnaires. After randomisation, patients could receive up to three injections at 1-month intervals. At the last visit Valsalva leak point pressure was measured. Of the 345 women 229 were randomized to PAHG and 116 were randomised to bovine collagen. At 12 months, a ≥50% decrease in leakage and incontinence episodes was seen in 53.2% and 55.4% of patients who received PAHG and collagen, respectively. At 12 months, 47.2% of patients with PAHG and 50% with collagen reported zero SUI episodes, while 77.1% and 70%, respectively, considered themselves cured or improved. Major AEs were rare in each group.

The Cochrane analysis concluded that all bulking agents appeared to provide similar overall improvements as compared to bovine collagen. (321) Eight trials compared different agents and all results had wide confidence intervals. Silicone particles, calcium hydroxyl apatite, ethylene vinyl alcohol, carbon spheres and NASHA-dx gave improvements which were not shown to be more or less efficacious than bovine collagen. Finally, a recent systematic review that included only RCTs has been published (339). The primary outcomes were clinical and urodynamic parameters. Initially, 942 studies were identified; however, only 14 eligible trials fulfilled the prerequisites. Altogether, the review included 1814 patients from trials of eight different types of bulking agents and confirmed the findings of the Cochrane Review. The most common complications of the bulking agents were urinary retention and UTI. The authors cautioned that the lack of adequate studies, the heterogeneous populations studied, the wide variety of materials used, and the lack of long-term follow-up limit guidance of practice.

4.5. Bulking Agents vs. Surgery

In the two trials in the Cochrane Review that compared injection therapy with surgical management, better overall objective cure was obtained after surgery vs. injection (RR 4.77, 95% CI 1.96 to 11.64; and RR 1.69, 95% CI 1.02 to 2.79). (321) Of note, the latter trial data did not reach statistical significance if an intention-to-treat analysis was used.

A recent review assessed the objective and subjective outcomes of bulking agents in comparison with MUS, Burch colposuspensions, and PVSs for SUI (15). A PubMed and Medline search yielded three studies evaluating bulking agents in comparison with other surgical approaches for either primary or recurrent SUI. Two of these studies were RCTs evaluating the use of bulking agents vs. other surgical procedures for the treatment of primary SUI. The remaining article was a retrospective cohort study that compared the effectiveness and safety of repeat MUS with urethral bulking after failed MUS. The combined results of all analyses showed that the objective recurrence rate of bulking is significantly higher in comparison with other surgical procedures. Similar findings were observed when considering separately the treatment for primary or recurrent SUI. Furthermore, lower subjective recurrence rate was observed among patients undergoing other surgical treatment in comparison with those undergoing bulking agents; however, this trend was not statistically significant. As may be expected, women undergoing injection of bulking agents experienced a lower rate of voiding dysfunctions in comparison to surgery group.

4.6. Role of Bulking in Special Populations

4.6.1 Bulking in the Elderly

Twenty consecutive women with a mean age 84.5 years (range 80-87) were prospectively enrolled to undergo PAHG injection (340). All subjects were evaluated at baseline and re-evaluated at six-month intervals after treatment. A statistically significant decrease in the number of pads was observed at the 24-month follow-up ($p=0.0002$). Physical examination showed a statistically significant lack of, or reduction in, urine loss with CST ($p=0.0163$). Urodynamic findings showed an increase in VLPP, MUCP, and functional urethral length. IIQ-7 showed a statistically significant improvement in QoL ($p=0.0001$). Patient satisfaction assessed with the VAS and PGI-I respectively produced evaluations of ″satisfied″ and "much improved" even after 24 months.

Table 11: Bulking Agents: Cohort Studies

Key:

EVA: Ethylene vinyl alcohol;

Ca-HA: calcium hydroxyl apatite

VDM-PDMS: vinyldimethyl-terminated polydimethylsiloxane polymer

4.6.2 Recurrent SUI

Several studies have indicated that bulking agents represent a viable option for treating persistent or recurrent SUI after failed primary surgery. Hansen et al. queried the Danish National Patient Registry to identify women who had undergone first-time synthetic MUS from 1998 through 2007. (341) The outcome was repeat surgery with any subsequent procedure code for urinary incontinence within a 5-year period of the first procedure. A total of 5,820 women (mean age 55.4±12.1 years) underwent a primary synthetic MUS, and 354 (6%) underwent reoperation. The first-choice treatment for reoperation was another synthetic MUS (45.5%) followed by urethral injection therapy (36.7%) and miscellaneous operations (13.8%). PVSs (2.8%) and Burch colposuspension (1.1%) were seldom used. A secondary analysis of the UITN SISTEr and ToMUS trials of women who underwent primary SUI treatment was assessed for retreatment-free survival rates by initial surgical procedure (273). Half of the women in the SISTEr trial met inclusion criteria for this analysis (329/655, 174 Burch and 155 fascial sling), as did 444/597 (74%) of subjects in ToMUS (221 TO and 223 PVS). Types of surgical retreatment included autologous fascial sling(339), synthetic sling (321), and bulking agent (338).

Studies evaluating individual bulking agents have demonstrated some success with injection for recurrent SUI. In a retrospective study of 23 women who had received therapy with PDMS or carbon-coated zirconium beads after a failed MUS, the authors noted a cure rate of 34.8% at a median follow-up of 10 months and improvement in secondary outcomes (342). Overall, 92% of these patients reported benefit from therapy and the authors reported no complications. Another observational study included 60 patients who underwent PAHG injection after a failed MUS (343). Patients were considered cured based on a negative CST, <2 g urine loss on 1-hr pad test, and a VAS score improved by ≥90%. Women considered improved were those with the loss of only a few drops of urine on CST and 2-10 g urine loss on 1-hr pad test, or a reduction of >50% compared with preoperative urine loss and a VAS score improved by ≥75%. The volume of PAHG injected ranged from 1-3 mL. Cured/improved rates were 93.3% (56/60), 88.3% (53/60), and 83.6% (46/55) at 1, 6, and 12 months, respectively. Those with MUI had UUI resolution rates of 36.8%, 47.4%, and 38.9%, respectively. Voiding dysfunction rates were 13.3% (8/60), 8.3% (5/60), and 1.8% (1/55) at 1, 6, and 12 months, respectively, while UTI rates were 5% (3/60), 11.7% (7/60), and 3.6% (2/55), respectively. Other AEs were short-term and/or observed in <4% of patients.

Another retrospective study described outcomes in 52 women who underwent PAHG, 40 of whom had failed previous anti-incontinence surgery (344). Cure was evaluated by VAS (0-100 (dry)) and a 5-point Likert scale. A negative CST was observed in 19.6% of women at a mean follow-up of 22 months. Subjective assessment by the ICIQ-UI SF questionnaire showed that 15.7% of patients were completely dry, while 45.1% of patients were dry or improved. The mean VAS score was 51.3, and, on the Likert scale, the cure effect was evaluated as 5 or 4 ("cured" or "improved") in 54.9% of patients.

An open multicentre study of VDM-PDMS recruited 105 women from three tertiary gynecological clinics, 91 of whom had recurrent SUI (345). At each follow-up visit, CST and 1-hour pad test were performed. Objective success rate after 12 months in those women with recurrent SUI was 59.3%, compared with 71.4% of patients treated for primary SUI.

While bulking may be considered and used for recurrent SUI, the outcomes following injection therapy appear to be inferior to repeat sling surgery. A retrospective cohort study of women within the Kaiser Permanente Southern California Medical Group who underwent a MUS from 2008-2011 assessed the outcomes following either MUS or urethral bulking for recurrent SUI (346). The primary outcome was either subjective failure defined by SUI or objective failure defined as a positive CST, urodynamic SUI, or retreatment for SUI. Secondary outcomes included perioperative complications and AEs. Of 6,914 MUS performed, 165 women underwent a repeat procedure for recurrent SUI, including 98 MUS and 67 urethral bulking. Of those 165, there were 11 failures (11.2%) in the MUS group and 26 (38.8%) in the urethral bulking group (p=0.004). There were no differences in perioperative complications or AEs between the groups. In multivariable logistic regression, risk of failure was significantly higher in those undergoing urethral bulking compared with those undergoing MUS (OR 3.49, 95% CI 1.34-9.09, p=0.01).

Finally, an electronic database search was performed (1980-2014) using the keywords: stress urinary incontinence, failure, recurrence, and treatment (347). The search was restricted to female patients and currently-used surgical procedures, including studies with five or more cases. The authors found that the pooled objective cure rate for urethral bulking in recurrent SUI was 38% (95% CI ±10.7), compared to 66.2% (95% CI ±4) for repeat MUS and 79.3% (95% CI ±6.54) for PVSs.

4.6.3 Radiation-Associated Incontinence

A multicentre prospective trial enrolled a total of 46 women with severe SUI who underwent PAHG (348). Group A consisted of 24 women with previous pelvic radiotherapy for a gynecological malignancy, while Group B consisted of 22 women without previous radiotherapy. At a mean follow-up of 12.4 months, complete continence was achieved in 25% of patients in group A and in 36.4% of patients in group B. Significantly reduced urinary leakage was observed in

both groups (p=0.0164 in group A and p=0.0002 in group B). Total scores in the ICIQ decreased by 5.2 in group A (p=0.0000) and 6.36 in group B (p=0.0001). The scores for the Total Patient Perception of Bladder Condition decreased by 1.54 in group A (p=0.0001) and 2.59 in group B (p=0.0000), with a significant difference between groups (p=0.0224). No clinically significant changes in urodynamic parameters were observed and no severe AEs were noted.

4.6.4 Neurogenic SUI

SUI related to a relevant neurologic condition can be considered neurogenic SUI. A systematic review of the published literature from Pub Med and Web of Science was undertaken for studies describing surgical treatment of neurogenic SUI between 1990 and 2013 (349). Thirty studies were identified, all with Level 3 evidence. None of the studies followed a RCT design, so the quality of evidence is modest. Three primary surgical procedures were used in 29 of 30 studies: artificial urinary sphincter (AUS), urethral slings, and urethral bulking agents. One study used a ProACT device. AUS was considered more successful than urethral bulking agents (77 ± 15% vs. 27 ± 20%, p=0.002). Urethral bulking agents reported higher failures than urethral sling procedures (49 ± 16% vs. 21 ± 19%, p=0.016) and AUS (21 ± 19% vs. 10 ± 11%, p<0.002).

A retrospective cohort study reported outcomes in 22 children (16 females, 6 males) who had NASHA-dx injections from January 2001 to June 2011 for persistent incontinence from either the BN (7), Mitrofanoff (10), or both (5) (350). Median age at injection was 13 years (range 4-21). All patients had adequate bladder capacity and compliance on maximized medical therapy before injection. "Success" was defined as either "continence" (daytime dry interval >3 hours) or "improvement" (daytime dry interval >2 hours). Children underwent an average of 1.6 injection sessions per patient with an average of 2.6 mL of NASHA-dx per session. At a median follow-up of 72 months (range 4-104), 19 (86.4%) patients had successful results (16 continent, 3 improved). For those incontinent from BN, 42% became continent after 1, 75% after 2, and 83% after 3 injections, for a success rate of 91% (10 continent, 1 improved). For those incontinent from Mitrofanoff, 20% became continent after 1, and 73% after 2 injections, for a success rate of 86% (11 continent, 2 improved).

4.7. Complications

As mentioned in several studies above, bulking therapy is infrequently associated with severe complications. The most frequent AE in the trial by Lose et al. was UTI in 10 women. (327) Occasionally, the injectables themselves cause unique complications. Malabarey and Walter described a case of urinary retention and a large firm para-urethral vaginal mass as a complication of periurethral collagen injections three years before presentation. (351) The patient was managed successfully with complete surgical resection of the mass and subsequent, recurrent SUI was managed using a rectus fascial sling. Likewise, Crites et al. reported a single case of bladder mass post bovine collagen injection which required transurethral resection for improvement of symptoms. (352) Kumar et al. reported a pseudo-diverticulum of the urethra due to an encysted collagen implant. (353) The use of PAHG has also been linked to a periurethral abscess which required surgical drainage (354) .

Of note, NASHA-dx was associated with injection site sterile abscesses in 8.4% of patients, injection site mass in 4.4%, and pseudo cyst formation in 2.2% of patients(337). Irritative voiding symptoms and injection site pain were more common with NASHA-dx than with bovine collagen. Additionally, Lightner et al. reported a single-institution retrospective case series of 35 women with ISD who underwent implantation with NASHA-dx. (355) Four of these women developed pseudo abscess formation requiring multiple operative interventions. It must be noted that the NASHA-dx was the only bulking agent injected using the implacer device, a template used to position four syringes (0.7 mL each) in the urethra. Furthermore, the bulking agent was not injected under direct visual control and the volume injected was typically large, potentially accounting for some of the abscesses and other complications.

Summary

Limited Level 1 information has emerged regarding bulking therapy since compilation and publication of ICI-5. While bulking agents provide a treatment option for primary SUI, optimal results may be obtained with repeated injections as effect wanes with time.

The few RCTs that exist (Level 2b/3) suggest that outcomes are similar regardless of bulking agent used, with no single bulking agent demonstrating superiority to bovine collagen.

There appears to be no difference in outcomes whether the transurethral or paraurethral technique is used. Likewise, there appears to be no difference in outcomes whether the bulking was performed at the BN or the midurethra (Level 2b).

Limited data suggest that bulking is inferior to surgical therapy for both primary and recurrent SUI (Level 3b/4).

Limited, non-randomised data suggest some benefit of bulking therapy in special populations, such those women with SUI following pelvic irradiation (Level 4).

Overall complication rates associated with bulking agents continue to be relatively low (Level 2b/3b/4); however, the long-term implications of permanent bulking agents in the periurethral milieu is unknown.

Recommendations

Bulking agents should not be offered as first-line therapy for those women desiring a "one-time" durable solution for primary or recurrent SUI (Grade B).

Bulking therapy is an option for selected individuals with SUI (e.g. poor candidates for anti-incontinence surgery or those desiring an office-based, minimally-invasive procedure) after appropriate counseling regarding lack of long term durability (Grade B)

Bulking agents may be offered to women as first-line therapy for recurrent or persistent SUI following anti-incontinence surgery, although these outcomes are likely inferior to repeat anti-incontinence surgery in the long term (Grade C).

5. ARTIFICIAL URINARY SPHINCTER FOR WOMEN

The artificial urinary sphincter has been used to treat some female individuals with SUI for several decades. It has been used as a salvage procedure, for patients with special circumstances (e.g. neurogenic sphincter dysfunction, etc.), and as a primary procedure in some centres.

In the 5th Edition there were 13 publications on AUS in women performed vaginally, abdominally and laparoscopically from 2007 to 2012. Nine of these will be shared in this 6th Edition.

Roupret, et al .,(356) reported 12 women who underwent laparoscopic insertion of an artificial sphincter over a 2 year period, 11 of whom had undergone previous procedures. After a variable period of activation ranging from 4 to 14 weeks, with a mean follow-up of 12.1 month (range 5.2 to 27 months) incontinence was cured in 88% of the women. Complications included the need for open conversion in 2 patients, 2 bladder injuries, 2 vaginal injuries with an overall complication rate of 25%.

Mandron, et al ., (357) reported their experience with 25 patients undergoing laparoscopic AUS implantation over four years. No cases required open conversion and the authors reported only an intraoperative complication, of vaginal perforation. Five of the patients developed urinary retention which required re-catheterisation of less than 4 weeks. At a mean follow-up of 26.1 months, two patients failed due to vaginal erosion and required removal of the AUS. Overall, 23 patients reported continence, either total (19) or social (minimal pad use) (4).

Vayleux, et al., (358)reported an analysis of 215 women undergoing sphincter implantation over a 22 year period. 88% of women had undergone previous treatment for incontinence. 73.5% of the patients were considered continent (0 to 1 pad use) and 170 (79%) were satisfied at follow-up. The revision rate in this group was 15.3% after a mean interval of 8.47 years. 15 explantations (7% of total) were performed. The major risk factor for intraoperative complications was a history of smoking (10.7%). Multivariate analysis revealed age to be the major risk factor for failure (odds ratio 2.46), which occurred in 23.7% of the subjects. In addition, pelvic radiotherapy was also associated with failure (4.37 odds ratio).

The largest long term analysis was published by Costa, et al. (359) Over a 20 year period, 376 devices were implanted in 344 women. At mean follow-up of 9.6 years, 85.6% of patients were fully continent (no incontinence), 8.8 were socially incontinent (occasional incontinence episode) and 5.6% were incontinent (defined as one pad or more incontinence). 3, 5 and 10 year device survival rates by Kaplan-Meier analysis were 92%, 88.6% and 69.2%. Mean mechanical survival time was 176 months (14.7 years). The authors identified three factors for AUS survival including number of previous incontinent procedures, presence of associated neurogenic disease, and simultaneous augmentation procedure.

Chung, et al., (360)reviewed 29 patients in whom AUS was implanted after failed anti-incontinence procedures. 5 (17%) of those patients required explantation of the device either due to erosion or infection. In addition, 13 revisions were performed with device malfunction accounting for 95% of those cases. Overall survival analysis revealed 90% malfunction of the device at less than 100 months from the time of implant. There was a significant decrease in pad use noted in the trials and overall continence rates (no pad use) were 70% in this study.

Other additional device modifications have included the use of a larger implanted cuff (greater than 8cm). Revaux, et al., (361) reported 50 women who underwent implantation with a large cuff device over a 23 year period, of whom 86% had undergone previous incontinence procedures. At a mean follow-up of eight years, 34 women had complete resolution of their incontinence (68%). Factors that were associated with device survivability included less than two pregnancies, urethral closure pressure higher than 19cm of H_2O and a cuff size equivalent to 8 cm.

Several consensus statements regarding use of the artificial urinary sphincter have been published. Chartier-Kastler, et al., (362)noted a higher risk of erosion and revision rates in women after multiple previous procedures. The authors concluded that the AUS should be implanted at high volume specialist centres with appropriate knowledge and experience in the management of complex cases of incontinence.

Richard, et al., (363) reported the recommendations of the committee in Women's Urology and Pelviperineology of the French Association of Urology. This guideline recommended avoidance of patients who had not had multiple prior procedures and where a well standardised technique performed by surgeons with regular experience and sufficiently long deactivation after implantation, long term monitoring as key aspects for device success.

Lovatsis, et al., (364) summarised the guidelines for the evaluation of treatment of urinary incontinence for the Society of Obstetricians and Gynaecologists of Canada. The authors concluded that the AUS was an option in patients with significantly decreased dexterity and mobility (recommendation of III-C).

Since the 5th Edition, there were five publications: two on long-term functional outcomes, two on robotic-assisted laparoscopic approach and the last on a retrospective comparison of robot-assisted and open approaches which would be summarised in this 6th Edition.

Phe , et al., (365) studied 34 women retrospectively with ISD who underwent an AUS between 1994 and 1992. Their median age at surgery was 56.5 (IQR 50-64.7) years and the median follow-up was 17 (IQR 12-19) years. The 10-, 15- & 20-year survival rates without explantation were 80, 80 & 74% respectively. The 10-, 15- & 20-year survival rate of the device without revision were 79, 65 & 40% respectively. After 20 years of follow-up, 11 (61%) women still had successful outcome.

Phe , et al.,(366) reported the long-term functional outcomes of AUS implantation in 26 female adult neurological patients suffering from ISD between 1984 and 2011. Their median age was 49.2 years (IQR 28.5–59.7) and at the end of the median follow-up time of 7.5 years (IQR 3.9–23.8), 15 patients (57.7%) still had their primary AUS. The AUS was explanted in five women because of infection or erosion. Survival rates, using Kaplan-Meier curves, without AUS explantation were 90%, 84%, 84%, and 74% at 5, 10, 15, 20 years, respectively. Survival rates without AUS revision were 75%, 51%, 51%, and 51% at 5, 10, 15, 20 years, respectively. 71.4% of patients with AUS were continent. When considering the 26 initial patients, including the patients in whom the AUS was explanted, the continence rate was 57.7%.

Fournier , et al., (367)reported the initial results of six women with ISD who underwent a robotic-assisted AUS implantation between 2012 and 2013. The mean age was 65 ± 9.6 years. Five patients had previous surgery for incontinence. The mean duration of follow-up was 14.3 months. A transperitoneal approach with a lateral positioning of the robotic arms was performed. The cuff implantation, positioning of the reservoir, and the pump were carried out similarly to the laparoscopic technique. Operative time, intraoperative occurrence of injuries of the bladder or vagina, postoperative complications, and continence (pad per day) were assessed. The robotic-assisted AUS implantation was feasible in all cases without intraoperative injury and 1 grade 1 postoperative complication. Mean operative time, postoperative bladder catheterisation, and hospitalisation time were 210 ± 32 minutes, 7 days, and 6 days, respectively. At the end of the follow-up, 83% of cases were fully continent.

Biardeau, et al., (368) reported the feasibility and short-term outcomes of a robot-assisted laparoscopic approach for AUS implantation in 11 women with stress urinary incontinence. The authors reported successful AUS implantation in 8 of 11 patients (72.7%), with a complete continence rate of 87.5% (7 of 8 patients) after a mean follow-up of 17.6 (interquantile range 10.8-26) months. However the intraoperative complication was 36.4% (4 of 11, of which 2 each were bladder and vaginal injuries) and similar rate of post-operative complications (2 each of minor and major).

Peyronnet B, et al., (369)retrospectively compared the robot-assisted and open approaches of AUS implantation in 24 women with SUI. Twenty-four women were assessed: 16 in the open group and eight in the robot-assisted group. Three patients had neurogenic stress urinary incontinence. Most patients had undergone previous procedures for urinary incontinence (15 in the open group and seven in the robotic group). Mean operative time was similar in both groups (214 vs. 211 min; p = 0.90). Postoperative complications rate was lower in the robot-assisted group (25 vs. 75 %; p = 0.02). There was a trend toward a lower intraoperative complication rate (37.5 vs. 62.5 %; p = 0.25), decreased blood loss (17 ml vs. 275 ml; p = 0.22), and shorter length of stay (3.5 vs. 9.3 days; p = 0.09) in the robot-assisted group. Continence rates were comparable in both groups (75 vs. 68.8 %; p = 0.75). Three AUS explantations were needed in the open group (18.8 %) compared with one in the robot-assisted group (12.5 %; p = 0.70).

Summary

There is a paucity of data regarding the use of AUS in women with SUI (EL=3)

Although short term efficacy of the AUS in females is satisfactory, durability in the long term is unproven (EL=3).

The procedure has a high rate of complications and surgical revision (EL=3).

Recommendations

AUS for female SUI should be limited only to highly selected individuals usually with recurrent SUI and only with appropriate counseling regarding the likely need for revision over time and the lack of long term RCT data (Grade C).

6. STEM CELL TECHNOLOGIES

The use of stem cell modalities for the treatment of urinary incontinence and bladder dysfunction has been proposed for more than a decade. (370-373) Basic and clinical science reports of stem cell use for the indication of PVS(SUI) or DO based incontinence (OAB) are extant and indicate potential utility for both of these indications. Varying types of stem cell populations have been utilised for these indications as delineated below. For purposes of this discussion, the literature and evidence will be surveyed for the indication of SUI in women only.

As a premise, stem cells are categorised by their differentiation capabilities. The term embryonic stem cell incorporates the concept of toti-potentiality of the cells. (374) Adult stem cells, in contradistinction, are pluripotent and/or multipotent and cannot undergo differentiation into as many different cell types as embryonic cells. Generally, adult stem cells are specific for unique tissues based upon their derivation. Stem cells have been found in a variety of tissues. Cells from these unique sources are somewhat similar in phenotypic expression and cellular characteristics dependent on the cell source. Stem cells are thought to have local beneficial effects in host tissues including the ability to alter immune function, release paracrine factors and to be capable of proliferation. (375) Key surface inclusion (including CD73, and α7β1 integrin), exclusion (such as CD45) and intracellular markers (for example vimentin and Pax 7) contribute to the unique local effects that these cells induce in host tissues. Vascular endothelial growth factor (VEGF) has been noted to promote host tissue incorporation of expanded stem cells. (376) Additionally exogenous materials such as microbeads (377) or calcium alginate gels (378), nanoparticles (379), or polyglycolic acid (380) have all been posited to benefit cell viability.

There are six common cell types that have been evaluated for the indication of female SUI inclusive of embryonic, muscle derived (satellite cells), bone marrow derived (381), mesenchymal, adipose, urinary and human umbilical cord blood types. Also human amniotic fluid stem cells (hAFSCs) have been proposed as an alternative source. (382, 383) Other potential stem cell sources do exist in the mammalian systems but have yet to be studied extensively for purposes of the indication of stress urinary incontinence. Pluripotent stem cells (PSC) have been proposed as a potential contributor of smooth and skeletal sphincter components. (384)

The actual mode of effectiveness of stem cell injection for urinary incontinence is as yet unspecified. There is some evidence of cell fusion into the host tissue, although this has not been definitively proven. There may also be benefits of stem cells by release of local factors which stimulate injured and uninjured host tissue to respond more effectively. Cytokines may actually upregulate the functional activity of normal cells. These include hepatocyte growth factor (HGF), insulin-like growth factor (IGF-1), IGF-2, and basic fibroblast growth factor(bFGF)], transforming growth factor-b (TGF-b 1), and platelet derived growth factor (PDGF). (385) Actual cellular differentiation into different cell types is controversial as there is some evidence of stem cell differentiation into myoblast lines on the basis of studies done in cardiac smooth muscle. (382) Also, in the case of SUI, the injected volume of viable cells may produce a bulking effect similar to other biologic and synthetic agents but with durability conveyed by viable cell persistence.

After extraction, all stem cells are post treated by a process known as an expansion in which either as progenitor cells or by incubation in differentiation media, either smooth muscle cells or myoblasts (if from striated muscle) are derived which then further develop into multinucleated myofibers. (386) The route of administration of stem cells into the urethra has been performed by either transurethral or periurethral injection technique. There is also some recent evidence of improved deposition of cell load when an ultrasound aided injection technique is used. (387)

Most of the data that is extant in clinical trials are reported in small, uncontrolled, non-randomised settings.

6.1. Clinical Trials

Several of the stem cell concepts have resulted in clinical trials. In a pilot study, five patients were treated with ASCs combined with bovine collagen gel and saline. (388) Prior to the treatment, the ASCs were isolated from subcutaneous fat and expanded for three weeks followed by transurethral injection via cystoscope. Patients were followed-up at 3, 6, and 12 months after the injections. The primary objective and subjective endpoints were CST and validated questionnaires, respectively. After six months, one of five patients had a negative CST with 500 mL in the bladder. At one year, the CST was negative with three patients, two of whom were satisfied with the treatment and did not wish further treatment for SUI. Validated questionnaires showed some subjective improvement in all five patients.

A total of 20 and 15 women with uncomplicated and complicated SUI, respectively, received intraurethral injections of minced autologous skeletal muscle tissue and were followed for one year(389). Efficacy was assessed by the number of leakage episodes in a 3-day diary and by ICIQ-SF scores. Cure was defined as zero leaks in 3 days plus an ICIQ-SF score of 5 or less, while improvement was defined as simultaneous decreases in each outcome measure. Significant reductions were observed in each group in the mean number of leakages ($p<0.01$) and in ICIQ-SF scores ($p<0.001$). In the uncomplicated group, cure and improvement were observed in 25% and 63% of patients, and in the complicated group they were noted in 7% and 57%, respectively. No voiding dysfunction developed and only minor AEs were reported.

Autologous muscle derived cells have also been evaluated in a feasibility study for intrasphincteric injection (390). A total of 38 women in whom SUI had not improved with conservative therapy underwent intrasphincter injection of low doses (1, 2, 4, 8 or 16×10^6) or high doses (32, 64 or 128×10^6) of autologous muscle derived cells obtained from biopsies of their quadriceps femoris. All patients could elect a second treatment of the same dose after 3-month follow-up. Assessments were made at one, three, six, and 12 months after the last treatment. The primary end

point was the incidence and severity of AEs. In addition, changes in SUI severity were evaluated by pad test, incontinence diary, and QoL surveys. Of the 38 patients 33 completed the study. Treatment related complications were limited to minor events such as pain/bruising at the biopsy and injection sites. Of those patients who received two injections and were eligible for analysis, a higher percentage of those in the high dose vs. the low dose group experienced a 50% or greater reduction in pad weight (88.9%, 8 of 9 vs. 61.5%, 8 of 13), had a 50% or greater reduction in diary reported stress leaks (77.8%, 7 of 9 vs. 53.3%, 8 of 15) and had 0-1 leaks during a 3-day period (88.9%, 8 of 9 vs. 33.3%, 5 of 15) at final follow-up.

A 12-month safety and efficacy update was recently published (391). Pooled data from two phase I/II studies with identical patient selection criteria and outcome measures were analyzed. Patients received intrasphincter injection of 10 (16), 50 (16), 100 (24) or 200×10^6 (24) autologous muscle derived cells for urinary sphincter repair. A total of 80 patients underwent injection and 72 completed diaries and pad tests at 12-month follow-up. As with the feasibility study, no AEs attributed to autologous muscle derived cells were reported. Likewise, higher dose groups tended to have greater percentages of patients with at least a 50% reduction in stress leaks and pad weight at 12-month follow-up. All dose groups had statistically significant improvement in UDI-6 and IIQ-7 scores compared to baseline.

Strangel-Wojcikiewicz et al recently reported two year follow up demonstrating safety and 50 % resolution of incontinence. (392)

Autologous myoblasts have also been injected into the external urethral sphincter under ultrasound-guidance followed by electrical stimulation (ES) as a possible 2-step treatment for SUI (393). Autologous myoblasts isolated from the biceps muscle were injected into the external urethral sphincter of 38 females followed by postoperative ES to enhance cell integration. The effects of the myoblast injections followed by an ES cycle were compared to those of a preoperative ES cycle undergone by the same patients. No serious AEs or complications were noted and the procedure was well tolerated. Compared with the objective and subjective measurements collected after the preoperative ES cycle, the corresponding measurements obtained after a second ES cycle six weeks postoperatively indicated considerable improvement. CST was negative for 29 (78.4%) of the patients and 5 (13.5%) and 29 (78.4%) considered their SUI cured and improved, respectively. Additional improvement or a plateau was observed at three and six months postoperatively, and was not negatively influenced by discontinuation of injection therapy(387). Of the patients, 23.7% considered their SUI cured and 52.6% reported improvement at six months, while 95% would recommend this treatment to others.

In 2013, Aref-Adib, assessed the current evidence for the use of stem cell therapy for stress urinary incontinence. Overall, they found eight studies that met inclusion criteria (7 observational and one randomised). The outcomes, as reported in these various trials varied from urodynamic to quality of life improvement outcomes. Additionally, there were limited radiographic assessments using urethral ultrasound done in the reported trials. Additionally, three studies noted increases in rhabdosphincter function and structure with two suggesting increases in the EMG activity. Unfortunately, these authors found the data to be somewhat limited due to lack of durability and inconsistent quality of reporting. Of the included articles, seven of eight used autologous mesoderm derived stem cells (MDSC) and one used umbilical cord derived stem cells. Follow-up in those trials ranged from 1.5 to 24 months and the trials included from 8 to 123 patients. Only one was randomized. Of note, complications were minimal. Interestingly, when done, urethral ultrasound revealed increase in sphincter thickness and contractility after stem cell injection. (394)

In the most recent assessment of the extant literature, Pokrywczynska et al again note inconsistencies in outcomes reporting and follow up. (395)They identified 16 articles which met inclusion criteria which included 383 female patients and noted that mean cure and improvement rates over a 12-month follow-up were 37.2 ± 29.7% and 33.1 ± 14.3% (of included patients). Cell types included; myoblasts, muscle-derived stem cells (MDSCs), and fibroblasts (most common). Less commonly, adipose-derived regenerative cells, cord blood stem cells and total nucleated cells (TNCs) and platelets were used. The number of cells used for the trials was noted to range between 0.6 million to 1020 million cells with some studies suggesting higher cell numbers to be associated with improved outcomes. (391)

In studies where only cells were implanted as compared to those where implantation together with a bulking agent (collagen or adipose) was performed, cure rates over 12-month follow-up was lower ($p < 0.001$) for the cell only patient (21.7 ± 8.9%) compared to the cell-bulking agent combination (60.8 ± 36%). No serious AEs or major complications were reported. The most common AEs were; exacerbation of incontinence, short term urinary retention, injection site pain, and urinary tract infection.(391)

Notably, a randomised Phase III regulatory trial evaluating muscle derived stem cells is in progress in North America currently.

6.2. Other Technology

A macro/nanogel composed of in situ forming gelatin-based macrogels and self-assembled heparin-based nanogels served as an injectable and bioactive bulking material for SUI (396). The hybrid hydrogels were prepared via enzymatic reaction in the presence of horseradish peroxidase and hydrogen peroxide. Incorporating a growth factor (GF)-loaded heparin

nanogel into a gelatin gel matrix enabled the hybrid gel matrix to release GF continuously up to 28 days. The hydrogel composites stimulated the regeneration of the urethral muscle tissue surrounding the urethral wall and promoted the recovery of their biological function when injected in vivo.

Plasmid DNA (pDNA; encoding for bFGF) complex-loaded poly(DL-lactic-co-glycolic acid) (PLGA)/Pluronic F127 mixture dispersed with polycaprolactone (PCL) microspheres was prepared as an injectable bioactive bulking (397). This thought was that this agent may provide bulking effect (via the PCL microspheres) and allow stimulation of the defective periurethral tissues around (via synthesis of bFGF from cells or tissues transfected by the pDNA complex). From in vitro experiments, the pDNA complex incorporated in the bulking agent was released in a sustained manner over 84 days (≥80% of the initial loading amount). The pDNA complex was effectively transfected into fibroblasts and the cells were continuously producing the target protein, bFGF. From the in vivo study using hairless mice and Sprague-Dawley rats, it was confirmed that the pDNA complex released from the bulking agent is transfected into surrounding cells/tissue, and the cells/tissues synthesised sufficient bFGF to regenerate smooth muscle with biological function around the urethra.

Summary

It is clear that the science of stem cell use for the indication of SUI continues to evolve. Current evidence is limited by a lack of comparator arms or other study design flaws. Additionally, the optimal cell type, injection method, and final administration characteristics for cell transfer (inclusive of volume of viable cells) remain areas for improvement and study.

Recommendation

The use of stem cell technology for the treatment of female SUI remains investigational, and such therapy should not be offered to individuals with primary or recurrent SUI except in the setting of clinical trials. (Grade D)

7. OTHER SURGERY FOR FEMALE SUI

7.1. Transurethral Radiofrequency Collagen Denaturation

Radiofrequency ablation (RFA) is a method of heating tissue that can cause tissue ablation and necrosis (higher temperatures) or denatured protein (lower temperatures, 65°C to 75°C)(398). In the treatment of female urinary incontinence low-level radiofrequency energy has been used for localized collagen denaturation of the BN and proximal urethra for the treatment of female stress urinary incontinence.

In 2005, Novasys Medical received US Food and Drug Administration (FDA) clearance to market transurethral radiofrequency collagen denaturation under the trade name Renessa® in the United States. More recently, the device used to perform this procedure has been marketed under the trade name Lyrette® by the Verathon Company (lyretterf.com)(399) Perceived or potential advantages of this procedure are that it can be done in the office setting with the patient under local anesthesia or intravenous sedation, without imaging, in less than one hour.

7.1.1 Mechanism of Action

The low levels of radiofrequency energy at 65°C are thought to create localised microscopic collagen denaturation sites within the BN and proximal urethra without creating strictures, fibrosis, significant tissue necrosis, gross shrinkage, or neurovascular injury. The denatured collagen results in reduced dynamic compliance of the surrounding untreated tissue(400).

In a preclinical porcine study employing transurethral RF, Valsalva leak point pressure was higher in the treatment group receiving 24 foci of RF energy at 65°C as compared to controls at 8 weeks (P = 0.06)(400).

7.1.2 Outcomes

The Cochrane review(401) included only one small sham-controlled randomized trial of 173 women with (402). In this study, 110 women underwent transurethral radiofrequency collagen denaturation in the treatment arm and 63 underwent sham treatment in the control arm. Mean participant age was 50 years (range 22 to 76 years), and mean duration of SUI was eight years (range one to 49 years). All participants were treated with the same type of radiofrequency probe (Novasys Medical, Inc., Newark, California) and one of two similar radiofrequency generators (Novasys Medical, Inc.; CuronMedical, Inc., Fremont, California).

In this study, 48% of the treatment arm subjects and 44% of the sham treatment arm subjects demonstrated≧10 point I-QOL score improvement at 12 months (P = 0.7). However, in a subgroup analysis, 74 percent of women suffering from moderate to severe SUI experienced ≧10 point I-QOL score improvement at 12 months following RF micro-remodeling versus 50% of women who underwent sham treatment (P = 0.03).

The Cochrane review concluded that transurethral radiofrequency collagen denaturation was not associated with an increase in the number of women with an I-QOL score improvement greater than or equal to 10 points at 12months when compared with sham treatment in an analysis of available data (RR 1.11, 95% CI 0.77 to 1.62; participants = 142). Therefore, the Cochrane review concluded that evidence is insufficient to show whether the procedure improves disease-specific quality of life. [EL=4] The Cochrane

review evaluation downgraded the quality of the evidence by two levels to low because of the high risk of bias and imprecision. Furthermore, the number of women reporting UI symptoms after intervention was not reported in this paper.

In a sub-analysis of this study, Leihan showed that Menopausal status and HRT demonstrated no impact on the quality of life improvement experienced by women with moderate-to-severe SUI who underwent RF tissue micro-remodeling(403).

Appell et al. also showed that women who underwent RF micro-remodeling demonstrated an increase in mean LPP at 12 months (13.2 ± 39.2cmH20), while women who underwent sham treatment demonstrated a reduction in mean LPP at 12 months (−2.0 ±33.8 cmH20), and the difference in mean LPP change between the two arms was statistically significant (P = 0.02).(402)

7.1.3 Long Term Results

A summary of prospective trials of transurethral radiofrequency collagen denaturation is presented in Table 1(403-409). An early 12-month study(404) examined the use of four different timing and placement methods for the delivery of radiofrequency energy. Cure rates ranged from 22% to 67%, with reductions in episode frequency from 67% to 89% of patients. The longest follow-up period described was 3 years(405, 406) Appell et al. reported that 56% of women who underwent radiofrequency collagen denaturation continued to report a 50% or greater reduction in SUI episode frequency(405).

In a single-armed original cohort study by Elser et al (407). , 45% of patients were considered dry, with 29% experiencing no leaks and 16% leaking less than 1 gram on a standardized in-office pad weight test. Additionally, 69% of women experienced a 50% or greater reduction in leakage, and 71% reported improvements on quality of life measures. A follow-up report from the same study revealed that 61.7% of evaluated patients continued to experience at least a 50% reduction in SUI leaks at 18 months(408) , and showed that mean I-QOL score improved 17 points from baseline (P = .0004), while mean UDI-6 score improved (decreased) 19 points (P = .0005) at 36 months(406).

7.1.4 Complications

Appel, et al showed that dysuria occurred in 9.1% of actively treated participants and in 1.6% of sham-treated participants (RR 5.73, 95% CI 0.75 to 43.70), and dry OAB was more common in the transurethral radiofrequency collagen denaturation arm (7.3% vs 3.2%), but this finding was not statistically significant(402). Urinary tract infection was observed to occur equally in both groups (4.5% vs 4.8%). However, the Cochrane review concluded that evidence is insufficient to show whether the procedure causes serious AEs or other AEs in comparison with sham treatment.

Summary

There is only one small sham-controlled randomized trial of transurethral radiofrequency collagen denaturation. [EL=2/3] Evidence is insufficient to show whether the procedure improves disease-specific quality of life. Evidence is also insufficient to show whether the procedure causes serious AEs or other AEs in comparison with sham treatment, and no evidence was found for comparison with any other method of treatment for UI. There is a need for further prospective randomized assessments of this treatment.

Recommendation

There is insufficient evidence to recommend this procedure as a treatment for female SUI (Grade D)

7.2. Transvaginal and Transurethral Laser Treatment

Non-invasive laser applications utilising applied cooling have been successfully exploited for skin resurfacing (thermal denaturation and shrinkage of collagen for tissue remodeling), hair removal, tattoo removal, and treatment of vascular birthmarks (410). Erbium:YAG (λ=2.94mm) and CO2 (λ=10.6mm) skin resurfacing lasers have recently been applied in gynecology for sub-ablative resurfacing of atrophic vaginal tissue in post-menopausal women, and for treatment of female SUI. Short-term studies appear have been published for vaginal rejuvenation.

7.2.1 Mechanism of Action

Laser energy to achieve heat pulsing (i.e., temporarily increasing the temperature) of collagen is thought to improve collagen structure and initiate neocollagenesis. As a result of the temperature increase, intermolecular cross-links that stabilize collagen triple-helix structure are broken, which leads to the shrinkage of collagen fibrils and improvement in tissue firmness (411). Therefore, laser-mediated heat pulsing of the endopelvic fascia and pelvic floor tissue could represent an effective non-surgical method for treating female urinary incontinence and other disorders resulting from diminished pelvic floor support.

7.2.2 Outcomes

There are only a few original cohort studies with short-term results and there are no randomised control trials. Ogrinc et al (412) reported a prospective, single centre, non-randomised, pilot study of transvaginal Er:YAG laser treatment in 175 women with newly diagnosed SUI (66% of women) and MUI (34%). They used a 2940nm Er:YAG laser (SP Spectro, Fotona®, Slovenia) set in “smooth mode” (fluence 10.0 J/cm2; four pulses per packet, packet pulse duration is 250 ms; spot size 7mm; repetition rate 1.6 Hz) which enables non-ablative, thermal-only operation. At one-year-follow-up, Incontinence Severity Index decreased 2.6 ±1.0 points in patients diagnosed with mild UI before the treatment, 3.6 ±1.4 points in those with moderate UI, for 5.7 ±1.8 points in those

with severe UI and 8.4 ± 2.6 in those with very severe UI (P<0.001, paired samples t-test)[EL=4]. Fistonic et al (411) conducted a pilot clinical study recruiting 31 women with SUI. The procedure was performed with a 2940 nm Er:YAG laser (XS Dynamis, Fotona®, Slovenia), based on the pulsing sequence designed to achieve deep heating of the vaginal mucosa to around 60 °C. The International Consultation on Incontinence Questionnaire-Urinary Incontinence Short Form (ICIQ-UI SF) score was decreased on average by 6.3 points after 1 month, by 5.3 points after 2 months, and by 5.1 points 6 months after treatment[EL=4]. In this study, no serious AEs were observed or reported throughout the course of laser treatment and the follow-up period. All patients experienced a sensation of warmth or teasing during treatment. Most patients reported increased vaginal discharge in the next few days after the procedure and slight vulval oedema, which disappeared within 48 h after the treatment.

Summary

Evidence is insufficient to evaluate the efficacy and AEs.

There is a need for further prospective randomised assessments and long-term follow up data for this treatment. [EL=4].

Recommendation

There is insufficient evidence to recommend this procedure as a treatment for female SUI (Grade D)

7.3. Intravesical Pressure Attenuation Device

7.3.1 Mechanism of Action

The Vesair™ Device (Solace Therapeutics, Framingham, MA, USA) is an intravesical pressure attenuation device which is a novel approach to the treatment of female SUI. As opposed to treatments for SUI which are directed toward improving urethra/bladder outlet closure (slings, colposuspension, bulking agents, etc.), this intravesically placed balloon device works by attenuating intravesical/intraabdominal explusive forces without having a direct effect on the outlet.

After intravesical placement, the polyurethrane balloon filled is filled with 15 or 30 ml of air with liquid perfluorocarbons sealing the balloon. Because gas is more compressible than water, the intravesical balloon floats near the dome of the bladder and attenuates the rapid intravesical pressure increases from rises in abdominal pressure to decrease SUI episodes.

7.3.2 Outcomes

The Vesair™ device has been studied in two prospective, single-blind, randomizsd, sham-controlled trials in North America[1] and Europe(413, 414).

The North American trial recruited 166 women with SUI in a 2:1 randomisation scheme for a 6 month trial with replacement of the balloon device every 90 days (413). This trial had a very high withdrawal rate (31%). The primary outcome variable was a reduction in one Stamey grade. This was not achieved in the intent to treat (ITT) population with only 28.6% of the women with the active device having a reduction of one Stamey grade at 6 months versus 22.2% in the sham arm (p=0.455). Data for Stamey grade reduction was significantly different between the cohorts in the per protocol (PP) analysis [40.9% of active device patients versus 22.4% of controls (p= 0.046)]. A secondary composite outcome variable of a 50% reduction in pad weight and improvement in the patient impression of improvement scale was achieved by 50.8% of patients versus 16.3% of the controls (p<0.001) in the ITT population. Three day voiding diaries showed a significant reduction in incontinence episode frequency in the device group from 4.4 to 2.5 episodes/ day (43.2%) versus 5.4 to 4.1 episodes/day (24.1%) in the control group (p<0.001).

However, the active device group had a very high rate of AEs complicating its usage with 88.4% having at least one AE. Most common were symptomatic UTIs in 29.5% in the device group versus 9.3% in the sham group. The women with devices in their bladders also had urgency and hypertonic bladder in 18.7%, hematuria in 17%, dysuria in 11.6%, pelvic pain in 10.7%, UUI in 8.9% and bladder pain in 8% versus <2% in controls. The balloon ruptured in 8% of women and was voided out. Eight percent withdrew from the trial because of discomfort with the device and 4% because of urinary tract infections.

The European trial (414)was somewhat similar to the North American trial with a modified thicker balloon that was inflated with 30 ml of air (instead of 15 ml) with assessments over only 3 months in a smaller cohort. A proprietary delivery instrument further protected the urethra during insertion and removal of the device. Participants were given prophylactic antibiotics during instrumentation to prevent UTIs. These modifications led to lower AE rates and study withdrawls. They recruited only 63 women with 41 randomised to receive the intravesical balloon and 22 were in the sham arm. The outcome variables were different from the North American trial with the composite outcome of a ≥ 50% decrease in office pad testing and a ≥10 point increase in the incontinence quality of life survey (I-QOL) as the primary outcome and secondary outcomes of incontinence episode frequency and the patient global impression of improvement (PGII). Significant differences were found in the composite outcome with 63% of women in the active device group reaching this goal compared to only 31% in the sham group (p=0.02). Pad weight increases ≤1 gram on the office pad test (dryness) was found in 41.6% of the subjects with the intravesical balloon versus none in the control group (p<0.001). The PGII improvement was significantly better in patients than controls (p=0.025). The overall AE rate was reduced to 44% but the trial was only 3 months

in length. The symptomatic UTI incidence was only 7.3% but hematuria was frequent in 9.8% and dysuria occurred in 14.6% of women in the intravesical balloon group. Ten of the 41 women (24%) withdrew from the 3 month study prematurely because of AEs.

Examination of some of the removed balloons microscopically and chemically showed deposition of calcium oxalate on the balloon surface in the 6 month study group but not in the 3 month study group.

Summary

Based on these data the Vesair™ intravesical balloon appears to be efficacious in a selected population at short term followup (LE=2). However, the frequently seen AEs and patient acceptability may limit its clinical utility.

Recommendation

There is insufficient evidence to recommend this procedure as a treatment for female SUI (Grade C)

II. SURGERY FOR NON-NEUROGENIC UUI

1. SACRAL NEUROSTIMULATION (SNS)

1.1. Sacral (Interstim®)

SNS was developed in the early 1980s by Tanagho and Schmidt.(415, 416) They demonstrated that continuous stimulation of the sacral root S3 with an electrode connected to an implanted pulse generator could modulate detrusor and sphincter activity and improve LPP.(417) InterStim® Therapy (Medtronic, Minneapolis, MN, USA) is licensed by the US Food and Drug Administration (FDA) for the treatment of urinary urge incontinence (UI) since 1997 and for urgency-frequency (UF) and chronic non-obstructive urinary retention (UR) since 1999. SNS is a potential treatment for other forms of bladder dysfunction and has been used for disorders such as chronic pelvic pain and interstitial cystitis as well as for faecal incontinence.(418-421)

The mechanism of action of SNS is not completely understood. The therapeutic benefits of SNS may arise from the effects of electrical stimulation on afferent and efferent nerve fibers connecting the pelvic viscera and the spinal interneurons to the central nervous system. Although it is referred to as a "restorative" therapy for patients with various voiding dysfunctions refractory to conservative measures, compelling evidence of permanent remodeling, reinnervation or alteration of pathways in the central or peripheral nervous systems in humans following successful therapy is lacking. SNS seems to predominantly influence sacral afferents and modulate spinal cord reflexes and brain centers involved in lower urinary tract function.(422-424)

Continual improvements in SNS have been introduced and it is now a minimally invasive technique. Briefly, an electrode is implanted in the S3 foramen and connected to an implantable pulse generator (IPG). The patient undergoes a test phase lasting for days to weeks to determine whether SNS has provided a relevant benefit. If the results of the test phase are positive, the IPG is implanted in the upper buttocks. The introduction of the tined-lead electrode enabled a less invasive percutaneous implantation that is associated with lesser migration rates.(425-427)

The test phase of SNS may also be performed by peripheral nerve evaluation (PNE) using a temporary electrode or by staged implantation of a permanent, tined-lead electrode. Because PNE may underestimate treatment effect and result in significant false-negative rates, most physicians utilise the staged implantation of a tined-lead for the first stage.(428-430)

1.2. Efficacy

1.2.1 SNS vs No Therapy

At the time of the last ICI review, outcomes of SNS for UI and UF were based on a small number of studies that randomized patients to active or delayed therapy as well as numerous prospective and retrospective case series. Schmidt and coworkers (1999) reported on SNS therapy in 76 patients with refractory UI from 16 centers worldwide randomized to active or delayed therapy (control group) during the study period of 6 months.(431) Daily incontinence episodes and use of pads/diapers were significantly reduced in the stimulation compared to the delay group. Of the 34 patients receiving active SNS therapy, 16 (47%) were completely dry and an additional 10 (29%) demonstrated more than 50% reduction in incontinence episodes. Patients returned to baseline levels of incontinence when stimulation was inactivated. Hassouna and colleagues (2000) reported the outcomes of SNS for refractory UF in 51 patients randomised from 12 centers during an initial 6-month period that was extended to 2 years.(432) Outcomes at 6 months in the active SNS group showed improvement in the number of daily voids (16.9 ± 9.7 to 9.3 ± 5.1), volume voided (118 ± 74 mL to 226 ± 124 mL), degree of urgency (rank score of 2.2 ± 0.6 to 1.6 ± 0.9), and SF-36 quality of life (QOL) measures. At 6 months after implantation, stimulators in the active group were turned off and urinary symptoms returned to baseline values. After reactivation of SNS, sustained efficacy was documented at 12 and 24 months.

A Cochrane review from 2009 (433) examined the evidence of the effects of SNS in the treatment of UI, UF and UR. Eight RCTs were considered eligible and were included in the analysis. At 6 months follow-up, SNS was found to be superior to no treatment for all indications with highly significant improvements in all

the outcomes measured (leakage episodes, number of voids, rating of urgency, pad usage, bladder capacity). Both the SF-36 mental and physical scales favoured the immediate implant group but the results were not statistically significantly different between the treatment and no treatment groups. The review concluded that SNS can be of benefit in selected patients with OAB and chronic non-obstructive UR. (Level of evidence 2)

1.2.2 SNS vs Medical Therapy:

The InSite trial is an ongoing two-phase study including a prospective, multi-centre, randomised clinical trial comparing SNS to standard medical therapy (SMT) consisting of anticholinergic medication for patients with refractory mild to moderate symptoms of OAB including urinary urge incontinence (UI) and/or urgency-frequency (UF), within a six-month follow-up period (430). The primary hypothesis of the randomised portion of the study was that SNS is superior to SMT in OAB patients for whom at least one medication had been tried, but other pharmacologic agents were still available. The second phase is a prospective long-term evaluation of the safety and efficacy of SNS, which was an FDA mandated requirement to evaluate the cumulative five year rate of AEs (AEs) including need for surgery, rates of infection and lead migration as well as therapeutic success and QOL. Investigators have published results for one (434) and three years (427) of follow-up. The primary outcome measure of the randomized phase of the study was OAB therapeutic success, which was determined using voiding diaries collected at the 6-month follow-up visit. Success was defined for patients with UI and UF as a ≥ 50% improvement in average leaks/day or voids/day from baseline or a return to normal voiding frequency (<8 voids/day), respectively. Additional objectives were to compare QOL, impact on sexual function and depressive symptoms between groups using the ICI Modular Questionnaire (ICIQ)-OABqol, the ICIQ—Male/Female Lower Urinary Tract Symptoms-Sex, and the Beck Depression Inventory II. Overall, 147 subjects were randomised (70 to SNS and 77 to SMT); 93% were female and mean age was 58. Subjects randomised to SNS underwent a staged procedure using the InterStim requiring a 14-day test stimulation period. If successful test stimulation was demonstrated, the neurostimulator was implanted. Of the 70 subjects randomised to SNS, 59 underwent test stimulation and 51/59 (86%) received a full system implant. The primary intent to treat analysis showed OAB therapeutic success was significantly greater in the SNS group (61%) than in the SMT group (42%; P = 0.02). In the as treated analysis, OAB therapeutic success was 76% for SNS and 49% for SMT (P = 0.002). Complete continence was almost doubled in the SNS group (39% vs 21% in the SMT group; P=0.06) which also showed significant improvements in QOL versus the SMT group (all P < 0.001). SNS females had a greater improvement in sexual function and a greater improvement in depression compared to SMT. The device-related AE rate was 30.5% and the medication-related AE rate was 27.3%, none of which were serious. The most common device-related AE's in SNS subjects were undesirable change in stimulation in 10.2% (6/59), implant site pain 8.5% (5/59), lead migration/ dislodgment 3.4% (2/59), and implant site infection 3.4% (2/59). For the 51 SNS subjects with full system implant, the 6-month post-implant surgical intervention rate was 3.9% (2/51). The most common OAB medication-related events were constipation in 9.1%, drug toxicity in 6.5% and dry mouth in 5.2%.(Level of evidence 1)

1.2.3 SNS vs OnabotulinumtoxinA (BTX-A)

1.2.3.1 Efficacy

The use of BTX-A has been approved by the FDA for use in patients with refractory idiopathic OAB.. SNS is more invasive but offers long-term efficacy whereas treatment with BTX-A injections is less invasive but needs to be repeated on a less than a year basis in order to provide sustained efficacy. Each treatment modality has its own range of possible AEs.

The ROSETTA Trial (Refractory OAB: Sacral Neuromodulation vs Botulinum Toxin Assessment) is an ongoing RCT comparing SNS versus intradetrusor injection of 200 U BTX in women with refractory OAB.(435) Results for 6 months follow-up were presented during the AUA Meeting in San Diego (May/2016). A total of 386 women were randomly assigned and 369 were treated, including 364 who were available for the primary outcome analyses. Mean age in the study cohort was approximately 63 years, and more than 80% of both treatment groups rated themselves as severely or very severely incontinent. In the SNS group, women underwent a two-stage procedure. The rate of clinical response — defined as a reduction of at least 50% in urgent urinary incontinence episodes on a 3-day bladder diary — was similar in the injection and neurostimulation groups (83% vs 84%). This was measured at 1 month in the injection group and during the test phase in the neurostimulation group.

In both the intention to treat and clinical responder, primary outcome analyses, the BTX group reported significantly greater mean reduction in daily UUI episodes per day compared to the neurostimulation group. In the intention-to-treat analysis at 6 months, the change in the mean number of daily incontinence episodes from baseline was–3.9 in the injection group and –3.3 episodes/day in the SNS group; P = .01).

More patients in the injection group than in the SNS group achieved complete symptom resolution at 6 months (20% vs 4%; P < .0001) and a reduction of at least 75% in episodes per day (46% vs 26%; P = .0002).

OAB symptom bother scores, measured with the OAB Questionnaire Short Form, were significantly better in both groups after treatment, but the change from baseline was greater in the injection group than in the SNS group (–46.71 vs –38.5; P = .002).

Treatment satisfaction was better in the injection group than in the neurostimulation group (P = .01), as was endorsement, assessed with the OAB Satisfaction of Treatment Questionnaire (P = .0009).

1.2.3.2 Adverse Events

At 6 months, the rate of urinary tract infection was higher in the injection group than in the neurostimulation group (35% vs 11%; P < .0001).

In addition, in the injection group, intermittent catheterisation was required by 8% of patients at 1 month, by 4% at 3 months, and by 2% at 6 months. In the neurostimulation group, 3% of patients required surgical revision or removal.

An important drawback of this study is the fact that it used a 200 U dose of onabotulinum toxin A but the FDA-approved dose is 100 U. Longer term follow-up will be necessary to better understand how these treatment modalities differ in the treatment of refractory OAB.

(Level of evidence 1)

The use of SNS in patients who discontinued BTX-A treatment has been evaluated by Smits et al, who reported on a group of 14 patients who had discontinued BTX-A treatment due to lack of efficacy (85%) or the desire for a more permanent treatment (15%).(436) At one year post-implant, 11 of 14 patients (79%) reported satisfaction with treatment.

(Level of evidence 4)

1.3. Testing procedure: PNE vs Staged

The application of the two-stage procedure using the permanent tined lead appears to be superior to the percutaneous PNE technique. (437), in a retrospective case control study, the authors examined urodynamic and clinical outcomes of the two different testing techniques and found that permanent quadripolar electrodes led to significant differences in the overall response rate (81.8% versus 47.6%) and urodynamic parameters (max detrusor pressure, bladder capacity) compared to the PNE. This has to be balanced against the cost implications (e.g. the permanent electrodes are several times the cost of the cheaper PNE wires) and invasiveness (e.g. the staged or tined lead approach requires 2 anesthetics: one for lead implantation, and if successful, a second anesthetic for IPG implant, whereas the PNE is done under local anesthesia). In a recent study (438) 41 of 76 (54%) patients who failed to respond to PNE were subsequently tested with the tined lead or staged procedure.. Of those, 18 (44%) were implanted with a neurostimulator after a successful response suggesting that the tined lead procedure is a more sensitive screening tool. At 53-month follow-up, 12 of these patients (67%) had a successful outcome, which was not statistically different from the success rate in patients with a positive response to an initial PNE test.

The response rate to PNE as compared to the 1st stage tined-lead placement test (FSTLP) was compared in a prospective single centre study.(428) One hundred patients with refractory idiopathic OAB or non-obstructive UR, screened with both PNE and FSTLP. The positive response rate on PNE was 47%. FSTLP showed a 69% positive response rate, which was negatively related to age. The 22% gain in positive response was statistically significant (p < 0.001) and positively associated with female gender and younger age. This study also suggests that the FSTLP may be a more sensitive screening method than PNE. (LE=2)

1.4. Use of Computed Tomography (CT) for Lead Placement

In an attempt to improve the efficacy and accuracy of neuromodulator lead placement into the S3 foramen, investigators have evaluated alternative imaging techniques as compared to fluoroscopic guidance. Amoroso et al used CT with the patient in the prone position to identify the location of S3 foramina and guide electrode placement.(439) Thirty patients underwent PNE under CT guidance. Electrode placement through the S3 foramen was successful at the first attempt in 36/38 attempts (8 patients had bilateral PNE test). Two cases required several attempts. In one patient who had a nonconsolidated sacral fracture, CT guidance enabled insertion of the electrode inside the only practicable foramen, which would probably not have been possible under fluoroscopic guidance. A positive response to the PNE was obtained in 18/30 patients (60%). The procedure lasted about 45 minutes. Other authors successfully used CT guidance for lead placement in small case series and recommend that it should be considered especially in patients with an altered anatomy in the sacral region.(440-443) (Level of evidence 4)

1.5. Unilateral vs Bilateral SNS

A retrospective study by Pham et al. (444) compared the success of the bilateral to unilateral neuromodulator lead placement in 124 patients undergoing screening for permanent placement of sacral neurostimulation. Fifty-five (44%) patients underwent unilateral stage I lead placement and 69 (56%) received bilateral S3 leads. Successful stage I trials were reported in 32/55 (58%) and 53/69 (76%) of unilateral and bilateral cohorts, respectively (P = 0.03). There was no difference in wound infection or other complications.

In a prospective randomised crossover trial, Scheepens et al investigated 33 patients who underwent bilateral implantation of a temporary test lead.(445) Patients were randomly assigned to start with bilateral or unilateral stimulation. Eight patients were excluded due to lead migration. Of the 25 patients included in the analysis, 12 patients had UI and 13 had urinary retention. A significant and comparable improvement of symptoms was seen during the test stimulation for both the bilateral and unilateral stimulation. Two patients with urinary retention only

started voiding to completion during bilateral stimulation. The authors concluded that bilateral is in general not superior to unilateral SNS but a few individuals may have improved results with bilateral stimulation.

A recent randomized single-blinded crossover study failed to demonstrate superior results with bilateral SNS compared to unilateral stimulation for faecal incontinence.(446)

(Level of evidence 2/3)

1.6. SNS and Different Programming Parameters

A crossover study evaluated the effect of three different stimulator settings on OAB symptoms and AEs.(447) Patients in this study had an SNS implant with a tined lead for at least three months prior to the start of the study. Twelve women were randomised to one of three rate-setting sequences: 5.2, 14, and 25 Hz. Each rate setting was tested for 1 week in every subject. Rate had a significant effect on the number of incontinent episodes ($P < 0.001$) and number of pad changes ($P = 0.039$) with more incontinent episodes in the 5.2-Hz setting compared to the 14- and 25-Hz settings ($P < 0.04$) for both measurements. The number of AEs was similar across the three rate settings with programming-related AEs lowest in the 14 Hz group.

Hoen et al evaluated the effect of intermittent SNS (iSNS) in OAB patients.(448) In this prospective cohort study, 19 women who had received a SNS implant for refractory UI for a minimum of 6 months, had their neurostimulator programmed to 8 hr "on" and 16 hr "off" per day, for 12 weeks. Prior to iSNS, data were collected during no SNS and continuous SNS (cSNS). Twelve (63%) patients showed an improvement of >50% of incontinence episodes during iSNS compared to pre-SNS, of which seven (37%) had an improvement of > 90%. iSNS was superior to pre-SNS in incontinence episodes/24 hr, voiding episodes/24 hr and voided volume. The UDI-6 and the IIQ-7 scores were also improvemed during iSNS compared to pre-SNS. No difference was demonstrated between iSNS and cSNS, indicating that iSNS could be a cost-effective alternative prolonging battery life of the IPG. (Level of evidence 3)

1.7. Long Term Results for OAB

The long-term results of SNS have been addressed by several case studies. It is important to highlight that most studies reporting on long term data refer to older SNS technology and it is possible that with the newer techniques used, efficacy and complication/re-intervention rates will improve.

De Groen et al (449) evaluated the long-term results of SNS in 60 patients with refractory UI. Patients were assessed prospectively at regular intervals for at least 5 years after implantation. The success rate gradually decreased from 52 patients (87%) at 1 month to 37 (62%) at 5 years. Complete continence persisted in 15% of patients. The analysis was extended to the 41 patients who passed the 10-year follow-up. At least 25 of these women (61%) were still on active SNS. The 10-year success rates did not appear to be different from the 5-year results suggesting that a deterioration of the results is observed during the first 5 years, which stabilised thereafter. A total of 57 AEs occurred in 32 (53%) patients, the majority of those being related to hardware failure and pain or discomfort at various sites. A total of 23 reoperations, including 2 explantations, were done in 15 patients (25%). Different long-term studies evaluated the same groups of OAB patients and reported that, at 5 years post-surgery, greater than 50% improvement was achieved by 68% of those with UI and 56% of those with UF (450-452).

A number of retrospective studies reported on the long term efficacy of SNS for different urological conditions. Peeters et al reported on 217 patients with a mean follow-up of 47 months.(453) The success and cure rates for UI were 70% and 20%, and for UF were 68% and 33%, respectively. In those with unsuccessful outcome, the mean time to failure was 24.6 months after implantation. At least one re-intervention was needed in 88 (41%) patients, most of which (47%) were performed within the first two years of follow up.

In the InSite study, an ongoing multicentre prospective study, authors evaluated the success rates of SNS at 12 (434) and 36 months (427). A total of 340 subjects went through test stimulation and 272 were implanted with SNS. Of these, 91% were female with a mean age of 57 years. UI subjects had an average of 3.1 leaks/day. The completers analysis included all subjects with diary data at baseline and 12 or 36 months and showed a sustainable effect of SNS through 36 months, with a mean reduction of 2.2 leaks/day after 12 months and 2.3 leaks/day after 36 months ($P < 0.0001$). Subjects showed significant improvements from baseline in all measures of ICIQ-OABqol and 80% reported improved changes in their urinary symptom interference at 12 and 36 months.

Device-related AE's occurred in 16% (56/340) of subjects during test stimulation, 30% (82/272) of subjects 12 months post-implant and 47% (127/272) after 36 months. The most frequent AE types reported were undesirable change in stimulation (49/272, 18%), implant site pain (34/272, 13%), and therapeutic product ineffective (16/272, 6%). Lead migrations were reported in 4% of subjects (12/272), with the majority occurring between 12 and 24 months post-implant. Implant site infections were reported in 4% of implanted subjects (10/272), with half reported between the implant procedure and 3 months post-implant. Surgical interventions related to the neurostimulator, lead, or chronic extension were experienced in 32% of subjects (86/272) after implant. The rate of device replacement was 20% (55/272) and device revision was 4% (11/272). Surgical interventions due to battery replacement occurred in 11% (29/272) of subjects, and 93% (27/29) of these neurostimulators were assessed to be within the expected longevity

ranges based on the set parameters of the device. In total, 13% (34/272) of subjects underwent permanent explant. The top reason for permanent explant was due to an AE (8%). Other reasons were lack and/or loss of efficacy in 3% (9/272), subject's need for magnetic resonance imaging and "other".(Level of evidence 2)

Although the medium/long-term clinical efficacy of SNS has been demonstrated by several case series, its impact on patient satisfaction and improvement of QOL has not been clearly defined bearing in mind that there are technical problems and adverse effects requiring constant medical attention and surgical revisions in a significant proportion of patients. Leong et al (454) examined the long-term satisfaction of patients with an implanted SNS for various medical indications such as OAB syndrome, non-obstructive UR, combined OAB and UR, and pelvic pain. Overall, 275 patients received a postal questionnaire regarding satisfaction and experiences with the system, such as side effects, complications, burden, impact on sexuality and defecation changes. The response rate was 75% (207 patients) with a median post-implantation period 77 months (range 12 to 214). The patient satisfaction rate was high at 90% and significantly related to the perceived clinical effect and 85% of all explanted cases (13 patients) were considered as failures. Satisfaction had no direct relationship with patient age, gender, duration of therapy or type of complaint for which SNS was offered, but was lower in patients with more than 1 pelvic floor comorbidity. The patient's attitude towards yearly follow-up and the ability to use the programmer was positively related to the degree of satisfaction. Overall 40% reported having some limitations or concerns with SNS such as exclusion from MRI and passing through metal detectors. Most patients perceived regular pain (56%) and discomfort (40%). (Level of evidence 3)

1.8. Effect of SNS on Sexual Function

The effect of SNS on female sexual function (FSF) has been investigated in a number of studies. Lombardi et al have recently reviewed nine studies that investigated the impact on sexual response when the aim of the SNS was to resolve urinary symptoms mainly due to OAB (seven studies) or fecal incontinence.(455) Most women included were of menopausal age. Three studies included sexually inactive women. Post-SNS follow-up varied from 3 to 36 months. Meta-analysis of efficacy results was not possible due to the heterogeneity of the sexual and pelvic dysfunctions. The most specific questionnaire assessing FSF was the Female Sexual Function Index (FSFI), which was used in six studies. During follow-up women showed statistically significant improvement in at least one FSFI domain compared to baseline. In one study significant improvement in the FSFI pain domain was exclusively detected in women with neurological disease. Two studies, however, using the questionnaire to screen for sexual dysfunction did not find any statistically significant differences after SNS. Authors concluded that available data were still insufficient to definitely assert the positive effect of SNS on FSF.

In the InSite study, FSF was investigated as a secondary outcome measure. Women who underwent SNS had a greater improvement in sexual function based on the Female LUTS-sex questionnaire than those treated with SMT after 6, 12 and 36 months.(427, 430, 434) (Level of evidence 1-2)

1.9. Predictors of Outcomes

Authors have investigated a number of possible predictors of success for SNS in OAB patients, including age, severity of incontinence, obesity, prior medication use, previous spinal surgery, urodynamic findings and other.

Davis et al showed comparable success rates at the testing phase for patients who presented for SNS because of lack of medication efficacy versus intolerable medication side effects (70% and 71% respectively).(456)

Yazdany et al also reported on testing phase success in a group of patients with severe incontinence (mean 10.4 episodes/day); the authors note that patients with >10 incontinence episodes per day were more likely to have a successful stage I trial compared to those with less than 5 episodes/day.(457)

Levin (2012) reported on the impact of obesity on stage I success rates.(458) Of 149 patients, 80 (53.7%) were obese (BMI mean 37.3) and 69 (46.3%) were non-obese (BMI mean 25.6). The overall stage I success rate was 81% and the success rates for non-obese patients (83%) was comparable to rates for obese patients (78%).

Peters et al. evaluated the impact of age on the outcomes of SNS.(459) They analysed urologic diagnosis, rate of IPG placement, complications, and revisions from medical records of adults enrolled in a prospective observational study. Urge incontinence was predominant in the older groups and more patients <40 years had IC/PBS. A total of 266 patients had a sacral lead placed. In this group, the rate of IPG implant (89-90%) and explant (9.3-13%) did not vary between different age groups (<40 years, 40-64 and >/=65) but there was a tendency for higher complication rates in younger patients (23% vs. 15% vs. 8.5%, respectively; P= 0.08). Angioli et al reported their results of SNS in patients older than 65 years (mean patient age 76 years).(460) At 12 months post-implant, 27.8% of patients reported improvement and 55.5% of patients reported complete success with cessation of UUI episodes. Overall, UUI episodes decreased from mean 6.3/day to mean 0.5/day. Incontinence episodes, frequency, nocturia, and number of pads used daily also significantly decreased. All subscales of the OAB-q were significantly improved.

Peters et al evaluated predictors of reoperation after SNS in a single centre retrospective study.(461) Of a total of 407 patients, 134 (33%) had at least one re-

operation over a median follow-up of 28.9 months, including 78/407 (19%) revisions and 56/407 (14%) explantations. The most common reason for reoperation was lack and/or loss of efficacy (65%). On multivariate analysis, only longer follow-up (P = 0.0011; OR 1.048; CI 1.019, 1.078) and having a complication (P < 0.0001; OR 23.2; CI 11.47, 46.75) were significant predictors of reoperations. (LE=3)

The role of urodynamics as a predictor of outcome for SNS has been evaluated by different authors. Groenendijk et al reported on 111 patients with UI undergoing permanent SNS after a successful PNE test of whom 67 had, and 44 did not have, DO on urodynamics. (462) Both groups improved bladder volumes at first sensation of filling and at maximum fill volume compared with baseline. Resolution of DO post treatment occurred in 51% of patients, however the success in those patients was not significantly different from those with persistent DO. Interestingly patients with UI and no DO had a higher rate of clinical success (73%) than those with UI and DO (61%), although this did not reach statistical significance.

South et al had similar results evaluating 104 patients with refractory UI who underwent SNS test stimulation and compared responders to the test stimulation and non-responders. (463) There was no relationship between the presence or absence of DO and the likelihood for test stimulation success.

Drossaerts et al. explored the predictive role of conventional and ambulatory urodynamics for SNS outcome.(464) Over a period of more than ten years, 98 patients who performed conventional and ambulatory urodynamics and underwent SNS test were evaluated. They found similar success rates for SNS in patients with storage dysfunction according to either conventional-UDS or ambulatory-UDS. However, conventional-UDS overestimated the amount of patients diagnosed with hypocontractile or acontractile bladder, for whom SNS success rates were 67 % and 35 %, respectively. According to ambulatory-UDS diagnosis, success rates for patients with reduced bladder contractility were much lower, with 32 and 17 %, respectively for hypocontractile and acontractile bladder. (LE= 3)

1.10. Magnetic Resonance Imaging (MRI) Recommendations

MRI is a relative contraindication for patients who may be considering or who have an implantable electrical stimulation device. Magnetic fields produce currents in neuroelectrodes and heating of the leads has been demonstrated in vivo and in vitro.(465, 466) Whereas the clinical significance of the small temperature changes observed in the leads is questionable, the potential exists to produce nerve damage, and the magnetic field may change the generator itself.(467) There is limited evidence that MRI may be performed with no harm to the patient based on few case reports or small case series that have reported on the use of MRI under very specific conditions.(468, 469)

For patients who have InterStim devices in place, current manufacturer recommendations advocate removal of the device in preparation for elective MRI.(470) The only exception are patients who received the new models of Interstim II, who may be eligible to have MRI examinations of the head only. However, the manufacturer indicates that it must be performed under specific conditions. Before ordering a head MRI for a patient with a SNS system, it is important to certify his eligibility with the manufacturer support team or review the MRI Guideline for the Interstim Neuromodulation Systems. (Level of evidence 5)

1.11. Pregnancy

Electrical stimulation has the potential to induce teratogenicity or abortion and SNS has been considered contraindicated in pregnant women. However, whether electrical stimulation can cause abortion or malformation is not known. Wang and Hassouna (471) reported no adverse effects of electrical stimulation on pregnant rats. They counseled that termination of pregnancy is not advised for prospective mothers when electrical stimulation has been performed unknowingly in early pregnancy. Women with electrical stimulation devices for pelvic health conditions who become pregnant should turn off their devices during pregnancy. (Level of evidence 5)

1.12. Neurostimulation with Pudendal Nerve stimulation

Neurostimulation techniques other than SNS have been used for the treatment of different urological conditions with varying techniques and results.

Pudendal nerve efferent activation directed toward the urethral sphincter is an important mechanism for the control of bladder contractions. In addition, many of the sensory afferent nerve fibers contained in the sacral spinal nerves originate in the pudendal nerve. Thus, the pudendal nerve fibers are important targets for neuromodulating the inhibitory reflex on the micturition reflex.(472-476)

Pudendal nerve stimulation has been used with different techniques to treat numerous pelvic floor function impairments such as urinary and/or fecal incontinence, urinary retention and constipation. Spinelli and associates (477) modified existing SNS technology and adapted it to pudendal nerve stimulation. They performed a staged procedure similar to that of sacral neurostimulation (SNS) to place tined leads near the pudendal nerve, using neurophysiological guidance that allowed accurate pudendal nerve stimulation through either a perineal or posterior approach. Few trials using pudendal neurostimulation have been reported for patients with neurogenic voiding dysfunction (477), interstitial cystitis (478) and non neurogenic voiding dysfunction (479). Despite the good results reported, studies are based on small patient samples with short term follow up. (Level of evidence 3/4)

Summary

There is limited evidence for long term efficacy for SNS beyond 12-36 months.(LE = 2)

Maintenance of therapeutic effect requires reprogramming and surgical revision rate in a substantial number of patients. (LE= 2)

Preoperative predictors of optimal patient response to this invasive therapy remain unclear except for a positive response to PNE or staged implant (LE=2)

Recommendations

SNS is an effective therapy for selected individuals with urgency/frequency and UUI refractory to behavioural therapy and oral medications (Grade B).

Patients should be counseled regarding the potential for AEs, need for long term monitoring and intervention/adjustment of the implant, and additional surgeries to maintain favourable therapeutic effects. (Grade B)

2. PERCUTANEOUS TIBIAL NERVE STIMULATION (PTNS)

2.1. Mechanism of Action

The exact mechanism of action of PTNS on bladder function is unclear but it is thought to be mediated through the retrograde stimulation of the sacral nerve plexus. The posterior tibial nerve is a peripheral nerve with mixed sensory and motor fibers. It originates from spinal roots L4 through S3, which also contribute directly to sensory and motor control of the urinary bladder and pelvic floor. Current literature suggests that a plastic reorganisation of the cortical network triggered by peripheral neurostimulation could be a mechanism of action of PTNS.(480)

Based on translational findings of the traditional Chinese practice of using acupuncture points over the common peroneal or posterior tibial nerve to inhibit bladder activity, McGuire and associates (1983) used transcutaneous stimulation of the common peroneal or posterior tibial nerve for inhibition of DO.(481) PTNS (Urgent PC, Cogentix Medical) as approved by the FDA currently consists of weekly 30-minute stimulation treatments provided by insertion of a small-gauge stimulating needle approximately 5 cm cephalad from the medial malleolus and just posterior to the margin of the tibia with the grounding electrode pad placed on the medial surface of the calcaneus. Treatment usually consists of 12 weekly PTNS sessions followed by additional maintenance sessions.(482)

2.2. Efficacy

Recent studies have shown, with level of evidence I, that PTNS can effectively improve OAB symptoms (frequency, urgency, nocturia, and incontinence) and quality of life with no serious AEs in patients with refractory OAB. The 2015 AUA/SUFU Guideline Amendment for Diagnosis and Treatment of OAB (Non-Neurogenic) in Adults (483) recommends PTNS as a 3rd line treatment option for refractory OAB.

2.2.1 PTNS vs Placebo (Sham Device)

Peters et al in a multicentre, double-blind, RCT (SUmiT trial) compared the efficacy of PTNS to sham through 12 weeks of therapy.(484) A total of 220 adults with OAB were randomized 1:1 to 12 weeks of treatment with weekly PTNS or sham therapy. In the sham group, a Streitberger placebo needle was used to simulate the location and sensation of PTNS needle electrode insertion. In addition, two active TENS surface electrodes were placed and sham stimulation was performed. Patients were evaluated by OAB and QoL questionnaires as well as 3-day voiding diaries before treatment and at week 13. At 13 weeks follow-up there was moderate or marked improvement in overall bladder symptoms in 54.5%(60/110) and 20.9% (23/110) of subjects respectively ($p<0.001$). All individual symptoms such as frequency, nighttime voids, voids with moderate to severe urgency and UUI episodes were significantly improved from baseline to 13 weeks for the PTNS group compared to the sham group. This was also confirmed on voiding diaries. There were no serious AEs, with 4% (5/110) reporting bleeding and discomfort at the needle site, one case of ankle bruising, and one with leg tingling.

In a double-blind RCT, Finazzi-Agro et al randomised 35 patients that did not respond to anticholinergics into PTNS or a control group.(485) The control group (17 patients) received an original placebo treatment using a 34 gauge needle placed in the medial part of the gastrocnemius muscle and stimulated for 30 seconds. Patients were considered to be responders if they had a reduction in UI episodes greater than 50%. After 12 weeks of weekly treatments, 71% (12/17) in the PTNS group and 0% (0/12) in the placebo group were considered responders ($p < 0.001$). The number of UI episodes and voids, voided volume, and I-QoL score significantly improved only in the PTNS group. (Level of evidence 2/3)

2.2.2 PTNS vs Antimuscarinics

A multicentre RCT showed comparable efficacy of PTNS to medical treatment (OrBIT trial).(486) A total of 100 adults with OAB (urinary frequency > 8 times/day) were randomised 1:1 to 12 weeks of treatment with weekly PTNS or to 4 mg daily extended-release tolterodine. Voiding diaries and an OAB questionnaire were completed at baseline and at the end of therapy. Global response assessments (GRA) were completed by subjects and investigators after 12 weeks of therapy. At 12 weeks, 79.5% (35/44) of the PTNS and 54.8% (23/42) of the tolterodine patients considered themselves to be cured or improved ($p=0.01$). Urinary frequency, UI episodes, urgency severity, nighttime voids, voided volume and QoL improved significantly in both groups.

A long-term follow-up of the OrBIT Trial evaluated the durability of PTNS benefits.(487) Patients who were randomised to weekly PTNS in the OrBIT trial were offered an additional 9 months of treatment with assessments at 6 and 12 months from baseline. A total of 33 PTNS responders continued therapy with 32 and 25 subjects completing 6 and 12 months of therapy, respectively. Subjects received a mean of 12.1 treatments at various intervals during an average of 263 days, with a mean of 21 days (median 17) between treatments. Sustained improvement was shown with 94% (30/32) of patients continuing periodic treatment considering themselves to be cured or improved at 6 months and 96% (24/25) at 12 months follow-up. OAB questionnaire symptom severity was significantly improved from 12 weeks to 12 months as well as from 6 to 12 months (both $p < 0.01$). No serious AEs were reported. (LE= 2)

In a recent RCT, Preyer et al randomised 36 patients with OAB to 3 months treatment with PTNS weekly or tolterodine 2mg twice a day.(488) Micturition frequency did not decline significantly in either group. QoL scores showed improvement over time compared to baseline measurements but no significant differences between treatment groups ($p=0.07$). UI episodes/day significantly declined during therapy in both groups comparably ($p=0.89$). PTNS had fewer side effects than tolterodine ($p=0.04$).

In a randomised controlled crossover study, Vecchioli-Scaldazza et al divided 40 women in two groups – A) 20 patients received solifenacin succinate (SS) 5mg/day for 40 days, then went on a 3 month washout period followed by PTNS (twice a week for 30 minutes for a total of 6 weeks); B) 20 patients received PTNS, then went on a 3 month washout period followed by the same SS therapy.(489) Micturition diary, OAB Questionnaire Short Form and Patient Perception of Intensity of Urgency Scale were used to assess patients and were completed before and after each treatment. A reduction in the number of daily micturitions, episodes of nocturia and urge incontinence were found with both SS and PTNS in all groups, but PTNS showed greater effectiveness than SS. PTNS also showed a greater effect in patient perception of urgency and QoL. (Level of evidence 2)

2.2.3 Systematic Reviews and Meta-Analyses

Six systematic reviews (490-495) of which two provided meta-analysis (494, 495) concluded PTNS improves OAB symptoms with success rates varying from 37% to 100%. Definition of success was variable across studies. Overall, these reviews showed that PTNS is better than sham procedures or placebo with minimal AEs (painful sensation during procedure without interfering with it and minor bleeding at insertion site) and comparable to antimuscarinics.

Burton et al in a meta-analysis of four RCTs where PTNS was compared to placebo demonstrated that all studies favour PTNS over sham procedures, with overall risk ratio of 7.02 (95% CI of 1.69–29.17).(494) PTNS treated patients were seven times more likely to be successful in treatment when compared to placebo treated patients. Compared to antimuscarinic treatment, PTNS showed comparable efficacy results. Wibisono et al also provided a meta-analysis with similar results, based on four RCTs comparing PTNS to sham procedures.(495) When PTNS was compared to antimuscarinics both groups showed significant reduction of symptoms with no significant difference. (Level of evidence 1)

2.2.4 Functional assessment

Musco et al in an observational prospective study assessed female sexual dysfunction (FSD) in patients with dry OAB.(498) They completed the FSFI to assess sexuality, the OAB short-form questionnaire and a 24-hour bladder diary at baseline and at the end of the PTNS treatment, 3 months later. Twenty-one women were considered to have FSD. FSFI domains showed significant improvement in FSD symptoms. Women without FSD at baseline also reported statistically significant improvement in their sexual function based on FSFI scores. (LE=3)

2.3. Long Term Data / Maintenance Therapy

Peters et al reported outcomes in patients that met the primary effectiveness end point of the SUmiT trial and were willing to enroll in a 36 month protocol, the STEP (Sustained Therapeutic Effects of Percutaneous Tibial Nerve Stimulation) Study.(482) A total of 29 patients completed the 36 month protocol receiving a median of 1.1 treatments/month. At 3 years, 77% (95% CI 64-90) of patients maintained moderate or marked improvement in OAB symptoms. Median voids/day decreased from 12.0 to 8.7, nighttime voids decreased from 2.7 to 1.7 and UI episodes/day decreased from 3.3 to 0.3 (all $p < 0.0001$), when compared to baseline numbers. All QoL parameters improved when compared to baseline through all 3 years (all $p < 0.0001$). No serious AEs were reported.

Yoong et al (496) reported a long-term (2 years) follow-up of 23 women from a previous study (497) who had a positive response to PTNS treatment. Patients in this follow-up study were instructed to contact the hospital to undergo maintenance PTNS treatment whenever they felt it was required. At 2 years from the beginning of the treatment, patients were assessed with diaries and the IIQ-7 and were compared to baseline and initial response to treatment at 6 weeks. Urinary frequency, UI, nocturia, pad use, and IIQ-7 scores were comparable to those recorded after initial responses to treatment at 6 weeks. Patients received a median of 8.4 treatments/year and median time between treatments was 64.3 days. Only one patient reported hypoaesthesia in the toe lasting 4 months. (LE=2)

Summary

PTNS shows efficacy in the treatment of OAB with no serious AEs in the short/mid term (LE=2)

There is limited evidence for long term efficacy.(LE = 2)

PTNS is superior to no therapy/sham, and at least as effective as drug. (LE=2)

Recommendations

PTNS is an effective therapy for selected individuals with refractory OAB who are willing to comply with the PTNS protocol in the short/mid term. (Grade B)

Patients should be counselled regarding the need for frequent office visits during the initial treatment phase as well as the likelihood in needing maintenance treatments, and the lack of long term data as a stand-alone treatment and vs. other therapies. (Grade B).

3. AUGMENTATION (ENLARGEMENT) CYSTOPLASTY

Augmentation cystoplasty (AC), has been used for many years with varying degrees of success for refractory DO and related incontinence.

3.1. Enterocystoplasty

Enterocystoplasty is the main form of AC and involves a segment of the bowel that is removed from continuity with the fecal stream, detubularised, and patched into the bisected bladder. This method increases bladder capacity and decreases bladder pressure caused by uninhibited detrusor contractions. Virtually any portion of the GI tract can be utilised for enterocystoplasty, and each segment has its own unique favourable properties as well as inherent complications.(499-503)

Other than idiopathic OAB, indications for enterocystoplasty include mainly small capacity bladders due to fibrosis, tuberculosis, radiation, chronic infection or neurogenic DO (NDO).(500, 501, 504, 505) AC has been used as a last resort in cases of refractory OAB. With the introduction of third line therapies such as SNS and the intradetrusor injection BTX-A, there has been a dramatic decline in the use of AC and only one addition to the literature for idiopathic OAB since the publication of the 5th International Consultation on Incontinence (see below).

3.1.1 Efficacy and safety:

At present there is no RCT published to compare the efficacy and safety of AC with other methods. The 2015 AUA/SUFU Guideline Amendment for Diagnosis and Treatment of OAB (Non-Neurogenic) in Adults recommend that AC should only be considered in extremely rare cases. (483)

In a recent study, El-Azab et al (506) compared patient satisfaction with AC versus intradetrusor injection of BTX. A total of 31 patients were allocated to each treatment group based on personal preference, including 16 for BTX (nine men and 7 women) and 15 for AC (four men and eleven women). In a short-term follow-up of six months, significant improvements in LUTS and QoL were observed after both treatments based on the UDI-6, IIQ-7 and OAB-Sat questionnaires. Improvements in symptoms and QoL were greater in patients who underwent AC. Those undergoing AC had worse scores in the UDI-6 question regarding difficulty for voiding (1.7 vs 0,81 for the BTX group; p= 0.004). Four (26.7%) patients required CIC after AC and two in the BTX group. The need for repeat treatments to maintain symptom control was the primary reason for dissatisfaction in those who received BTX. (LE= 4)

Apart from the inherent risks of open, laparoscopic or robotic abdominal surgery associated with bowel and bladder anastomoses, AC carries several distinct long-term risks. The risks of this surgery include kidney or bladder infections, new-onset recurrent UTIs, metabolic derangements, mucus production, and, in rare cases, bladder tumours.(507, 508) As a segment of bowel is used for AC, the available absorptive surface area of the bowel is reduced, and the incorporation of bowel segments into the urinary tract may have metabolic consequences.(509) Hyperchloraemic metabolic acidosis can occur if ileal and/or colon segments are used, as well as malabsorption of vitamin B12 and bile acid after the use of ileal segments. Blackburn et al demonstrated a reduction in serum B12 level with time following ileocystoplasty in 44% of their patients at 7-year follow-up and recommended that these patients should have their B12 levels measured in the long term.(510)

There has been concern about the incidence of secondary malignancies that may develop as a long-term consequence of bladder augmentation. The carcinogenesis pathway is still not clearly understood but several factors are involved. In a recent study, Biardeau et al systematically reviewed the evidence regarding the risk of malignancy after AC. The probability to develop a malignant tumour after AC ranged from 0 to 5.5% and the estimated incidence ranged from 0 to 272.3 per 100,000 patients/year. Adenocarcinoma was the commonest (51.6%) histological type. Malignant lesions predominantly occurred at the entero-urinary anastomosis (50%). The mean latency period was 19 years and most tumours were diagnosed more than 10 years after AC (90%). Long-term surveillance by cystoscopy is still controversial because of its lack of efficiency. Tumours were often diagnosed at an advanced stage within surveillance protocols, because of urinary tract related symptoms (64.1%). The authors recommended that studies regarding carcinogenesis and surveillance strategies should be performed to develop a more efficient follow-up protocol and allow early diagnosis. The authors cautioned that the level of evidence of the studies was usually poor and results should be interpreted with caution. (LE=4)

3.1.2 Other Evidence:

The conclusions of recent reviews on the role of AC indicate that the overwhelming predominance of literature is dedicated to AC in patients with a neurogenic bladder.(503, 511) The few reports in the literature

that have examined the results of AC in adults with idiopathic OAB are case series (LOE=4). Since the publication of the 5th International Consultation on Incontinence, there has been only one addition to the AC literature for iOAB. The studies differ in several ways. Most include both males and females, and some include patients with NDO. Additionally, length of follow-up differs widely and success definitions may be different and inconsistently reported. Outcome measures have included mostly non-validated questionnaires and subjective patient assessments. Furthermore, continence rates must also be considered with caution, since many procedures are combined with bladder outlet surgeries.

Several variations on the standard AC have been described, most of which were applied to children or adult patients with neurogenic DO or contracted bladders. These include novel bowel options such as urothelium lined seromuscular colocystoplasty and an appendicular-based caecal flap (512-514). Techniques using robotic assisted laparoscopic surgery (RALS) and laparoendoscopic single site (LESS) procedures have also been introduced and have further added to the surgical options for AC.(515-519) While the initial results are encouraging, long-term outcomes are uniformly absent. Overall, due to its invasive nature and potential for long-term adverse effects, AC is considered to be one of the last choices of treatment in refractory IDO cases.(483)

Summary

There have been no randomised controlled trials, double blind or sham-controlled trials or long-term cohort studies which have examined the effects of enterocystoplasty for the treatment of idiopathic OAB. (LE=4)

Recommendations

Enterocystoplasty for idiopathic OAB should only be considered in rare cases where other therapies have been deemed unsuccessful or are not applicable. (GRADE D)

Patients undergoing enterocystoplasty should be counselled regarding the potential life altering changes postoperatively (e.g. need for self catheterisation, etc.) and the need for long term follow-up. (GRADE D)

3.2. Autoaugmentation

Initially described by Cartwright and Snow, auto augmentation of the bladder was developed as an alternative option to AC, especially in children with neurogenic DO.(520, 521) Auto augmentation may be performed by incision (detrusor myotomy) or excision (detrusor myectomy) of a portion of the detrusor muscle and may also be named as vesicomyotomy (522) or detrusorectomy (523). Either technique aims to create an iatrogenic bladder mucosal “bulge” or pseudodiverticulum and an increase in the storage capacity of the bladder with a concomitant decrease in storage pressures. The advantages of detrusor auto augmentation over enterocystoplasty is the avoidance of complications related to the use of bowel in the urinary tract including malignancy, mucous formation, stones, surgical morbidity related to opening and reanastomosis of the GI tract, and metabolic acidosis.(505, 524, 525)

3.2.1 Evidence

There have been no randomised controlled trials, double blind trials or cohort studies which have examined the effects of auto-augmentation as a treatment for non-neurogenic DO incontinence.

There are few studies on auto-augmentation in the adult non-neurogenic population and there have been no additions to the literature since the publication of the 5th International Consultation on Incontinence.

One small study of 5 patients with urgency incontinence showed promising results in all patients at the initial postoperative visit, but clinical deterioration and failure occurred in 4 of the 5 patients at three months follow-up.(522) Mean bladder capacity increased but mean volume to first involuntary bladder contraction decreased. Four of the 5 patients continued to have involuntary bladder contractions on cystometry. One additional retrospective study including 61 patients with NDO and IDO compared detrusor myectomy to AC.(526) Comparable clinical success was reported for the two procedures; however, there was a 22% incidence of serious complications in the 27 patients undergoing AC, compared to only 3% of the 33 patients undergoing detrusor myectomy. (LE= 4)

In an attempt to improve long-term outcomes with this procedure and create a biological “backing” and blood supply for the pseudodiverticulum, a number of variations of this procedure have been described. These variations have included the use of demucosalised bowel segments, stomach, peritoneum and rectus abdominis muscle.(524, 527-531) Additionally, the use of an inflatable balloon placed in the bladder for 2 weeks after auto-augmentation improved long-term capacity and compliance.(532) Long-term follow-up demonstrating favourable clinical results with these variations is lacking. This technique is no longer considered as an option for surgical management of DO.

Summary

There have been no randomised controlled trials, double blind or sham-controlled trials or long-term cohort studies which have examined the efficacy and safety of autoaugmentation for the treatment of adult idiopathic OAB. (LE=4)

Recommendation

Autoaugmentation is not recommended as a therapy for adult idiopathic OAB.

(GRADE D)

III.URETHRAL DIVERTICULA

Urethral diverticulum (UD) is an outpouching of the urethral lumen into the surrounding periurethral connective tissue. This is a relatively rare condition with an annual incidence of 17.9/1,000,000 in a recent study(533). UD are thought to arise from repeated obstruction, infection and subsequent rupture of periurethral glands into the urethral lumen, resulting in an epithelialised cavity that communicates with the urethra(534, 535). Iatrogenic damage to the urethra may also play a role, as up to 20% of women with urethral diverticula are noted to have a history of prior urethral surgery, dilation, or traumatic delivery(534, 536). Iatrogenic UD formation associated with MUS has also been reported(537-539).

1. UD AND URINARY INCONTINENCE

Although the presentation of UD is often non-specific and variable, these lesions can be associated with voiding dysfunction and urinary incontinence. One recent series reported stress urinary incontinence (SUI) occurring in 60% of patients with UD(540). Other presentations include vaginal mass, irritative LPP, and recurrent urinary tract infections(540, 541). Up to 20% of patients lack symptoms, with UD being an incidental finding on imaging.

A UD is most often located at the level of the midurethra. This location often overlaps with the external sphincter, however UD may also extend proximally toward the BN in the vicinity of the proximal sphincter mechanism. This morphology may, in part, explain the association between UD and SUI in some individuals with potentially more proximal lesions at risk for postoperative SUI (542). Alternatively, some patients may have pre-existing SUI unrelated to the UD, or may simply have post-void dribbling and paradoxical incontinence due to urine accumulation in the UD during normal voiding with subsequent discharge of the accumulated urine in the UD out through the urethral meatus upon movement.

UD may also be associated with bladder outlet obstruction due to the mass effect of the UD, urinary retention, or irritative LPP including urgency and urgency incontinence (543). Pain and dysuria associated with UD may also result in acquired voiding dysfunction.

Surgical treatment of UD may also be associated with urinary incontinence. Although resolution of UI may occur following surgical excision UD, either as a result of elimination of post-void dribbling/paradoxical incontinence, reconstruction of a damaged sphincter mechanism during UD repair, or concomitant anti-incontinence surgery (e.g. sling), de novo UI may also occur. Certain features seen on preoperative imaging may predict for recurrence of UD postoperatively or postoperative complications such as de novo or persistent SUI. Risk factors for de novo SUI may include the size of the diverticulum (>30 mm), more proximal location (542, 544), and wide excision (544). Another important cause of UI postoperatively from urethral diverticulectomy surgery is iatrogenic urethrovaginal fistula, which may occur in up to 6% of cases (534, 536, 541, 542, 544, 545).

2. PREOPERATIVE ASSESSMENT INCLUDING URODYNAMICS

Careful history, physical examination, and appropriate diagnostic studies are often pursued in the evaluation of the suspected UD. Cystourethroscopy will most commonly reveal the ostia of the UD in the dorsolateral midurethral segment. Imaging modalities including ultrasound, voiding cystourethrography, CT, and MRI have a role in defining the anatomy of the UD and, perhaps, planning surgical intervention.

Pressure flow urodynamics may have a role in the preoperative assessment of patients with UD and co-existing voiding dysfunction or urinary incontinence (546-549). Urodynamics may evaluate for co-existing detrusor dysfunction or document the presence or absence of SUI or obstruction prior to repair. Approximately 50% of women with UD will demonstrate SUI on urodynamic evaluation (550, 551).

Urethral pressure profilometry has also been utilised by some authors in the assessment or diagnosis of UD noting a biphasic pattern, or pressure drop at the level of the lesion during the study (547, 549, 552).

Videourodynamics may be helpful in differentiating SUI from paradoxical UI due to fluid accumulation in the UD. In addition, resting and straining images obtained during fluoroscopic imaging may document an open BN at rest, suggesting a compromised proximal sphincter mechanism in some patients. This may be a consideration in some patients with an extensive UD at the level of the midurethra and potential implications for postoperative incontinence due to compromise of both sphincter mechanisms.

3. UD AND STRESS URINARY INCONTINENCE

Patients with symptomatic, bothersome SUI in association with UD can be offered simultaneous anti-incontinence surgery. Although historical series have shown good results with concomitant BN suspension (551), more contemporary series have utilized pubovaginal fascial slings in patients with UD and SUI with satisfactory outcomes (553-556). Midurethral synthetic slings are not recommended as a concomitant, anti-incontinence procedure at the time of urethral diverticulectomy (557). Synthetic material adjacent to a fresh suture line following diverticulectomy in the setting of potentially infected urine may place

the patient at higher risk for subsequent urethral erosion and vaginal extrusion of the sling material, as well as urethrovaginal fistula formation and foreign body granuloma formation (EL=4).

Significant postoperative de novo SUI may occur in 7-16% of individuals undergoing urethral diverticulectomy surgery without a concomitant anti-incontinence procedure (542, 544, 558). However, Lee et al. noted at least some de novo SUI in 49% of patients following urethral diverticulectomy, the majority of which was minor and did not require additional therapy (559). Only 10% of these individuals underwent a subsequent SUI operation. UD may mask SUI due to mass effect especially when the UD is proximal and greater than 3 cm in size(560). De novo SUI may arise from the extensive suburethral or circumferential dissection required for a large UD, and the more proximal UD location may compromise the urethral sphincter BN anatomical support and the sphincter mechanism (542). Alternatively, large UD at the BN may cause obstruction (543), and occult SUI may be unmasked after removing the obstructing UD (561). Nickels et al. report de novo SUI in 1/11 (9.1%) after complex UD repair and 1/32 (3.1%) after simple UD repairs, noting a significantly higher rate of concomitant PV sling with complex repairs (541).

4. UD AND UUI

Stav et al. reported rates of storage symptoms decreased significantly postoperatively from 60% to 16% following UD surgery (542). Other series with long term follow-up, however, have demonstrated rates of postoperative urgency of 54% (545), and de novo urgency incontinence in 36% of patients (544). Such symptoms postoperatively may herald UD persistence, UD recurrence, or de novo urethral obstruction.

5. SUMMARY

The evidence pertaining to UD and urinary incontinence consists of retrospective, small- to medium-size case series with limited follow-up demonstrating that urinary incontinence and other voiding dysfunction is significantly associated with this condition (Evidence Level=3).

6. RECOMMENDATIONS

Patients with UD should be carefully questioned and investigated for co-existing voiding dysfunction and urinary incontinence. (Grade C)

Following appropriate counselling, bothersome SUI can be addressed at the time of urethral diverticulectomy with concomitant non-synthetic sling (Grade C)

Patients should be counselled regarding the possibility of de novo or persistent LUTS including urinary incontinence despite technically successful urethral diverticulectomy. (Grade C)

IV. CONFOUNDING VARIABLES

The purpose if this review is to update the previous report on confounding variables published in the 5th consensus report. A Medline search from 2012 along with any updates from NICE guidelines and from Cochrane were examined. The subdivision of variables is consistent with the previous report and serves as an update although some of the previous prose has been included in this update.

1. AGE

The previous report highlighted the data from Medicare Australia examining (562) stress incontinence procedures from 1994 – 2009. The number of procedures performed for SUI doubled in the three year period after the introduction of midurethral tapes. Over the 15 year period there was an 87% increase in procedures performed in women over 55 years old compared to a 1% increase in younger women.

Although less commonly performed both PVSs and colposuspension remain efficacious procedures for stress urinary incontinence. The Stress Incontinence Surgical Treatment Efficacy study investigated the effect of age on both perioperative and postoperative outcome of both procedures in 659 women (563). The older group (mean age 69.7 years) were compared with a younger group (mean age 49.4 years). Overall older women took longer to return to normal activities (50 vs 42 days; p=0.05) but there were no difference in return to normal voiding. The older group were more likely to have a positive stress test at follow up (OR 3.7;95%CI: 1.70-7.97; p=0.001), less subjective improvement in both stress and urgency symptoms and were also were more likely to require repeat surgery (OR 3.9; 95%CI: 1.30-11.48).

Toozs- Hobson et al (564) have recently published data collected from the British Society of Urogynaecology database to assess the impact of age on success rates and insertion complications of suburethral tapes used as primary procedures using the Patient Global Impression of Improvement (PGII) as the primary endpoint. 7600 cases were identified of which 757 were performed on women over 70 years of age and 119 on women over 80 years. Approximately 80% were PVS and 20% TO procedures. Short follow up was available for 54% of cases. The PGII remained high in all age groups but did decrease with age with 90% of women under 50 scoring highly to 70% 0f women over 80 scoring highly. Short term voiding was seen more frequently in the older group but there was no other increase in complications with age. Other studies have also confirmed increased short term voiding difficulty (110).

Malek et al (565) conducted a retrospective cohort study of women undergoing primary MUS surgery comparing women 70 years or older (mean age 75.4+- 4.5) with those under 70 years (mean age 56.2 +- 9.4) . Multivariable analysis revealed no difference in SUI failure rates (adjusted OR 1.7 95%CI 0.9-3.1). Women under 70 demonstrated greater improvement in the impact of urinary symptoms and women 70 and over had greater persistence of UUI.

The actual published information on surgery for stress incontinence in older women is quite sparse. A systematic review published in 2014(566) searched the literature from 1966 to October 2013.They included randomised controlled trials and prospective non-randomised studies. The population examined included those 65 years or older and they looked at sling procedures, bulking agents, artificial sphincters, onabotulinum toxin A injections and sacral neuromodulation. Only five studies fulfilled the inclusion criteria and they were all studying suburethral slings. Persistent SUI after surgery varied between 5.2 and 17.6%. One study evaluating quality of life showed significant improvement after surgery. Complication rates varied between 1-26% - mainly bladder perforation, short term voiding difficulties and de novo UUI.

2. RACE

There have been no new relevant publications since the last report. A large epidemiological study examined 129 778 women who underwent continence surgery in the United States in 2003(567) and found an overall rate of 12 surgical procedures per 10 000 women. The figure was 10 per 10 000 (95% CI: 7-12) in white women and dropped to 3 per 10 000 (95% CI: 0-9) and 6 per 10 000 (95% CI: 0-13) in women of other ethnicity. A further analysis of the Stress Incontinence Surgical Treatment Efficacy Trial in 654 women following colposuspension or PVS comparing Hispanic with non-Hispanic white and non-Hispanic black women showed no difference in any of the urinary incontinence measures investigated(563) .

The function of the continence mechanism has also been compared in a cross sectional population based study of 335 black and white women aged 35-64 years classified as continent (n=137), stress incontinent (n=102) and urge incontinent (n=96)(568). When comparing black women to white women the maximum urethral closure pressure(MUCP) was 22% higher (68.0 vs 55.8 cm H^2O p<0.0001).

3. OBESITY

There is considerable evidence suggesting obesity is linked with increasing severity of incontinence and weight loss (particularly that associated with bariatric surgery) can reduce incontinence. The evidence on the effect of obesity on surgical outcomes is less comprehensive. Older studies largely examining mid urethral tape procedures suggested no effect of BMI on outcome (569). Brennand et al (184) evaluated the impact of BMI >30 on objective and subjective outcomes 12 months after MUSs. 182 women were enrolled into a randomised trial of TVT vs TO MUS. There was no difference in outcomes between the two surgical approaches. Objective cure was defined as <1g urine loss on a one hour pad test. The cure for non obese women was 85.6% vs 67.8% for the obese group (p=0.006, risk difference 17.8%, 95%CI 4.2-31.4%). There was also a 15% difference in subjective outcomes in the obese women (85.8% vs 70.7%). Karaman et al (570) used the same definition of obesity and retrospectively compared 328 non obese women with 294 obese women who had undergone RP MUSs. After they had controlled for concomitant pelvic surgery the success rates were similar for both groups (76.9% vs 73.7%) with no difference in complication rates. Berger et al(571) also compared 56 obese vs 100 non obese women undergoing PVS TVT and and found a higher rate of short term complaints of SUI but by 2 months the failure rates were the same.

Two recent studies have looked at the impact of obesity on TO slings. Pereira et al (231) in a retrospective analysis of 122 obese and 159 non obese women found no difference in short and up to 4 year cure rates (95%vs 95.8%) with no difference in complication rates. Yonguc et al (572) had a series of 32 women all with BMI >35kg/m^2 with good success rates and low complication rates at three year follow up.

Weltz et al (573) published a systematic review pooling data from 13 studies comparing obese and non obese women and stress incontinence surgery outcomes at a minimum 12 month follow up. The subjective success was 76.4% and 74.7% and objective cure was 83.3% and 79.2%of non obese and obese women respectively. There was no significant difference in complications except non obese women were more likely to have bladder perforation.

4. PSYCHIATRIC ILLNESS

There have been no new relevant publications since the last report.

5. PHYSICAL ACTIVITY

There have been no new relevant publications since the last report.

6. PREVIOUS CONTINENCE SURGERY

Traditionally it has been believed that “redo” surgery for stress incontinence is associated with poorer outcomes the primary surgery. The numbers of colposuspension operations whether open or laparoscopic and fascial slings have diminished with the advent

and establishment of MUSs. The majority of recent studies examine the role of these MUSs when previous continence surgery has failed. This section will update on the more recent studies and the reader is referred to the ICI 5 document to read about older studies.

Lo et al (574) examined the records of 24 women who had undergone repeat MUS surgery. They used a mixture of transoturator, PVS and single incision slings and reported 79.2.% objective and 75% subjective success rates. ISD and low MUCP predicted failure.

A Dutch study (575) identified from a retrospective cohort 242 women having primary surgery and 197 women having repeat surgery. All women had predominant stress incontinence. The overall success rate for primary surgery at a median 205 days follow up was 86% and 79% for recurrent surgery the complication rates were the same for both groups. Gaddi et al (346) reported on the failures of 6914 MUSs performed between 2008-2011. 165 women had repeat surgery for recurrent SUI 98 had repeat MUSs and 67 had urethral bulking. There were 11 failures in the MUS group and 26 failures in the bulking group (11.2% vs 38.8%). The complication rates were similar.

Agur et al (576) carried out a literature search from 1945- 2013. Data were available for a total of 350 women in 10 randomised controlled trials having had surgery for recurrent SUI with a mean follow up of 18.1 months. They concluded that there was no difference between the PVS tape or TO approaches as the two most studied procedures. One trial showed no difference between PVS TVT and colposuspension. Nikolopoulos et al (347) carried out a systematic review but allowed pooling of data for small studies even with as little as five cases. Their pooled analysis shows objective cure rates for recurrent stress urinary incontinence treated with colposuspension of 76% (95%CI +-5.04). For MUSs the success rate was 66.2%(95% CI +/-4) and was higher for the PVS as compared to TO approach. PVSs had a success rate of 79.3%(95%CI+- 6.5).

7. CONCOMITANT HYSTERECTOMY

There have been no new relevant publications since the last report.

8. SEVERITY AND DURATION OF SYMPTOMS

There have been no new relevant publications since the last report.

9. OAB AND STRESS INCONTINENCE

Previous reports have suggested that women with MUI are more likely to have persistent urgency incontinence after surgery for stress urinary incontinence and may also be predisposed to higher rates of failure of surgery for stress urinary incontinence.

Lee et al(577) investigated 358 with SUI and another 598 women who had SUI and urgency but not UUI who underwent MUSs with a mean follow up of 50 months. Women who developed de novo urgency(dU) or denovo UUI(dUUI) were compared with those that did not. dU occurred in 27.7% (99/358) and DUUI occurred in 13.7%(82/598) of women at long term follow up after MUS. Pre-existing DO, history of prior incontinence or prolapse surgery and concomitant apical prolapse surgery were important predictors of dU and dUUI following MUSs.

Gleason et al (578) compared the outcomes of MUS surgery in women with either pure stress urinary incontinence(SUI) or mixed urinary incontinence (MUI) using the Urinary Distress Inventory (UDI-6) subscale of the Pelvic Floor Distress Inventory(PFDI-20) and the Urinary Impact Questionnaire(UIQ-7). Five hundred and thirty four women completed baseline and follow up questionnaires. The mean follow up time was 35 months (Standard Deviation (SD) 15 months) and women with MUI had a significantly lower success rate compared to those with SUI alone (64 vs 85%, p<0.001). Abdel-Fattah et al (23) performed a secondary analysis of 83 women with MUI of a total population of 341 women who had been randomised to either (247) the" outside in" or "inside out" TO tape and found no difference in patient reported success rates using the Patient Global Impression of Improvement(PGI-I).

In another secondary analysis (579)(24) the authors examined data from three multicentre urinary incontinence surgical trials of women with stress predominant MUI assigned to Burch colposuspension, autologous fascial sling or PVS or TO MUSs. Significant improvements in Urinary Distress Inventory-Irritative scores were reported by all surgical groups 1 year after surgery. Improvements were similar between MUS groups at 1 year(65.5% compared with 70.7%, p=.32;odss ratio (OR) 0.83, 95% CI 0.57-1.20 for PVS compared with TO) and this persisted at 5 year follow up. More women reported OAB symptom improvement after Burch compared with PVS (67.9% compared with 56.6%, p=0.01; OR 1.59, 95% CI 1.10-2.31 for Burch compared with sling) at five years. The pre-op use of anticholinergics or urodynamic parameters was not predictive of OAB change.

10. URETHRAL OCCLUSIVE FORCES

There have been no new relevant publications since the last report. In the previous report the role of urethral mobility and intrinsic deficiency on outcome has been investigated in two studies. The first of these investigated 134 women following TO tape insertion. Overall 86% reported subjective cure and 14% of persistent symptoms. Median preoperative urethral mobility was significantly lower amongst treatment failures compared to those women who were cured (40 (10-60) degrees vs 50 (10-90) degrees ; p=0.0049). In addition women with preoperative mobility < 45 degrees were at least four times more likely to report incontinence when compared to those with >45 degrees mobility (29.4% vs 6.9%; RR 4.29; 95% CI 1.59-11.60; p=005)(580).

A prospective 2 year study of 65 women has also found that ISD with a fixed urethra is associated with a poorer objective outcome at 24 months following TO MUS when compared to intrinsic deficiency and urethral hypermobility and hypermobility alone (66.7% vs 87.5% and 96.6% respectively) (581).

11. SUMMARY

More studies are needed that are adequately powered to examine confounding variables as the primary outcome measure. Most if not all studies reporting on confounding variables are secondary analyses of studies examining success rates of surgical procedures for SUI. Therefore the levels of evidence are generally low at 3/4

Older women have similar outcomes after MUS surgery for SUI as their younger counterparts but have higher rates of short term voiding difficulty and de novo UUI. EL 3/4

Obesity does not adversely affect the outcome of MUS surgery for SUI with no increase in complication rates. EL 3/4

Prior failed SUI procedures does not appear to adversely affect outcome of subsequent surgery for SUI if ISD and low MUCP are excluded. EL 3/4

V. CLINICAL TRIAL OUTCOMES USED IN UI RESEARCH

There is no single measure that adequately measures SUI surgery outcomes. Outcome measures for SUI surgery remain non-standardised in clinical trials because of several factors unique to the condition or the treatment of the condition. Unlike cancer treatments with a readily defined outcome, or even prolapse surgeries where an anatomic outcome can be objectively assessed, SUI is a quality of life condition whose presence, absence, or severity remains difficult to measure. Furthermore, the surgical treatment of SUI can improve or worsen other LUTS. Because we do not have a standard definition of success that is used in all studies, success rates from one study of one procedure cannot be compared to another study of a different procedure. Our best data for success comes from randomised trials where the same outcome criteria are applied to the same population and only then can 2 different surgeries be compared.

1. HISTORY OF SUI MEASURES

Outcome assessments can be broken down into subjective and objective measures. Early reports of SUI surgical outcomes were subjective. Often they were nothing more than surgeons asking the patient at the post-operative appointment if they were better. Of course, both the patient who decided to have the surgery, and the surgeon who did the surgery, were invested in the outcome and consequently success rates greater than 95% were not uncommon. This physician-reported subjective outcome measure was justifiably criticized. In one of the first systematic reviews of SUI surgery by Jarvis in 1994 he noted that subjective assessment of cure may be satisfactory in clinical practice, but it is clearly unsatisfactory for scientific assessment. (582) When the AUA SUI Guidelines Panel published their systematic review in 1997 they noted the paucity of clinical studies that met minimal criteria for good science in the conduct of clinical studies and reporting results. (583) The panel recommended 5 year outcomes with specific outcome measures including history/questionnaire, physical exam, diary, pad test, post void residual urine determination, and an assessment of complications/morbidity, including urinary retention, and de novo urgency.(583) Ten years later when Rovner et al reviewed the literature no articles met all criteria, but most complied with at least half of the recommendations. (584) Most SUI studies now report both subjective and objective measures and most of the Cochrane reviews of SUI surgery outcomes compare subjective and objective outcomes. Objective parameters typically include stress tests, pad tests, voiding diaries, urodynamic studies and the advantages and disadvantages of these measures are included in Table 12. Over time urodynamic studies have been used less commonly as an SUI surgical treatment outcome measure because of the limitations outlined in the table.

2. PATIENT REPORTED OUTCOMES

While many of the subjective self-reported measures can be considered “patient reported”, the concept of true Patient Reported Outcomes (PRO) is more complex and encompasses a more global assessment. PRO’s measure patient impressions in a more global context by encompassing 4 domains: 1) Symptoms,

2) Functioning, 3) General Health Perception and 4) HRQOL. The use of PRO's has gained acceptance as noted by the fact that most research funding sponsors, industry, and regulatory agencies now require inclusion of outcome measures that include the patient's perspective. The NIH recently established the Patient Reported Outcomes Measurement Information System (PROMIS) for women with urinary incontinence.(585) The International Consultation on Incontinence has adopted the use of PRO's and established the ICI Modular Questionnaire (ICIQ) Project that includes the assessment of a wide spectrum of urinary, bowel and vaginal symptoms along with their impact on HRQOL. Table 13 demonstrates PRO measures which have received an A grade from the ICI for female SUI outcomes from prior Consultations.

3. COMPOSITE MEASURES

No single instrument is universally accepted by all investigators. There are deficiencies with any single subjective or objective SUI research outcome measure. Therefore multiple measures are often reported and this makes definitive conclusions difficult. For this reason, especially with the advent of clinical trial networks, investigators have increasingly used composite outcomes (Table 14). While providing more comprehensive assessments, composite outcomes often create a stricter definition of success and lower success rates especially if all of the components of the composite must be satisfied. Because a provider may not always agree with the choice of measures used as a composite, investigators should also consider reporting the results of the individual components of the composite measure. An example of the reporting of individual composite components is shown in Figure 1.

4. SURVIVAL ANALYSIS REPORTING FOR SUI OUTCOMES -ONCE A FAILURE, ALWAYS A FAILURE

When assessing outcomes it is important to determine if the study used a survival type analysis (typically reported on a Kaplan-Meier graph which follows patients over time) or just assessed the patient at one specific postoperative time point. In these survival analysis types of studies an assumption is made that once a patient reports incontinence she will continue to have incontinence and she is considered a failure for the course of the study. Because of the waxing and waning nature of SUI symptoms, this may not fit the natural history of SUI symptoms. Survival analysis reporting will lead to lower success rates than single time reporting and may not be consistent with the patient's reported outcome.

5. SUCCESS RATES ARE DEPENDENT ON THE RIGOR OF THE ASSESSMENT

Further complicating the issue of outcome assessment is that few of our SUI treatments ever make a woman completely dry and therefore successful outcome rates decline with the rigor of the assessment. An example of both a rigorous outcome measure and a survival analysis approach is the UITN's randomised trial of Burch vs PVS which was criticized for low overall success rates of less than 50% in both arms. (21) In this study a composite measure was used which included administering a 3 day diary, a 24 hour pad test and a 15 question incontinence survey (MESA) every 6 months for 2 years. Any positive response during any assessment resulted in a failure for the duration of the study. In this study with composite rigorous assessments and survival analysis methodology, the low overall success rates of less than 50% were inconsistent with patient satisfaction rates of 78 and 86% in the 2 groups. (21)

If the definition of SUI surgical success is too rigorous outcomes will not meet face validity. In 2001, the NIH defined cure of stress urinary incontinence as: (1) resolution of the stress incontinence symptoms; (2) resolution of the sign (negative full bladder cough stress test, performed under the same conditions as before treatment); and (3) no new symptoms or side effects which could include new urinary symptoms such as urinary urgency, frequency, urge incontinence, with or without urodynamic changes of DO (detrusor instability); change in sexual function; development or worsening of POP; adverse effect on bowel function; onset of urinary tract infections; surgical complications, etc.(586) As Hilton noted in an editorial, if this definition was applied to the very well done United Kingdom TVT RCT, cure rates in the 2 arms would be 6 and 9%!(587)

6. MIXED INCONTINENCE AS A CONFOUNDER

Many patients undergoing stress incontinence surgery also have urgency incontinence (mixed incontinence) and this urgency component may get worse, remain the same, or improve after SUI surgeries. SUI surgery failures are often the result of worsening or de novo urgency incontinence. The true "pure" SUI patient is rare. In support of this, in the SISTeR trial where all women were reported to have pure or predominant SUI for study inclusion, the range of women with mixed incontinence ranged from 8.3% if mixed incontinence required DO on urodynamic studies to as high as 93.3% if they reported affirmatively to any urgency incontinence question. (588) Because inclusion criteria for studies vary and the amount of mixed incontinence in the populations vary, one study cannot be compared to another study. The effect of any

particular type of surgery on mixed incontinence varies and this is the reason why validated comprehensive measures of bladder function may be the best instruments to assess the outcomes of SUI surgery.

Quality of Life measures. If SUI is a quality of life condition, ideally we would have a quality of life tool that would capture changes with our intervention. Global quality of life instruments (like the SF-36 or SF-12) are not sensitive to SUI interventions and incontinence specific QOL instruments are recommended. The incontinence specific quality of life instruments that have received an ICI Grade A recommendation are shown in Table 13 and include the: ICIQ FLUTS, IIQ, IIQ-7, I-QOL, and LIS.

Stress-Specific vs Bladder Specific.

Any instrument that is stress-specific may give results about the surgery's effect on stress incontinence but may not give an overall accurate assessment of what the surgery did for overall bladder storage and emptying LUTS (urgency, frequency, urgency incontinence, or voiding difficulties). Therefore an overall bladder assessment tool is recommended for measuring SUI surgical outcomes. Patient reported bladder outcomes with ICI Grade A recommendations are shown in Table 13 and include the: ICIQ-UISF, ISS, KHQ, UISS, PPBC, UDI, and UDI-6.

7. GLOBAL MEASURES

Another outcome measure that has recently gained popularity is the patient global impression of severity (PGIS) and the patient global impression of improvement (PGI-I). Use of such global assessment instruments provides a single response which is easy for the patient and clinician to understand.(589) Furthermore, the measurement is all encompassing since the subject takes success and complications into account when responding. The PGI-I was part of the composite primary outcome in the UITN randomised trial evaluating preoperative urodynamics. (590)

8. SUMMARY

The last two decades has seen a massive expansion in the field of stress urinary incontinence (SUI) research. While initially criticised for poor quality research, significant advances have been made especially in the development of clinical trial networks that have allowed large scale multisite surgical studies necessary for high quality studies. We have also seen a maturation of outcome tools including validated patient reported outcome instruments. The standard clinical trial for SUI now is a prospective randomised comparative efficacy trial using patient reported outcomes as a component of the primary outcome.

9. RECOMMENDATIONS

Patient reported outcomes using ICI Grade A bladder symptom and incontinence-specific quality of life instruments should be utilized in stress incontinence clinical trials (Grade D).

A cough stress test standardised to bladder volume and patient position provides an objective assessment of stress continence outcomes (Grade D).

Composite measures address inadequacies of any individual stress outcome measure, but rates with these measures are often lower than any individual measure so the components should also be reported. (Grade D)

VI. RESEARCH RECOMMENDATIONS

1. GENERAL

It is becoming clear that there is not a single optimal intervention for all patients with SUI or UUI. Future high quality research is required to clarify the place of each SUI and UUI intervention for the individual patient, and establish the optimal materials and approach to the index and non-index UI patient.

Table 12: Female SUI Objective Outcome Measures

Measure	Advantages	Disadvantages
Stress test	Noninvasive or minimally invasive Inexpensive Specific for stress incontinence A positive test is predictive for urodynamic stress incontinence (590, 591)	Should be standardised (position and volume)
Pad test (1 hr or 24 hr)	Quantitative	Not SUI specific Can be burdensome to patient and investigator
Voiding diary (3 day or 7 day)	Can differentiate stress from urgency events.	Burdensome to patient
Urodynamics	Can detect urodynamic stress incontinence and DO	Invasive, uncomfortable, expensive

		Not sensitive for urgency incontinence
Need for repeat surgery	Identifies the worst failures	Uncommon outcome Not sensitive for less severe outcomes.

Table 13: Female SUI Patient Reported Outcomes with ICI Grade A Recommendations

Tool	Measures	Items
ICIQ FLUTS	QOL, Treatment outcome	34
ICIQ-UI SF	Symptoms and impact	4
IIQ (Incontinence Impact Questionnaire)	Impact of UI on HRQOL	30
IIQ-7	Short version of IIQ	7
I-QOL (Incontinence QOL)	Incontinence specific QOL	22
ISS (Incontinence Symptom Severity Index)	Severity of storage and voiding symptoms	8
KHQ (ICIQ-LUTSqol) King's Health Questionnaire	Symptoms impact of LUTS	21
LIS (Leicester Impact scale)	LUTS QOL	21
UISS (Urinary Incontinence Severity Score)	Severity and impact of UI	10
LUSQ (Leicester Urinary Symptom Questionnaire	Presence and severity of storage abnormalities	10
PGI-I (Patient Global Impression of Improvement)	Symptom bother	1
PGI-S (Patient Global Impression of Severity)	Symptom bother	1
PPBC (Patient Perception of Bladder Condition)	Impression of bladder condition	1
UDI (Urogenital Distress Inventory)	Symptom bother related to UI	19
UDI-6	Symptom bother related to UI/LUTS	6

Table 14: Examples of Composite Primary Outcomes used in RCT's of SUI Surgery with more than 200 Subjects.

1st author, year (ref)	Surgery	Composite Outcome
Ward, 2002 (147)	TVT vs. Burch	No USI and Negative pad test
Albo, 2007 (21)	Fascial sling vs Burch	Negative pad test and No UI on 3 day diary and Negative cough stress test and No self-reported SUI on MESA and No SUI retreatment
Barber, 2008 (208)	PVS vs. TO	Abnormal bladder function defined by presence of Incontinence symptoms of any type Positive cough stress test Retreatment of SUI Elevated PVR
Rinne, 2008 (202)	TVT vs TVT-O	Objective Negative stress test Negative pad test Subjective condition-specific quality of life questionnaires and general health by the EQ-5D questionnaire.
Wang W, 2009 (211)	TVT vs TVT-O	Negative cough test Negative pad test Reduction by 50% of incontinence episodes
Krofta , 2010 (216)	TVT vs. TVT-O	Objective Negative stress test Negative pad test Subjective No leakage on questionnaire
Richter, 2010 (217)	PVS vs TO	Objective Negative stress test Negative pad test

		No SUI retreatment Subjective No self- reported SUI symptoms No UI on 3 day diary
Nager, 2012 (590)	UDS vs No UDS	70% reduction in UDI and PGI-I of much better or very much better

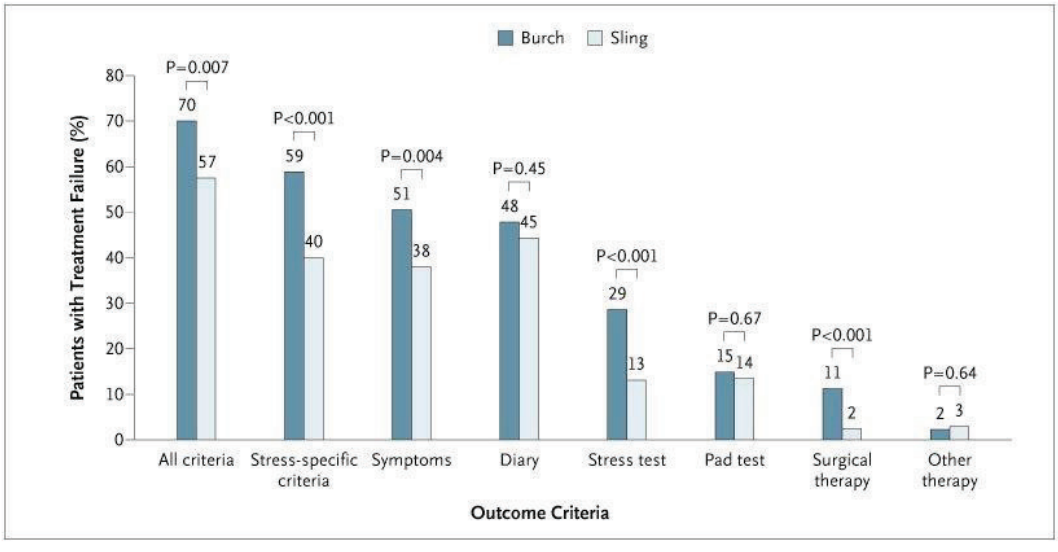

Figure 1. Proportion of Subjects with Treatment Failure at 2 years according to different criteria in the UITN randomized trail comparing Burch vs. Autologous sling. (21)

Future studies should systematically record in a standard, quantifiable, and reproducible manner (e.g. Clavien-Dindo, etc.) all AEs and complications associated with each of the interventions for UI.

Future studies should utilise appropriate outcome measures to better understand and address the broader effects of UI interventions with respect to health economics in individuals, populations, payers, and health care systems.

2. STRESS URINARY INCONTINENCE

Studies should investigate the subpopulations and characteristics of patients (e.g. urethral function, medical comorbidities, BMI, vaginal atophy, POP, etc.) in whom each of the interventions for SUI is the optimal choice.

As the use of foreign and synthetic materials for the treatment of SUI evolves and expands (mesh, bulking agents, stem cells, etc.), a better understanding of the long-term implications of these implanted materials is needed.

3. URGENCY URINARY INCONTINENCE

Prospective randomised trials comparing third line treatments for refractory OAB/UUI are needed, especially with respect to the long term efficacy, complications and cost of these interventions.

The role and efficacy of third line therapies in combination with each other (e.g. SNS and BTX) as well as in combination with other non-invasive therapies (e.g. medications) is unknown.

The mechanism of action of the SNS, and PTNS remains unknown.

Optimal patient selection for each of the third line therapies is undefined.

The role and efficacy of third line therapies such as SNS and PTNS is unknown in the non-refractory OAB patient who declines other therapy (e.g. behavioral therapy and/or pharmacological therapy).

The long term impact of the newer SNS technology currently used in terms of durability and complications is not defined as the current data in the literature is limited to older SNS devices.

The role of different programming settings in SNS and PTNS for different urological conditions is not well understood.

The optimal long term maintenance regimen for PTNS is unknown.

Alternatives to enlargement cystoplasty for refractory patients are lacking despite initial enthusiasm for tissue engineering.

4. URETHRAL DIVERTICULA

There is a need for prospective, assessment of LPP, including urinary incontinence with respect to surgical and non-surgical management of these patients.

I. EPIDEMIOLOGY

Pelvic organ prolapse (POP) is a common problem affecting up to 50% of parous women and between 6-20% of women will have undergone a surgical correction for pelvic organ prolapse by the age of 80.[1, 2] Prolapse surgery is an increasingly important aspect of gynaecological practice due to our ageing population, and already prolapse surgery is performed at least as frequently as continence surgery and, the operating and admission times are at least three times greater than for continence surgery. Given the increasing time and resources that will be required for POP surgery in the future it is paramount that we perform effective, durable, cost effective interventions with minimal morbidity. This chapter serves to outline and summarise the information relating to POP surgery reported in the English-language scientific literature after searching PubMed, Medline, Cochrane library and Cochrane database of systematic reviews, published up to July 2016.

1. INCIDENCE AND PREVALENCE OF PELVIC ORGAN PROLAPSE (POP)

There is a lack of epidemiological studies of the natural history, incidence and prevalence of POP.

It is widely accepted that 50% of women will develop prolapse but only 10-20% of those seek evaluation for their condition.[3] In the current literature, the overall prevalence of POP varies significantly depending upon the definition utilised, ranging from 3-50% (Table 1). Where POP is defined, and graded on symptoms the prevalence is 3-6% as compared to 41-50% when based on examination, as mild prolapse on examination is common and frequently asymptomatic.[3-6] On examination anterior compartment prolapse is the most frequently reported site of prolapse and is detected twice as often as posterior compartment defects and three times more commonly than apical prolapse.[7, 8] Following hysterectomy 6-12% of women will develop vaginal vault prolapse[9, 10] and in two-thirds of these cases multi-compartment prolapse is present.[11]

There is little knowledge about the natural history of POP. The reported incidence for cystocele is around 9 per 100 women-years, 6 per 100 women-years for rectocele and 1.5 per 100 women-years for uterine prolapse.[7] Some data show that there is a 1-year incidence of POP of 26% and a 3-years incidence of 40% with regression rates of 21% and 19%, respectively. In general, older parous women are more likely to develop new or progressive POP than to show regression. Over a three year period 11% of the women aged over 65 had prolapse progression of more than 2 cm whilst only 2.7% had a regression by the same amount.[12]

Luber has shown in a large demographic study that the peak incidence of symptoms attributed to prolapse is between ages of 70 to79 whilst POP symptoms are still relatively common in women of younger age.

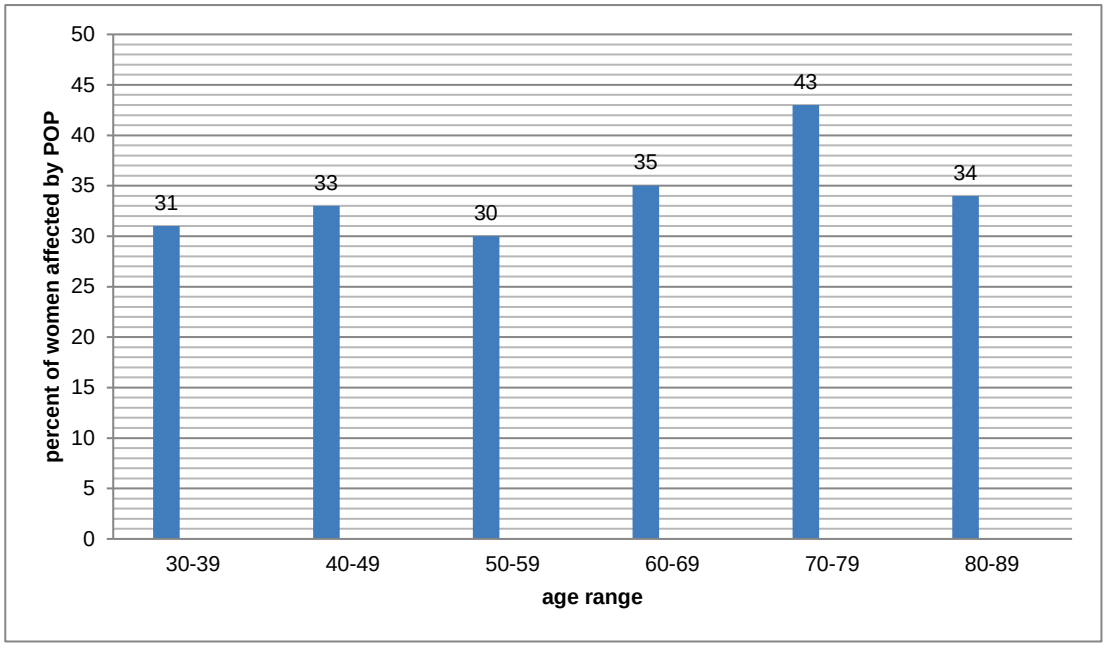

Figure 1. Shows the distribution of POP among women seeking care, US 2000 (Modified Luber 2001[13])

Demographic changes including an ageing population have significant implications for the future planning of women 's health services. Wu et al[14] have predicted that by 2050 the number of women suffering from symptomatic POP in the United States will increase at minimum by 46% (from 3.3 up to 4.9 million women and in a "worst-case scenario" up to 200% or 9.2 million women with POP. These figures were based upon population growth statistics in the United States however models that evaluate the impact of decreasing parity and increasing elective caesarean section rates are required to more accurately predict future rates of POP.

Table 1. Prevalence and Incidence of Pelvic Organ Prolapse

Study	Definition	Prevalence	Incidence	Country
Rorveit, 2007	Symptom-based	5.7%		US
Nygaard, 2008	Symptom-based	2.9%		US
Hendrix, 2002	WHI-Study, Examination	Any prolapse: 41.1% Cystocele: 34.3% Rectocele: 18.6% Uterine: 14.2%		US
Swift, 2003	Examination	6.4% stage 0 43.3% stage 1 47.7% stage 2 2.6% stage 3		US
Handa, 2004	WHI-Study, Examination	Cystocele: 24.6% Rectocele: 12.9% Uterine: 3.8%		US
Nygaard, 2004	Examination	2.3% stage 0 33% stage 1 63% stage 2 1.9% stage 3		US
Bradley, 2007	Examination	23.5 - 49.9%	26%/1 year 40%/3 year	US
Maccharoni, 1999	Examination	Vault-prolapse: 12%		Italy
Aigmueller, 2009	Examination	Vault-prolapse: 6-8%		Austria

2. INCIDENCE AND PREVALENCE OF PELVIC ORGAN PROLAPSE SURGERY

Both incidence and prevalence for prolapse surgery increase with age. Women older than 80 years are currently the fastest growing segment of the population. The estimated lifetime risk of an American woman undergoing at least one surgical intervention by the age of 80 was frequently reported as 6.3%.[1] More recently the estimated lifetime risk of prolapse has been reported at 13.7% in the USA[16], 18.7% in Denmark[17] and 19% in Western Australia.[2] Also the reoperation rate reported by Olsen et al was 29.2% rate however, a more recent, prospective study showed a significantly lower reoperation rate of only 13% at 5 years, which may be explained by improved surgical procedures.[18]

Not only is there significant variation in the reported lifetime risk of prolapse surgery there is also wide variation in the rate at which surgical interventions for pelvic organ prolapse are performed. Haya et al[19] demonstrated significant variation in the rates and types of surgical interventions for prolapse in 2012 in various countries in the Organisation for Economic Co-operation and Development (OECD). The rate of prolapse procedures were five times higher in the USA (2.6/1000 women) as compared to Switzerland (0.5/1000 women). There was also very significant variation in the type of interventions undertaken. Transvaginal mesh for anterior compartment prolapse were used eight times more frequently in Germany (26%) than in England (3.3%). Sacral colpopexy was employed 13 times more frequently in France (66%) than in Sweden (5%) for apical vaginal prolapse. Such large variation in rate and types of surgery performed for pelvic organ prolapse maybe explained by a variety of factors including women's preferences, cultural and demographic variables, access to healthcare professionals, health professional training and a lack of clear consensus guidelines on the surgical management of prolapse. The lack of consistency in the rates and types of surgical intervention for pelvic organ prolapse needs further evaluation and ensures difficulty in the allocation of health

care resources for future planning for pelvic organ prolapse.

The annual incidence for POP surgery is stated to be between 1.5 and 1.8 cases per 1000 women-years with the incidence peaking in women between 60-69 years.[20, 21] Shah et al[21] also demonstrated a peak incidence in 70 year old women however surprisingly high numbers of younger women were also undergoing surgical treatments reflecting a similarity in the prolapse symptoms reported in younger women by Luber 2001[13] (Figure 2). Wu et al found the annual incidence of prolapse surgery increased linearly with age and peaked at 72 years of age at 4.3 cases per 1000 women.[16]

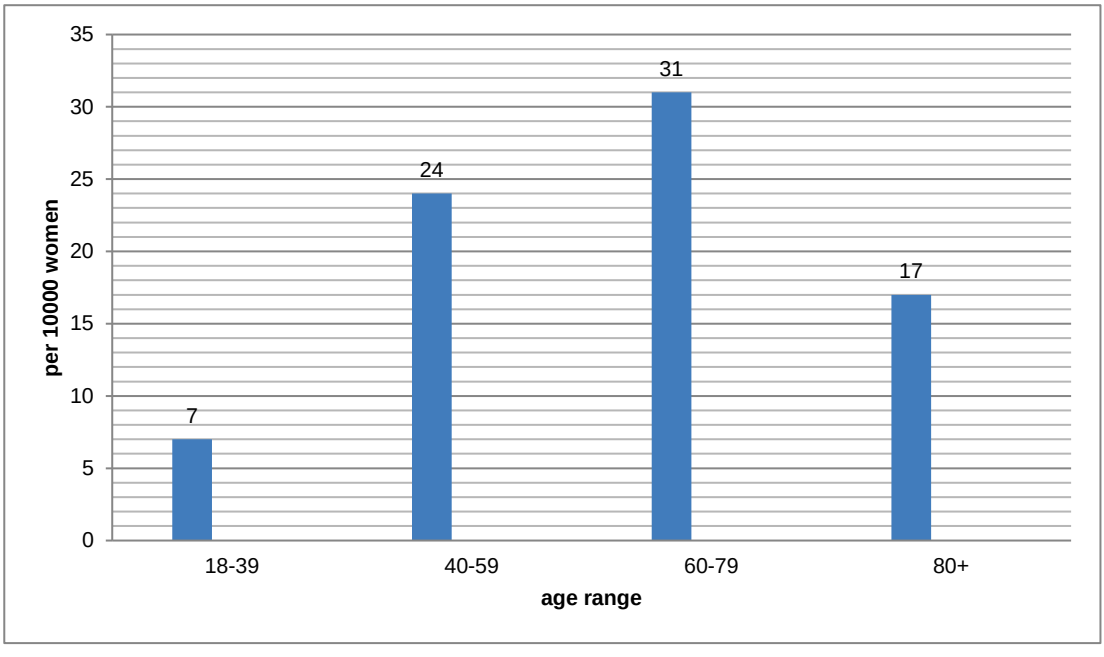

Figure 2. Shows the surgical treatment for POP/ rate per 10000 women (2003)

In the US, POP is thought to be the leading cause for more than 200,000 surgical procedures per year (22.7 per 10,000 women) with 25% undergoing re-operations at a total annual cost of more than 1 billion dollars.[20-23] Also of note during a nine-year period (1996 – 2005) the ambulatory costs related to pelvic floor disorder increased by 40% and if these figures are extrapolated to POP surgery the total annual cost would be over 1.4 billion dollars. While it has been predicted that due to our aging populations the rate and cost of surgery for prolapse will rise by as much as 40%, counter-intuitively some studies are in fact demonstrating decreasing rates of surgical interventions for prolapse. In Denmark, the lifetime risk of prolapse surgery by age of 80 decreased from 26.9% in 1978 to 18.7% in 2008.[17] Over a similar time period in Washington state USA, the rate of surgery for pelvic organ prolapse decreased from 2.1 in 1987 to 1.4 per 1000 women aged 20-84 years in 2009.[24] The authors eloquently linked the decrease in the rate of inpatient prolapse surgery to higher rates of caesarean section and lower rates of instrumental delivery during the same time period. Further detailed modelling of factors that will impact on future rates of POP in the community are required so that services can be provided to match the future demands of POP surgical interventions.

II. OUTCOME ASSESSMENT

Pelvic organ prolapse, like all pelvic floor disorders, is a multidimensional phenomenon and "success" of treatment is often difficult to define. Historically, most studies evaluating the treatment of pelvic organ prolapse have focused exclusively on anatomic success without considering other important areas such as symptoms, vaginal compliance, quality of life, or socioeconomic outcomes. For an individual patient, the most important outcome of a surgical procedure is the relief of her symptoms and improvement in her quality of life[25], yet until recently these areas have largely been ignored. Fortunately, over the last 15 years, measures to evaluate POP have improved; there is now an internationally-accepted and reliable assessment of the anatomic support of the uterus and vagina (POPQ) and a number of valid, reliable and responsive symptom questionnaires and condition-specific HRQOL instruments.[26-31] A recent joint report from the International Continence Society (ICS) and International Urogynaecology Association (IUGA) recommended that the following outcomes be reported in studies of POP surgery: Objective (e.g. POPQ), Patient reported outcomes (particularly the presence or absence of vaginal bulge symptoms), Satisfaction,

Quality of Life, and Perioperative data (e.g. operative time, hospital stay, etc.).[32] A careful report of short- and long-term complications are also essential to properly weigh the risk-benefit ratio of each procedure.
